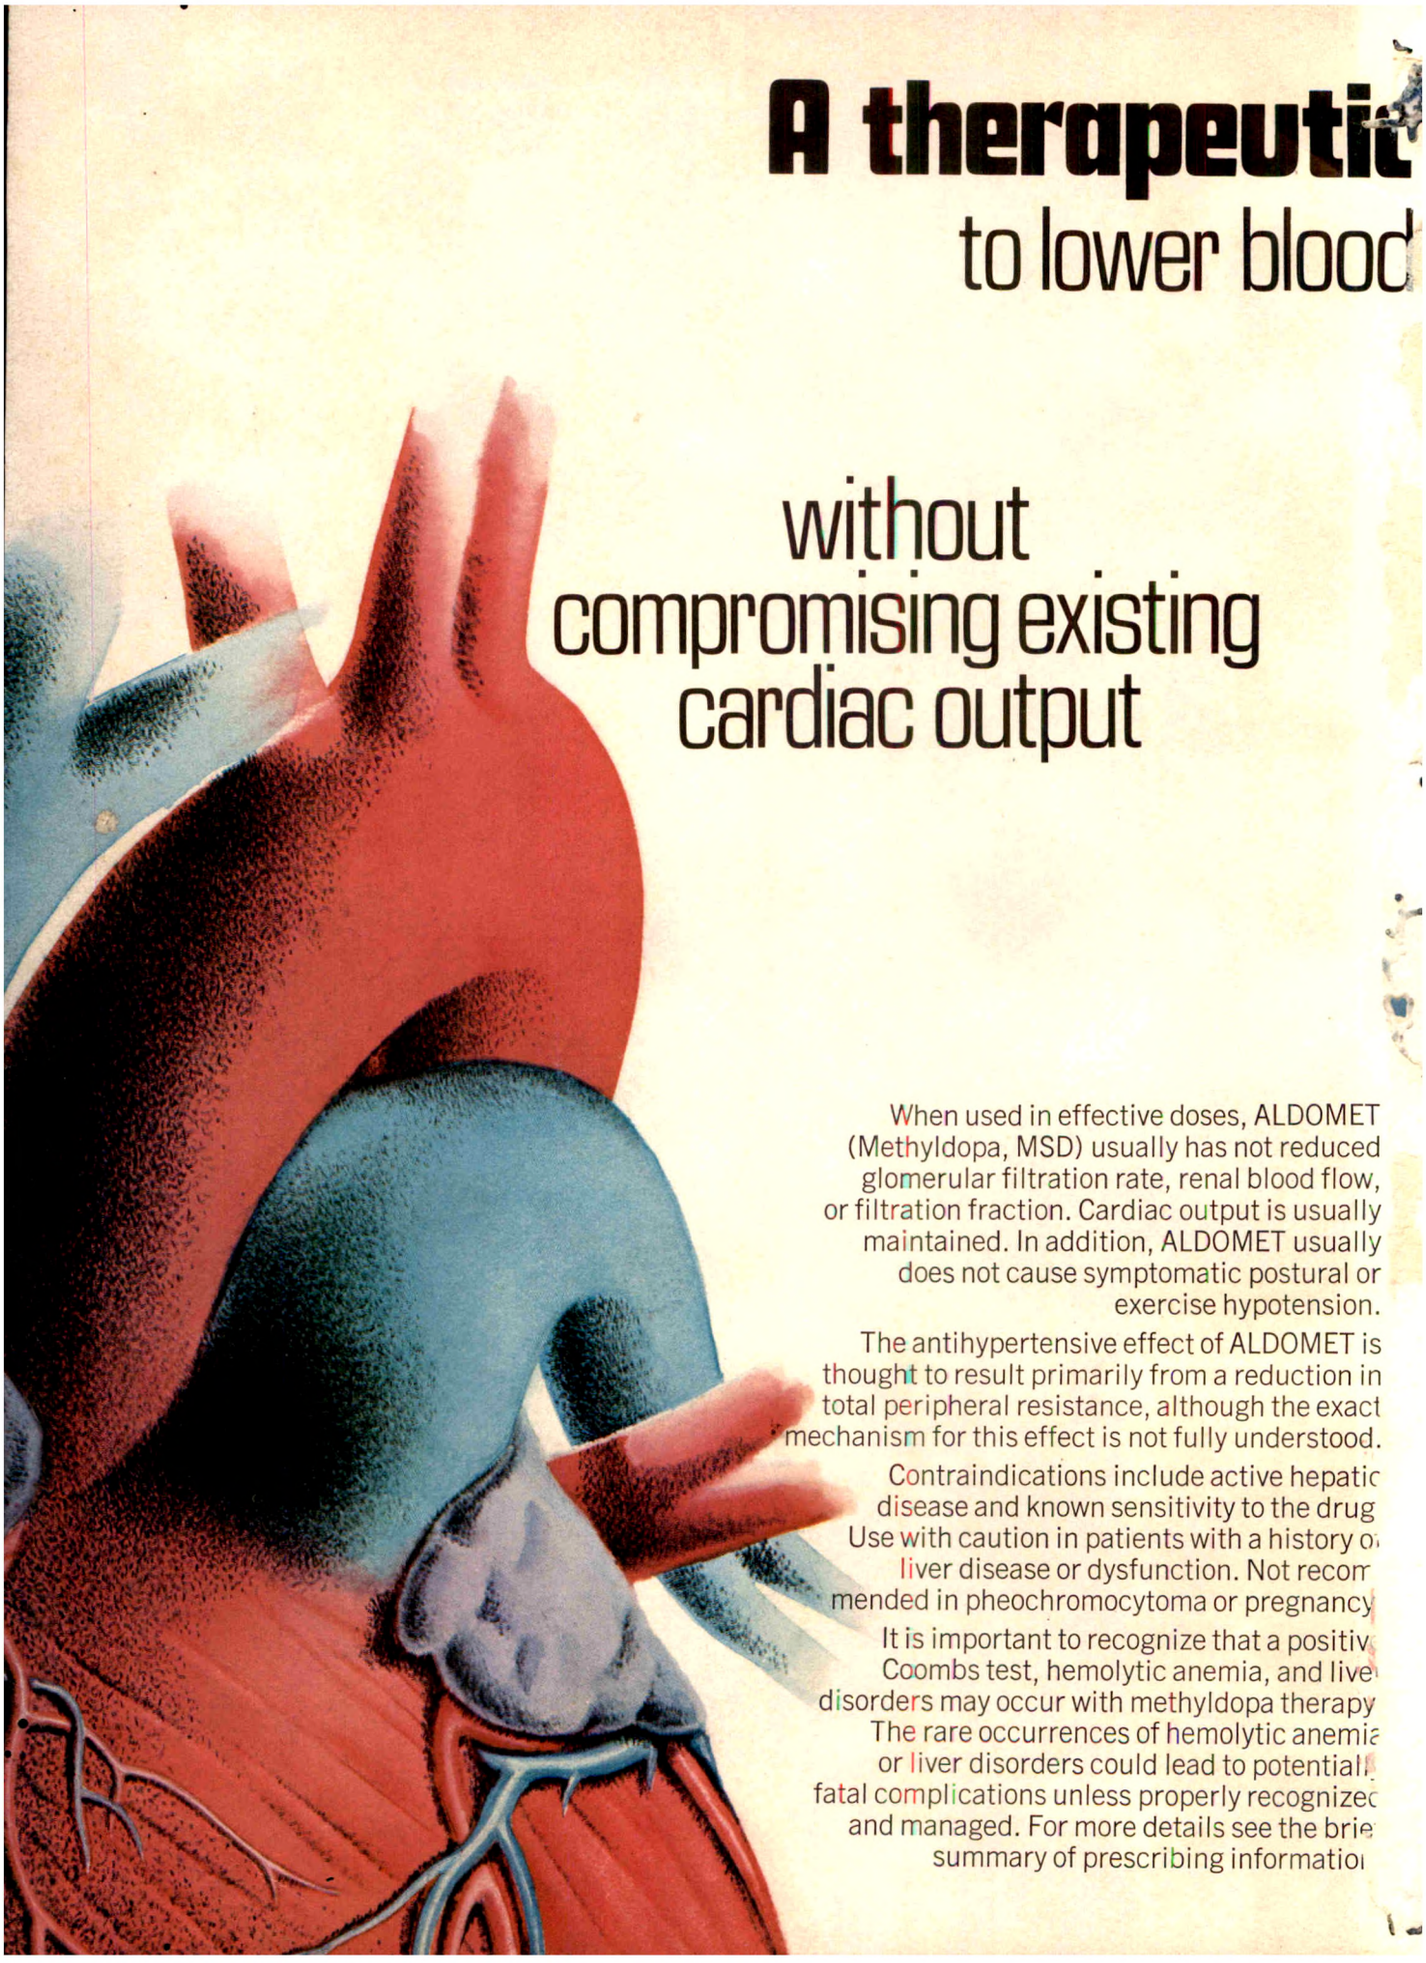
A YORKE MEDICAL JOURNAL



A therapeutic
to lower blood
without compromising existing cardiac output

When used in effective doses, ALDOMET (Methyldopa, MSD) usually has not reduced glomerular filtration rate, renal blood flow, or filtration fraction. Cardiac output is usually maintained. In addition, ALDOMET usually does not cause symptomatic postural or exercise hypotension.

The antihypertensive effect of ALDOMET is thought to result primarily from a reduction in total peripheral resistance, although the exact mechanism for this effect is not fully understood.

Contraindications include active hepatic disease and known sensitivity to the drug. Use with caution in patients with a history of liver disease or dysfunction. Not recommended in pheochromocytoma or pregnancy.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. For more details see the brief summary of prescribing information.

For a brief summary of prescribing information, please see following page.

in most cases of sustained moderate hypertension

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis. Known sensitivity. Not recommended in pheochromocytoma. Unsuitable in mild or labile hypertension responsive to mild sedation or thiazide therapy. Use cautiously in patients with history of previous liver disease or dysfunction.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between six and twelve months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at six and twelve months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first three weeks of therapy, sometimes with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first two to three months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first six to twelve weeks of therapy or whenever an unexplained fever occurs. If fever, abnormalities in liver function tests, or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, reversible reduction in leukocyte count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur.

Use in Pregnancy and Childbearing Age—Not recommended in pregnancy. In women of childbearing age, weigh potential benefits against possible fetal hazards.

Precautions: Methyldopa may interfere with measurement of: uric acid by the phosphotungstate method, creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, spuriously high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has occurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: Sedation, usually transient, may be seen during initial therapy or when dosage is increased. Headache, asthenia, or weakness may be noted as early, transient symptoms. Symptoms associated with effective lowering of blood pressure are occasionally seen and include dizziness, lightheadedness, and symptoms of cerebrovascular insufficiency. Angina pectoris may be aggravated. Symptoms of orthostatic hypotension may occur; if symptoms occur, reduction of dosage is suggested. Bradycardia, nasal stuffiness, mild dryness of mouth, and gastrointestinal symptoms including distention, constipation, flatus, and diarrhea occur occasionally; these generally can be relieved by reducing dosage. Nausea and vomiting have been reported in only a few patients. Sore tongue or "black tongue," pancreatitis, and inflammation of salivary glands may occur.

Weight gain and edema occur infrequently and are relieved by administering a thiazide diuretic; if edema progresses or signs of pulmonary congestion appear, discontinue drug. A rise in BUN has been observed. Other rare reactions include breast enlargement, lactation, impotence, decreased libido, skin rash, mild arthralgia, myalgia, paresthesias, Bell's palsy, parkinsonism, psychic disturbances including nightmares, reversible mild psychoses or depression. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Note: Dosage should be limited initially to 500 mg daily when following previous antihypertensive agents other than thiazides. Maximal recommended daily dose is 3.0 g. Patients with impaired renal function may respond to smaller doses than patients with normal kidney function. Syncope in older patients has been related to increased sensitivity in those with advanced arteriosclerotic vascular disease; this may be avoided by lower doses. Tolerance occasionally seen either early or late, but more likely between second and third month after initiation of therapy; increased dosage or combined therapy with a thiazide frequently restores effective control.

How Supplied: Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100.

addendum

to further simplify therapy for many patients

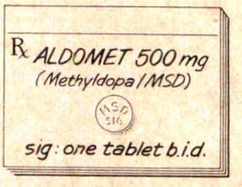
now available
ALDOMET® 500 mg
(METHYLDOPA | MSD)

- **often more practical to prescribe**
- **easier for patients to remember**

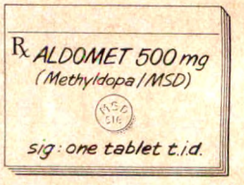
Now offered in addition to the standard 250-mg tablet, the new ALDOMET 500 mg tablet is a patient convenience. An especially important one, since in hypertension convenience of the dosage schedule is one factor that can make the difference in compliance of the patient. The minimum daily dose of ALDOMET is 250 mg b.i.d. The usual starting dose is 250 mg t.i.d. Dosage is adjusted as necessary by adding or deleting 250 mg or 500 mg at intervals of not less than two days. The maximum dose is 3.0 g per day.

Examples of b.i.d. or t.i.d. dosage convenience provided by ALDOMET 500 mg within the usual daily dosage range of 500 mg to 2.0 g:

1.0-g daily dose =



1.5-g daily dose =



2.0-g daily dose =

Long before
facing the
"ultimate" test
of stability...

Nitrostat has shown proof of stability

There are a lot of ways to say "stable" when you're dealing with nitroglycerin. Some more meaningful than others.

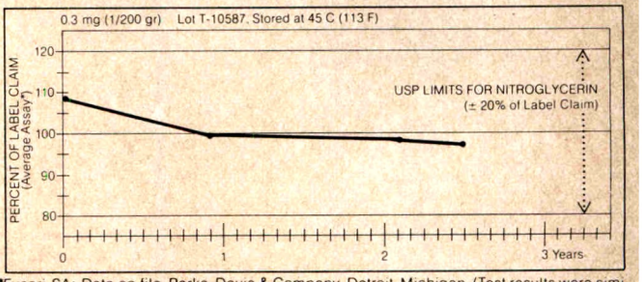
That's why the testing of Nitrostat *includes* tests to simulate, as closely as possible, the actual conditions of use.

For example, we test for **wickability** – a Parke-Davis test (the time in seconds required for water to wet the tablet completely by capillary action under controlled conditions) – to simulate under-the-tongue conditions.

Heat-stable? Yes. Up to 45 C (113 F) (considerably higher than your patient's pocket temperature). See graph.

What's more, the crucial question of maintenance of content uniformity of nitroglycerin is answered by Nitrostat as proved by assay.

Potency? The average assay still shows almost 100% of label claim more than 30 months after manufacture: less chance of your patient taking a superpotent or, more important, a subpotent tablet.



*Fusari SA: Data on file, Parke, Davis & Company, Detroit, Michigan. (Test results were similar for the 0.4-mg and the 0.6-mg strengths.)

Disintegration? We test it using the USP test in 800 ml of water – all tablets usually disintegrate within 30 seconds (USP limit – two minutes).

Dissolution? Using NF Method II, we show greater than 90% dissolution in 30 seconds.

Now, each factor taken by itself may not be decisive. But taken together, they add up to a good reason to specify Nitrostat.

Nitrostat® / sublingual tablets stabilized formula

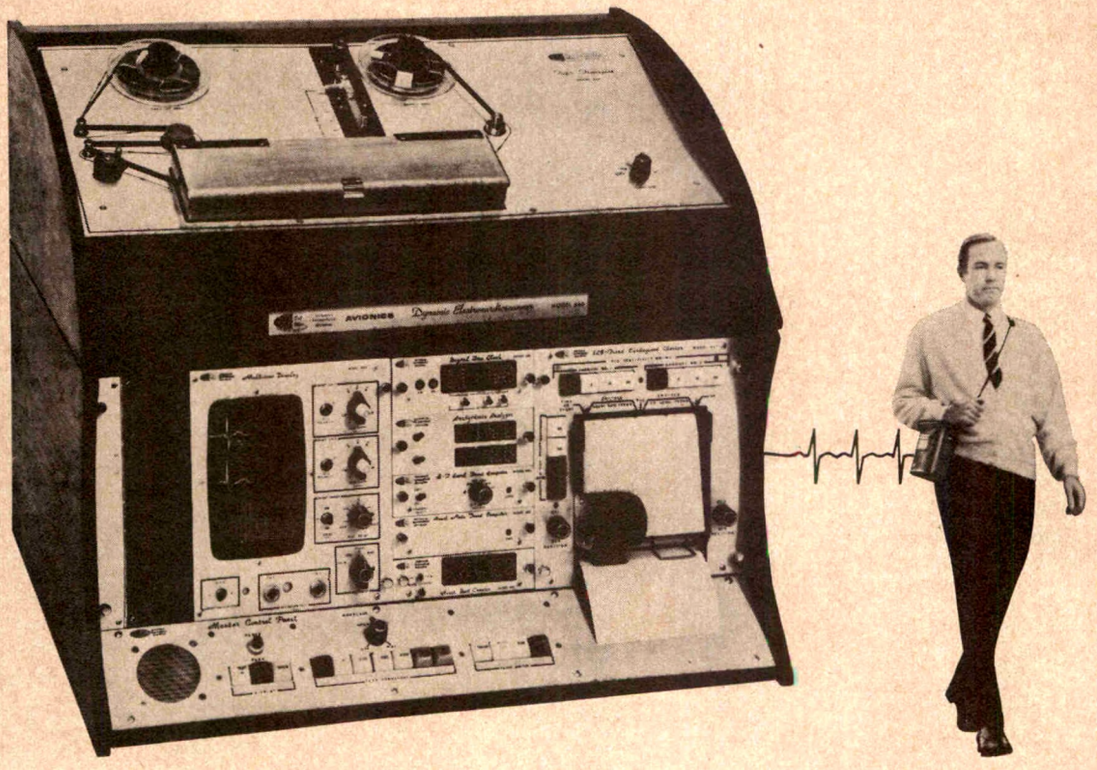
THE NEW 660 A DRAMATIC LEAP FORWARD IN DYNAMIC ELECTROCARDIOGRAPHY!



Model 660 Features:

- **2-channel playback of Holter recordings**
- **2-channel paper writer**
- **120:1 playback ratio (24-hour recording scanned in 12 minutes)**
- **Trend recording of S-T segment and heart rate**
- **Digital display and chart recording of ventricular and supraventricular ectopic beats**
- **Total heart beat counter**
- **Digital display clock**
- **Automatic time print-out on ECG write-out**
- **Adjustable delay loop for tape deck**
- **Solid state, modular design**

Now available to every physician . . . an advanced ECG system for post MI follow-up, pacemaker evaluation, evaluation of drug administration, and detecting the causes of such fleeting symptoms as phantom chest pains and dizziness.

Model 425 Holter Monitor
Provides a 2-channel, 24-hour ECG recording of ambulatory patients.

Model 660 Electrocardioscanner®
Performs a 12-minute scan of the 24-hour, 2-channel tape recording and provides standard ECG documentation of abnormalities and quantification of arrhythmia and ischemic data.

AVIONICS

☐ Please send me the literature. I would like to know more about Holter monitoring and the Avionics Dynamic Electrocardiographic Systems.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

CONTENTS

CLINICAL STUDIES

1 **Echocardiography in Acute Myocardial Infarction**

BETTY C. CORYA, SUSAN RASMUSSEN, SUZANNE B. KNOEBEL and HARVEY FEIGENBAUM with the technical assistance of MARY JO BLACK

Echocardiograms recorded in 64 patients with acute transmural myocardial infarction during their stay in the coronary care unit proved useful in detecting abnormalities of left ventricular wall motion corresponding to the electrocardiographic site of infarction and in determining prognosis. By combining the measurement of left ventricular internal dimension (correlating with heart failure) and mitral valve closure (reflecting left ventricular end-diastolic pressure), it was possible to predict hospital mortality from the echocardiograms.

11 **Echocardiography in Aortic Root Dissection and Dilatation**

RICHARD W. MOOTHART, RICHARD D. SPANGLER and S. GILBERT BLOUNT, Jr.

Echocardiography had a diagnostic accuracy equal to that of angiography and could be repeated easily and safely in six patients with aortic root dissection and in six with aortic root dilatation. Recording of a double echo from the anterior or posterior root was diagnostic of aortic root dissection. Echocardiography was helpful not only in diagnosis but also in patient management and follow-up.

17 **Echocardiographic Criteria for Aortic Root Dissection**

OWEN R. BROWN, RICHARD L. POPP and FRANK E. KLOSTER

Previously reported echocardiographic criteria of aortic root dissections—widened posterior or anterior aortic wall (or both), parallel motion of the separated margins of the aortic root walls and aortic root dilatation—were found not only in one patient with proved aortic root dissection, but also in 5 of 10 patients without clinical indication of this condition or aortic valve disease. At least two of these criteria were also recorded in the remaining five patients. The echocardiographic diagnosis of aortic root dissection is most reliable in the presence of positive clinical indications of this condition.

21 **Echocardiographic Differentiation of Infundibular from Valvular Pulmonary Stenosis**

ARTHUR E. WEYMAN, JAMES C. DILLON, HARVEY FEIGENBAUM and SONIA CHANG

Echocardiograms in three patients with infundibular pulmonary stenosis showed marked chaotic systolic fluttering of the pulmonary valve leaflet which lies in the turbulent stream of blood distal to the obstruction. This fluttering, absent in 24 normal subjects and in 16 patients with valvular pulmonary stenosis, appears unique and useful in separating infundibular from valvular pulmonary stenosis. Another observation was normal or absent presystolic opening motion of the pulmonary valve leaflet in infundibular stenosis contrasted to the increased posterior or opening motion in valvular stenosis.

CONTENTS

27 **Radiographic Appearance of the Thorax in Systolic Click-Late Systolic Murmur Syndrome**

CARL P. BON TEMPO, JAMES A. RONAN, Jr., ANTONIO C. de LEON, Jr. and HOMER L. TWIGG

A striking number of thoracic skeletal abnormalities observed in 39 of 64 patients with an isolated systolic click or a systolic click with a late systolic murmur suggest that these abnormalities should be considered diagnostic features of this syndrome. Scoliosis occurred in 39 percent, a "straight back" in 23 percent and pectus excavatum in 11 percent.

32 **Thoracic Skeletal Abnormalities in Idiopathic Mitral Valve Prolapse**

JOSEPH SALOMON, PRAVIN M. SHAH and ROBERT A. HEINLE

Thoracic skeletal abnormalities in 24 patients with proved prolapse of the mitral valve include pectus excavatum (62 percent), "straight back" (17 percent) and severe scoliosis (8 percent). Patients with such skeletal abnormalities should be checked carefully for mitral valve prolapse. The combination of mitral valve prolapse and these skeletal deformities may represent a forme fruste of Marfan's syndrome.

EXPERIMENTAL STUDIES

37 **Termination of Ventricular Fibrillation in Dogs by Depolarizing a Critical Amount of Myocardium**

DOUGLAS P. ZIPES, JOHN FISCHER, ROBERT M. KING, ANN deB. NICOLL and WALTER W. JOLLY

These experiments in dogs support the concept that a critical myocardial mass is required to maintain ventricular fibrillation initiated by rapid ventricular pacing. Successful defibrillation resulted when a critical amount of myocardium was depolarized by either potassium chloride or electrical discharge. Not every cell in both ventricles must be depolarized to terminate ventricular fibrillation in the entire heart.

45 **Influence of Sympathetic Tone on Ventricular Fibrillation Threshold During Experimental Coronary Occlusion**

BERNARD R. KLIKS, MARY JO BURGESS and J. A. ABILDSKOV

The ventricular fibrillation threshold in 14 open chest dogs with controlled heart rate decreased 35 percent during coronary occlusion, 42 percent during stellate stimulation and 63 percent during combined coronary occlusion and stellate stimulation. Stellectomy in seven animals increased the threshold 31 percent. After stellectomy, coronary occlusion decreased the ventricular fibrillation threshold by only 11 percent. These findings may have therapeutic implications for treatment of ventricular arrhythmias caused by myocardial infarction or central nervous system disease.

50 **Effect of Manganese Chloride and Verapamil on Automaticity of Digitalized Purkinje Fibers**

WARREN W. TSE and JAOK HAN

Manganese chloride and verapamil suppressed the ouabain-induced increase in automaticity of isolated spontaneously beating Purkinje preparations. This suggests that an inward calcium ion current may be involved in the development of digitalis-induced increase in the slope of phase 4 depolarization in Purkinje fibers.

2. BETTER SERVICE— full service and maintenance contracts available...

Compare the quality and performance of our system with all others. We'll bring the entire system, including the treadmill, to your hospital, clinic, or office and conduct an actual stress test under your control. You can prove the superior performance and diagnostic quality of our system to your own satisfaction.

Ask any competitor to bring and demonstrate his complete system to you, including treadmill exercising. If he refuses, that should tell you something! If you want the best, we've got it and we're ready to bring it to you.

For action, just use the coupon below.

METHODS

56 Use of a Balloon-Tipped Flotation Electrode Catheter for Cardiac Monitoring

KANU CHATTERJEE, H. J. C. SWAN, WILLIAM GANZ, RICHARD GRAY, HANNAN LOEBEL, JAMES S. FORRESTER and DAVID CHONETTE

This special balloon-tipped flotation catheter with two pairs of electrodes permits simultaneous monitoring of cardiac rhythms and hemodynamics at the bedside and, when indicated, atrial, ventricular or atrioventricular sequential pacing. Major problems associated with its use are the need for several catheters with differences in distance between the electrodes and the catheter tip and between electrodes to accommodate heart chambers and great vessels of various sizes. Important benefits for diagnosis and management can be achieved in patients with hemodynamic difficulties and arrhythmias.

62 Retrograde Catheterization of the Left Atrium in Idiopathic Hypertrophic Subaortic Stenosis

BERT WONG, RENE A. LANGOU, LAWRENCE S. COHEN and STEVEN WOLFSON

Retrograde catheterization of the left atrium utilizing the Shirey technique, easily and successfully performed in four patients with idiopathic hypertrophic subaortic stenosis, is recommended as an alternative to the transseptal approach to the left atrium in this condition. By traversing the inflow tract of the left ventricle during pullback from the left atrium to the aorta, differentiation of true subaortic stenosis from cavity obliteration is facilitated.

PEDIATRIC CARDIOLOGY

67 Right Ventricular Volume in Congenital Heart Disease

ELIZABETH A. FISHER, IRA W. DuBROW and ALOIS R. HASTREITER

This investigation indicates that a simple geometric model, a prism with a triangular base, is comparable in accuracy with Simpson's rule both in cast studies and in in vivo calculations of right ventricular volume. The normal right ventricle in children is slightly larger than the left and has a lower ejection fraction. In children the right ventricle can adapt to chronic increase in afterload and preload and is not necessarily overloaded by a ventricular septal defect or tetralogy of Fallot. It is relatively unaffected by severe myocardial disease.

REVIEWS

76 Advances in Clinical Vectorcardiography

ALBERTO BENCHIMOL and KENNETH B. DESSER

Experience in more than 5,000 patients subjected to complete right and left heart catheterization and selective coronary cineangiography demonstrates the clinical superiority of the vectorcardiogram over the electrocardiogram in the recognition of atrial and ventricular hypertrophy, identification of myocardial infarction and the diagnosis of multiple infarctions in the presence of fascicular and bundle branch blocks. It is suggested that the Frank lead system be used in all clinical vectorcardiographic laboratories and become part of the noninvasive evaluation of patients with cardiac disease.

Multi-Department Monitors

With rising overhead costs, multiple-use equipment is of critical importance. Burdick offers inter-departmental versatility to extend your coronary care skills in a variety of critical areas—with a minimum investment in instrumentation!

Burdick monitors move from area to area — ICU, CCU, Emergency, Recovery and Operating rooms, and for ECG and ExECG procedures. Check the applications of Burdick's interchangeable preamplifiers and integral heart rate meter for even greater versatility. Call your Burdick dealer for a demonstration, or write

DIAGNOSTIC SHELF

88 **Pseudomalfunction of a Beall Mitral Valve Prosthesis in the Presence of Paravalvular Aortic Regurgitation**

MILTON J. SANDS, THOMAS H. KREULEN, MICHAEL T. McDONOUGH, MONEIM A. FADALI and JAMES F. SPANN

A significant increase in the amount of paravalvular aortic regurgitation in a 32 year old man with aortic and mitral valve prostheses prematurely closed the mitral valve in mid-diastole. Oversewing of the aortic and mitral paravalvular leaks normalized mitral prosthetic function.

91 **Limitations of the Surface Electrocardiogram in Diagnosis of Atrial Arrhythmias. Further Observations on Dissimilar Atrial Rhythms**

DELON WU, PABLO DENES, FERNANDO AMAT y LEON, RAMESH C. CHHABLANI and KENNETH M. ROSEN

Electrophysiologic studies in two patients with atrial dysrhythmias demonstrate that under unusual circumstances the surface electrocardiogram may not accurately portray atrial activation in the presence of advanced atrial disease. Multiple intracavitary electrograms may be necessary for accurate diagnosis.

CASE REPORTS

98 **"Paradoxical" Prolongation of Sinus Nodal Recovery Time After Atropine in the Sick Sinus Syndrome**

JAMES A. REIFFEL, J. THOMAS BIGGER and ELSA-GRACE V. GIARDINA

After the administration of atropine in a 55 year old woman with sick sinus syndrome, the sinus recovery time became markedly prolonged and atrial quiescence persisted more than 10 seconds, presumably because of alterations in sinus nodal automaticity, sinoatrial conduction time or intra-sinoatrial nodal conduction. These results suggest that an increase in post-tachycardia bradycardia produced by atropine could aggravate symptoms in such patients.

105 **Demand Pacemaker Arrhythmias Caused by Intermittent Incomplete Electrode Fracture. Diagnosis with Testing Magnet**

PHILIPPE COUMEL, JACQUES MUGICA and S. SERGE BAROLD

Abrupt changes in resistance within a pacing system cause corresponding voltage changes between the anode and cathode and may generate false signals that can be sensed by a demand pulse generator. Such false signals should be suspected whenever demand pacing produces a chaotic pattern. This report shows how a testing magnet was used to diagnose intermittent partial electrode fracture in two patients with an implanted demand pacemaker.

ACCEPTED CONCEPTS IN ANGINA THERAPY*

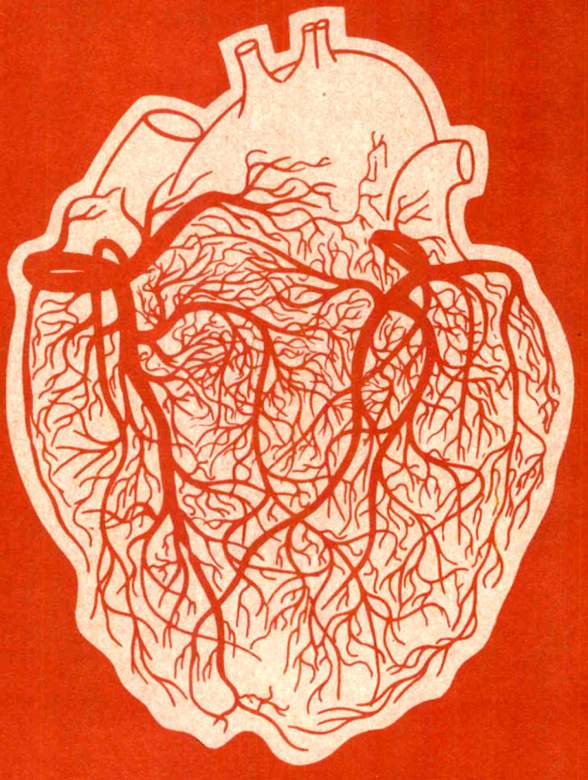
- Nitrates are the first line of defense against angina pectoris
- The therapeutic goal of oral nitrate therapy is an angina-free patient

When higher dosage is necessary in the prophylaxis of angina

prescribe

ISORDIL®
(isosorbide dinitrate)
20 mg.

Scored, oral tablets



Fewer tablets for patients on 80 mg. or more per day (up to a maximum of 120 mg./day)

- **To provide prophylaxis against anginal attacks often caused by unavoidable everyday stress.**
- **To reduce the frequency and severity of angina pectoris attacks. (Not intended to abort the acute episode.)**

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

CMS. It gives more

CMS — Clinical Monitoring Systems — is an advanced, computerized monitoring system developed by B-D Electrodyne, a medical instrumentation division of Becton, Dickinson and Company.

It provides more meaningful information more quickly, and in a more easily assimilated form, than conventional or even other computerized systems.

For example:

Status. Composite, moment-to-moment status displays of each patient for each variable. Easily visible, even at a distance.

Rhythm history. 8 or 24 hour history of each patient. Large-screen graphic display.

Trend graphs of any monitored variable.

Alarm limits individually selected for each variable, for each patient.

Alphanumeric-labeled ECG strips. Each automatically labeled with time, date, bed number, patient name, status, beat classification.

Hard copies of any display at any time.

Medication report. Type, amount, time.

In addition, CMS can be added to any existing solid-trace B-D Electrodyne system, and may be purchased or leased.

Obviously, there is much more to CMS than can be described in this space. To get details, send for CMS Booklet and abstract of an independent clinical evaluation. B-D Electrodyne, Division of Becton, Dickinson and Company, Sharon, MA 02067. 617-828-9080.

Schering

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action **Hyperstat®** I.V.
Brand of DIAZOXIDE
INJECTION
20 ml ampule
contains 300 mg

"The injection of the [diazoxide] bolus in 10 to 15 seconds results in a prompt blood pressure fall in a high percentage of cases. A maximal blood pressure response usually occurs within 5 to 10 minutes."*

☐ **Rapid reduction to normotensive levels**
Induces rapid reduction of blood pressure generally within 5 minutes . . . often in 1 or 2 minutes to the lowest level achieved. Blood pressure response facilitated by appropriate diuretic therapy.

☐ **Prolonged activity**
A single injection of HYPERSTAT I.V. generally maintains blood pressure below pretreatment levels for periods up to 12 hours.

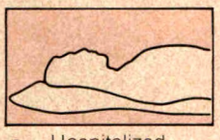
☐ **Protective action—helps avert target organ damage**
Cardiac output increases as diastolic pressure is reduced. Coronary and cerebral blood flow maintained. Increased renal blood flow after transient decrease.

☐ **Uncomplicated procedure**
Simple I.V. "push" in a peripheral vein in 30 seconds or less. Close monitoring at frequent intervals is necessary until blood pressure is stabilized (generally 15-30 minutes). Thereafter, hourly measurement should be taken during the balance of effect.

☐ **Stable . . . convenient . . . no preparation**
HYPERSTAT I.V. Injection supplied in a 20 ml. ampule containing a stable solution of diazoxide 300 mg. . . . ready to use.

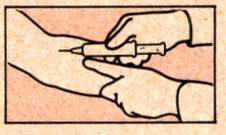
*Marvin Moser, M.D., Assistant Professor of Clinical Medicine, Albert Einstein College of Medicine, and Chief of Cardiology, White Plains Hospital, White Plains, N.Y., in Diazoxide—an effective vasodilator in accelerated hypertension. *Am Heart J* 87(6): 791-795, June 1974.

Administration guidelines



1. Hospitalized patient should be recumbent.

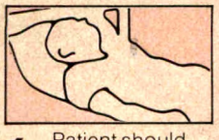
2. Fill dry syringe with appropriate dose of HYPERSTAT I.V. Injection (20 ml. ampule contains 300 mg. diazoxide).



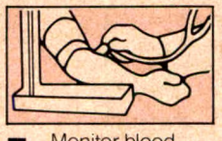
3. Insert needle only into a peripheral vein.

4. Inject entire dose I.V. in 30 seconds or less.

5. Remove needle carefully—avoid extravasation.

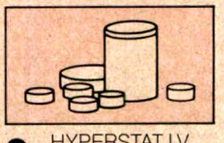


6. Patient should remain recumbent for at least half an hour after injection.



7. Monitor blood pressure closely until stabilized—usually 15-30 minutes.

8. If patient is to be ambulatory, blood pressure should be measured in standing position before surveillance is ended.



9. HYPERSTAT I.V. Injection should be continued until a regimen of oral antihypertensive medication becomes effective—generally within a few days.

Before prescribing HYPERSTAT I.V. Injection, please consult complete product information on next page.

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action

Hyperstat® I.V.

Brand of DIAZOXIDE

INJECTION
20 ml ampule
contains 300 mg

FOR INTRAVENOUS USE IN HOSPITALIZED PATIENTS ONLY

Description HYPERSTAT I.V. Injection is a rapidly acting antihypertensive agent. Each ampule (20 ml.) contains 300 mg. diazoxide, a nondiuretic benzothiadiazine derivative, in a clear, colorless, aqueous solution; the pH is adjusted to approximately 11.6 with sodium hydroxide. Diazoxide is 7-chloro-3-methyl-2H 1, 2, 4-benzothiadiazine 1, 1-dioxide.

Actions HYPERSTAT I.V. Injection produces a prompt reduction in blood pressure by relaxing smooth muscle in the peripheral arterioles. Cardiac output is increased as blood pressure is reduced by diazoxide; coronary and cerebral blood flow are maintained. Renal blood flow is increased after an initial decrease. Diazoxide has no known direct action on the central nervous system.

Patients refractory to other antihypertensive agents usually remain responsive to diazoxide.

Diazoxide is extensively bound to serum protein (>90%). The plasma half-life is 28 ±8.3 hours; however, the duration of its antihypertensive effect is variable, generally lasting less than 12 hours. Although an antihypertensive response has been obtained with slow intravenous injection, in general, a greater antihypertensive effect is obtained with rapid intravenous administration.

Indications HYPERSTAT I.V. Injection is indicated for the emergency reduction of blood pressure in malignant hypertension in hospitalized patients, when prompt and urgent decrease of diastolic pressure is required. Treatment with orally effective antihypertensive agents should be instituted as soon as the hypertensive emergency is controlled.

HYPERSTAT (diazoxide) I.V. Injection is ineffective against hypertension due to pheochromocytoma.

Contraindications HYPERSTAT I.V. Injection should not be used in the treatment of compensatory hypertension, such as that associated with aortic coarctation or arteriovenous shunt.

The drug should not be used in patients hypersensitive to diazoxide or other thiazides, unless the potential benefits outweigh the possible risks.

Warnings **Usage in Pregnancy:** The safety of HYPERSTAT I.V. Injection in pregnancy has not yet been established.

Information is not available concerning the passage of HYPERSTAT in breast milk. However, it is known that diazoxide crosses the placental barrier and appears in cord blood. Like other thiazides, the drug may produce fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, and possibly other adverse reactions that have occurred in adults.

Usage in Children: The safety of HYPERSTAT I.V. Injection in children has not yet been established.

Hypotension may occasionally result from the administration of HYPERSTAT I.V. If hypotension severe enough to require therapy occurs, it will usually respond to the administration of sympathomimetic agents, such as norepinephrine.

Hyperglycemia occurs in the majority of patients, but usually requires treatment only in patients with diabetes mellitus; it will respond to the usual management, including insulin. Therefore, blood glucose levels should be monitored especially in patients with diabetes or in those requiring multiple injections of diazoxide. Hyperglycemia and hyperosmolar coma associated with transient cataracts developed in one infant receiving repeated daily doses of oral diazoxide. The disturbed carbohydrate metabolism was successfully treated with insulin. Cataracts have been observed in a few animals receiving repeated daily doses of intravenous or oral diazoxide.

Since diazoxide causes sodium retention, repeated injections may precipitate edema and congestive heart failure. This retention responds characteristically to diuretic agents if adequate renal function exists. It should be noted that concurrently administered thiazides may potentiate the antihypertensive, hyperglycemic, and hyperuricemic actions of diazoxide (See Drug Interactions).

Since increased volume of extracellular fluid may be a cause of treatment failure in nonresponsive patients, it may be advisable to reduce this increased volume by means of a diuretic agent.

Although no evidence of excessive anticoagulant effects has been reported, patients, especially those who are hypoalbuminemic and receive HYPERSTAT I.V. Injection and coumarin or its derivatives, may require reduction in dosage of the anticoagulant (See Drug Interactions).

Precautions HYPERSTAT (diazoxide) I.V. Injection is a potent antihypertensive agent requiring close monitoring of the patient's blood pressure at frequent intervals. Its administration may occasionally cause hypotension requiring treatment with sympathomimetic drugs. Therefore, adequate facilities to treat such untoward reactions should be available when HYPERSTAT I.V. Injection is used.

HYPERSTAT I.V. Injection should be administered only into a peripheral vein. Because the alkalinity of the solution is irritating to tissue, extravascular injection or leakage should be avoided; subcutaneous administration has produced inflammation and pain without subsequent necrosis. If leakage into subcutaneous tissue occurs, the area should be treated conservatively.

Maximal antihypertensive effects occur after rapid administration (within 30 seconds) into the vein; a slower injection may fail to reduce blood pressure or produce a very brief response.

As with any potent antihypertensive agent, HYPERSTAT I.V. Injection should be used with care in patients who have impaired cerebral or cardiac circulation, that is, patients in whom abrupt and brief reductions in blood pressure might be detrimental.

Special attention is required for patients with diabetes mellitus and those in whom retention of salt and water may present serious problems (See Warnings). Nondiabetic patients may have a transient, reversible, and clinically insignificant increase in blood glucose following HYPERSTAT I.V. Injection.

Since peritoneal dialysis or hemodialysis can reduce levels of diazoxide in the blood, patients undergoing dialysis may require more than one injection.

Adverse Reactions

Frequent and serious adverse reactions: Sodium and water retention after repeated injections, especially important in patients with impaired cardiac reserve; hyperglycemia frequently requiring treatment in diabetic patients, especially after repeated injections.

Infrequent but serious adverse reactions: Hypotension to shock levels; myocardial and/or cerebral ischemia, usually transient but possibly leading to thrombosis and manifested by angina, atrial and ventricular arrhythmias, and marked electrocardiographic changes; unconsciousness, convulsions, paralysis, or confusion; persistent retention of nitrogenous wastes after repeated injections; sensitivity reactions, such as rash, leukopenia, and fever. Rarely, acute pancreatitis has been reported.

Other adverse reactions: Nausea, vomiting, and/or abdominal discomfort; vasodilative phenomena, such as flushing, generalized or localized sensations of warmth, headache (sometimes throbbing), and sweating; orthostatic hypotension, lightheadedness, and weakness of short duration; supraventricular tachycardia and palpitation; transient hyperglycemia in nondiabetic patients; transient retention of nitrogenous wastes; nonanginal "tightness in the chest"; warmth or pain along the injected vein; cellulitis without sloughing and/or phlebitis at the site of extravasation; anorexia and alteration of taste; ileus; bradycardia; back pain; chest discomfort; dyspnea, choking sensation; apprehension or anxiety, malaise, and blurred vision occurred on single occasions; parotid swelling, salivation, lacrimation; ringing in the ears; diarrhea and constipation; increased nocturia; euphoria.

Drug Interactions Since diazoxide is highly bound to serum protein, it may displace other substances or drugs which are also bound to protein, such as bilirubin or coumarin and its derivatives. These potential interactions must be considered when administering HYPERSTAT I.V. Injection. The concomitant administration of diazoxide with thiazides or other commonly used potent diuretics may potentiate the hyperglycemic, hyperuricemic, and antihypertensive effects of diazoxide.

Overdosage Overdosage of HYPERSTAT I.V. Injection may cause an undesirable hypotension. Usually, this can be controlled with sympathomimetic agents, such as norepinephrine; failure of the blood pressure to rise in response to such an agent suggests that the hypotension may have been caused by something other than diazoxide. Excessive hyperglycemia resulting from overdosage will respond to conventional therapy of hyperglycemia.

Diazoxide may be removed from the blood by peritoneal dialysis or hemodialysis.

Animal Pharmacology and Toxicology In studies involving a number of species, including the rat, cat, dog, and monkey, diazoxide has been shown to exert significant antihypertensive actions through its direct effect on peripheral arterioles, which neither impairs cardiac function nor seriously diminishes perfusion of kidneys. In addition, in each species tested, including the rat, dog, and monkey, diazoxide elicits hyperglycemia, increased serum-free fatty acids and decreased plasma insulin levels by a mechanism thought to involve both suppression of insulin release and enhanced catecholamine action.

Although the data are not conclusive, reproduction and teratology studies in several species of animals indicate that diazoxide, when administered during the critical period of embryo formation, may interfere with normal fetal development, possibly through altered glucose metabolism. Parturition was occasionally prolonged in animals treated at term.

Dosage and Administration HYPERSTAT I.V. Injection is administered undiluted and rapidly by intravenous injection. It should only be given into a peripheral vein. Do not administer it intramuscularly, subcutaneously, or into body cavities. Avoid extravasation of the drug into subcutaneous tissues.

The response to HYPERSTAT I.V. Injection varies from patient to patient. Generally, blood pressure decreases within five minutes, often within one to two minutes, to the lowest level achieved. The blood pressure increases relatively rapidly in the next ten to 30 minutes, and then more slowly over the following two to 12 hours, nearly reaching but rarely exceeding the pretreatment level. The response to successive injections is frequently better than that to the initial injection.

Treatment of hypertensive emergencies with HYPERSTAT I.V. Injection should be limited to a few days and a regimen of oral antihypertensive medications should be instituted as soon as possible.

With the patient recumbent, the contents of one 20 ml. ampule containing 300 mg. of HYPERSTAT I.V. Injection are administered intravenously in 30 seconds or less. Slow intravenous injection may fail to reduce the blood pressure or may produce an exceedingly short response.

Specific dosage is required in children or in unusually large or small patients. This dosage may be calculated on the basis of 5 mg./kg. body weight (0.3 ml./kg.) (See Warnings).

A second administration of HYPERSTAT (diazoxide) I.V. Injection may be required for a satisfactory reduction in blood pressure, if the first injection fails to give an adequate response within 30 minutes.

Repeated administration of HYPERSTAT I.V. Injection at intervals of four to 24 hours usually will maintain the blood pressure below pretreatment levels until a regimen of oral antihypertensive medication becomes effective. The interval between injections may be adjusted by the duration of the response to each injection. It is usually unnecessary to continue treatment with HYPERSTAT I.V. Injection for more than four to five days.

Following the use of HYPERSTAT I.V. Injection, the blood pressure should be monitored closely until it has stabilized. Thereafter, measurements taken hourly during the balance of the effect will indicate any unusual response. A further decrease in blood pressure at 30 minutes or more after injection should be investigated for causes other than the action of HYPERSTAT I.V. Injection. It is preferable that the patient remain recumbent for half an hour after injection. In ambulatory patients, the blood pressure should be measured with the patient standing before surveillance is ended.

Since repeated administration of HYPERSTAT I.V. Injection can lead to sodium and water retention, administration of a diuretic may be necessary both for maximal blood pressure reduction and to avoid congestive failure.

How Supplied HYPERSTAT I.V. Injection is supplied in a 20 ml. ampule containing diazoxide 300 mg. in a clear, colorless aqueous solution; box of one ampule.

Protect from light and freezing.

Store away from heat.

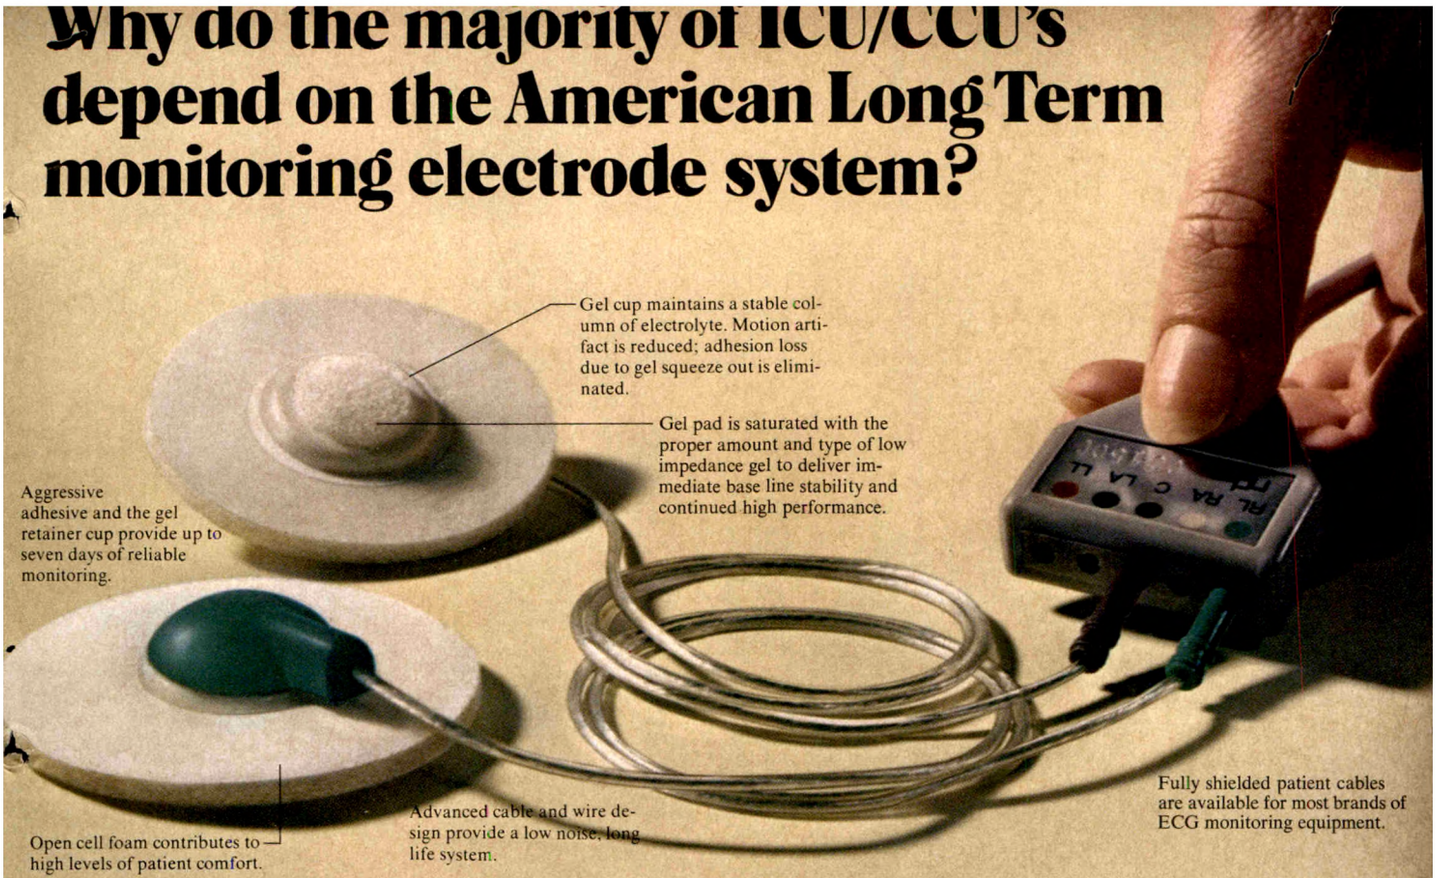
Schering

Schering Corporation
Kenilworth, N.J. 07033

Why do the majority of ICU/CCU's depend on the American Long Term monitoring electrode system?



This is the system that has established new standards for high performance in long term ECG monitoring.

Designed for single patient use, the self-adhering silver/silver chloride electrode is pregelled with the correct amount of proper electrolyte. Adhesion loss and electrolyte evaporation are virtually eliminated by the gel retaining cup. The results: Immediate base line stability and better long term performance than any other electrode —reusable or disposable—is capable of delivering.

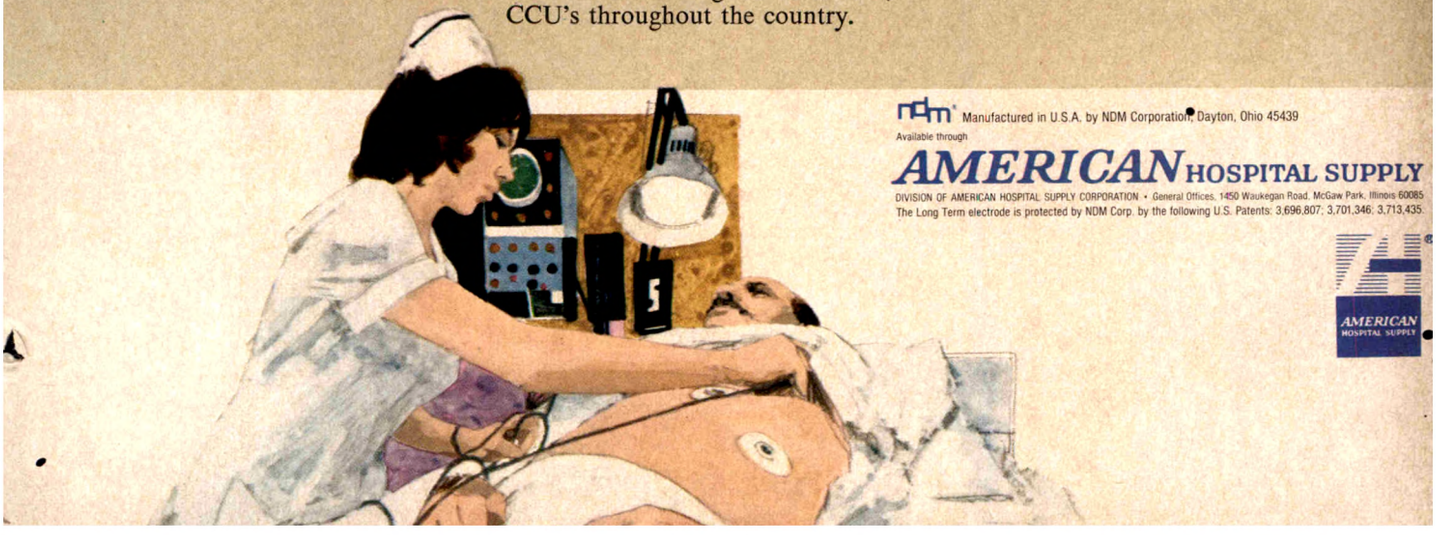
Open cell foam complements the electrode's mild gel formulation and low profile to enhance patient comfort. When used as directed, American's Long Term Electrode provides from five to seven days of continuous, accurate monitoring . . . with no discomfort to the patient.

This advanced electrode, used with the appropriate American leadwire and cable, is fully compatible with your present ECG equipment.

A clinical trial will show you why the American Long Term Electrode system is the overwhelming choice of ICU/CCU's throughout the country.

Please contact your American Hospital Supply or NDM representative and ask for:

- A demonstration of the system's benefits.
- A no obligation clinical trial. American will supply electrodes, leadwires and cables to adapt to your present monitoring equipment during the trial period.
- A total inservice for your staff.
- Information about our nationwide technical support program.



ndm Manufactured in U.S.A. by NDM Corporation, Dayton, Ohio 45439

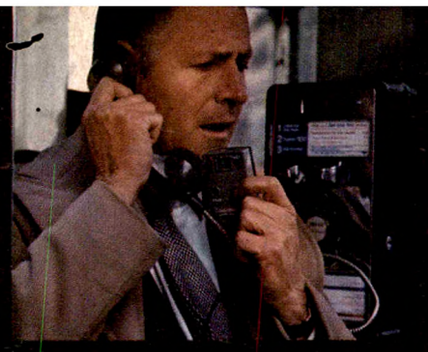
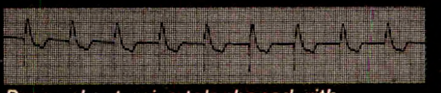
This is the heart of the new CardioBeeper® system.
TEST
BEEP
ECG
CardioBeeper® PM
PACER MONITOR
It can change your concept of patient care.



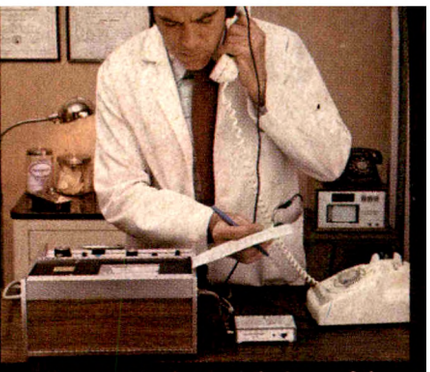
CardioBeeper®-PM pacer monitor are unlike any heart monitoring instruments now in use. They're five ounces, pocket-sized and relatively inexpensive. Yet they are unparalleled in electronic sophistication. The CardioBeeper monitors are engineered to permit your coronary patient, within seconds, to telephonically transmit his heart rate and rhythm or ECG. And to allow your pacemaker patient to transmit pacemaker rate interval and artifact, as well as confirmation of battery integrity and ventricular capture. At any time. From any conventional telephone. If indicated, you are then able to institute immediate, often life-sustaining action.



Pacemaker tracing telephoned with CardioBeeper-PM.

Normal ECG tracing telephoned with CardioBeeper.

The CardioBeeper system is simple to use. Your patient need not undress. Or be bothered with paste, gels or straps. He simply places a reusable electrode in each bare armpit. And to transmit, he merely holds the CardioBeeper



monitor next to the mouthpiece of the phone while touching a button. *Physician and patient stay in constant voice contact while sending and receiving.*

You can immediately receive the telephoned data as a series of audible "beeps" indicating each QRS complex or pacemaker spike. To receive a permanent record of ECG or pacemaker artifact, just connect a CardioBeeper® ECG Decoder to your telephone and to any conventional ECG machine. Or instead, connect a CardioBeeper® Decodalyzer to your phone to obtain a visual readout of heart rate or pacemaker rate in BPM, interval count in msec. or a direct ECG tracing for your records.

In life-threatening emergencies or routine checks, no remote cardiac monitoring instruments available today at any cost can rival the revolutionary CardioBeeper system. For further information, simply contact your Wyeth representative or Wyeth Laboratories, Box 8299, Philadelphia, Pa. 19101.

Manufactured for Wyeth Laboratories by Survival Technology, Inc.

Model 8114

Edwards Laboratories presents a whole new case for the STARR-EDWARDS™ Cardiac Pacer: the Model 8116 Hermetically Sealed Ventricular Tracking Pulse Generator.

This second-generation pulse generator utilizes the same electronic circuit design of the Model 8114, which has attained a record of reliable clinical performance in more than 3,000 confirmed implants.

Of most significance, the Model 8116 features a hermetically sealed metal case to protect **the entire** electronic circuit and power supply from body fluid infiltration. Critical components function in a totally dry environment, thereby contributing toward improved reliability and longer operating life.

Further, the all-metal surface offers added external shielding against electromagnetic interference. Haynes Alloy 25, a biologically compatible material, covers the entire surface, obviating the need for an epoxy barrier. Case width is reduced to 2.0 cm., thereby contributing to an improved cosmetic appearance.

Inside the pulse generator,

Hermetically sealed.

Model 8116

improved RM-1 Mallory Mercury Cells are employed. Pacing rates of 70, 78 and 85 BPM may be selected as standard. Fixed rate versions are also available.

Because of these numerous improvements, and past record of extended longevity, the Model 8116 carries a 48-month warranty and replacement allowance.

For complete details, clinical data, and a description of Edwards' complete Cardiac Pacer System, please contact Edwards Laboratories, 17221 Red Hill Avenue, P.O. Box 11150, Santa Ana, California 92711, 714/557-8910, Cable: EDSLAB, Telex: 68:5567.

If psychic tension interferes with cardiac rehabilitation, here's how Valium® can help.
(diazepam)

During hospitalization, Valium (diazepam) can relieve psychic tension that can disrupt bed rest and interfere with the rehabilitation program.

After the MI patient is stabilized, a certain amount of psychic tension is to be expected. Your reassurance, counseling and enlistment of family support can often minimize its effects. However, in some instances, the patient's thoughts may dwell constantly on his condition and how it will affect his life, thus producing excessive psychic tension that may present special problems. He may feel overwhelmed and be so burdened by these tensions that he is unable to rest and unable or unwilling to begin a program of rehabilitation. Under these circumstances, Valium® (diazepam) can often be a beneficial adjunct.

Valium can calm the cardiac patient and help reduce his psychic tension to appropriate levels. Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticoagulants, anticholinergics and antacids. Careful consideration should be given to the pharmacology of agents used with Valium, particularly those which may potentiate its action.

During convalescence at home, Valium (diazepam) can reduce excessive anxiety that may hinder participation in active rehabilitation.

Your counseling and the family's support do much to control the anxieties that may interfere with this stage of convalescence—a time when you may wish to encourage a gradual increase in activity. But in some patients, excessive anxiety may retard general progress. For them, Valium can be beneficial during the post-hospital transition to full ambulation. And, because the convalescent cardiac patient may be particularly prone to excessive tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *b.i.d.* or *t.i.d.* schedule can reduce these symptoms and thus may encourage sleep. Therapy with Valium should be discontinued when symptoms have been reduced to tolerable levels.

What an informed cardiac patient should know about Valium therapy.

The cardiac patient should know that he can generally expect Valium to help relax and calm him so that he won't feel so overwhelmed by his tension and anxiety. An explanation of the importance of the dosage regimen you prescribe may go a long way to ensure his cooperation. As with all CNS-acting agents, the patient taking Valium should be cautioned against driving or operating dangerous machinery.

Valium® (diazepam)

2-mg, 5-mg, 10-mg tablets can relieve the cardiac patient's undue psychic tension

ROCHE

For a summary of product information, see the following page.

Valium® (diazepam)
2-mg, 5-mg, 10-mg tablets

can relieve the cardiac patient's undue psychic tension

Prompt and Effective Response Valium acts promptly to help relieve psychic tension in the cardiac patient.

Wide Margin of Safety At recommended dosages, oral Valium is generally well tolerated and does not significantly affect respiration, pulse or heart rate.

Flexible Dosage Available as *scored* tablets, oral Valium allows dosage to be easily readjusted to suit patients' changing needs.

Predictable Pharmacokinetically Pharmacokinetic studies of Valium demonstrate a highly predictable pattern of absorption, distribution, metabolism and excretion.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

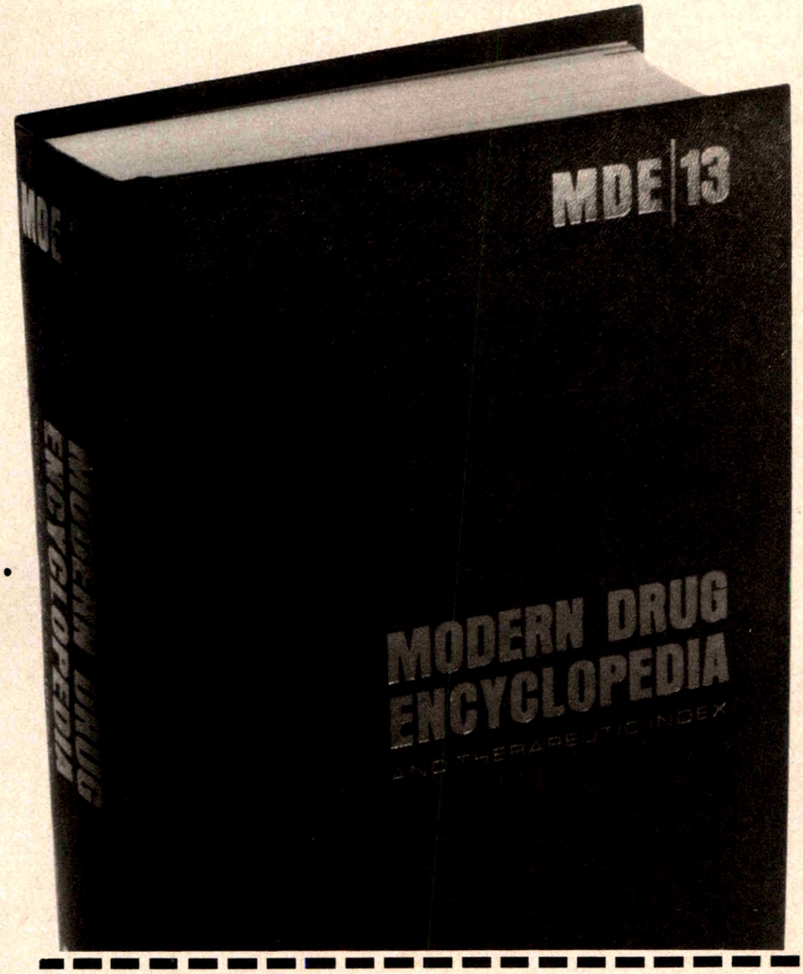
A different kind of drug reference designed with your needs in mind

The Modern Drug Encyclopedia is a compendium of over 3,000 pharmaceuticals, biologicals and allergens written, compiled and edited by an independent team of physicians and pharmacists. It is organized alphabetically by generic name with a *General Index* by brand and generic name. A *Therapeutic Index* pinpoints and locates which drugs are indicated, and, for even further flexibility, a *Manufacturers' Index* is also provided. The generic listing permits comparisons between drugs for the same indication and the free updating supplements insure that the information is the latest available.



The Modern Drug Encyclopedia is *not a bound set of package inserts*. It is an editorial product responsibly written to meet the specific drug referencing needs of all healthcare professionals. The Modern Drug Encyclopedia presents basic drug information objectively, comparatively and with regular updating.

But the proof of the pudding is in the eating. As a professional courtesy we would like to send you the new 1975 edition of the Modern Drug Encyclopedia to use for a full month at our risk and expense. If at the end of the month it has not provided you with an important and different source of drug information, simply return it and owe nothing.

To order, complete and mail the reply coupon. To avoid disappointment, order now since our printing run is limited.

The price of $33.00 includes MDE's two year supplement service—Modern Drugs.

Other Yorke Medical Group publications include The American Journal of Medicine, The American Journal of Surgery, The American Journal of Cardiology, Cutis, Laragh's Hypertension Manual, The Practitioners' Dermatology, Mason's Congestive Heart Failure.

The Modern Drug Encyclopedia-13th Edition-The Yorke Medical Group

666 Fifth Avenue, New York, New York 10019

You've piqued my interest. Send me _____ copies of the 13th Edition of Modern Drug Encyclopedia on a 30 day no risk approval basis, and enter my name to the 2 year free supplement service list. If MDE/13 is everything I hope it is, I will remit only $33.00* plus shipping. Otherwise, I will simply return it. [Note: Foreign Price—$40.00.]

☐ **Save more.** Check here if enclosing $33.00* now. You save Money an additional dollar. Publisher absorbs shipping costs. Money back if you return the book. Foreign, enclose $40.00 U.S. funds. **PT**

Yesterday he passed a resting ECG examination. Today he's on his way to a coronary care unit. A stress test may have made it a different story.

A Quinton Stress Test System may help you discover a cardio-vascular condition before serious symptoms are apparent.

A Quinton system is designed for the practicing clinical physician who needs a ruggedly durable, moderately priced unit that delivers all the information necessary for a complete evaluation.

For complete details on all Quinton controlled exercise devices and ECG monitoring systems, talk to the specialists who helped pioneer stress testing equipment. Talk to Quinton Instruments, Dept. E-75, 2121 Terry Ave., Seattle, Washington 98121. Phone 206/223-7373. **QUINTON**

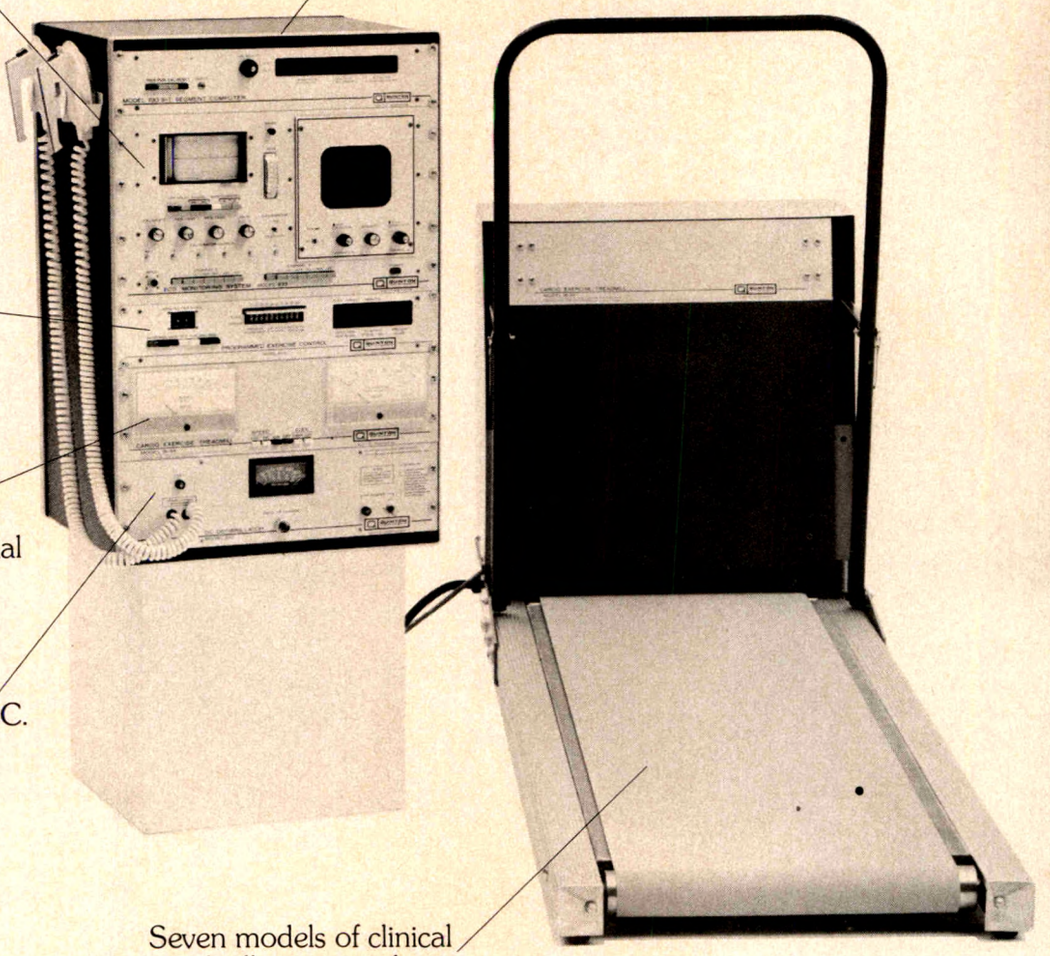
Multi-lead exercise ECG system includes 2-channel scope, recorder, and heart rate meter.

S-T Segment Computer displays S-T depression, S-T slope and heartrate.

Automatic programmer controls the treadmill while you concentrate on the patient.

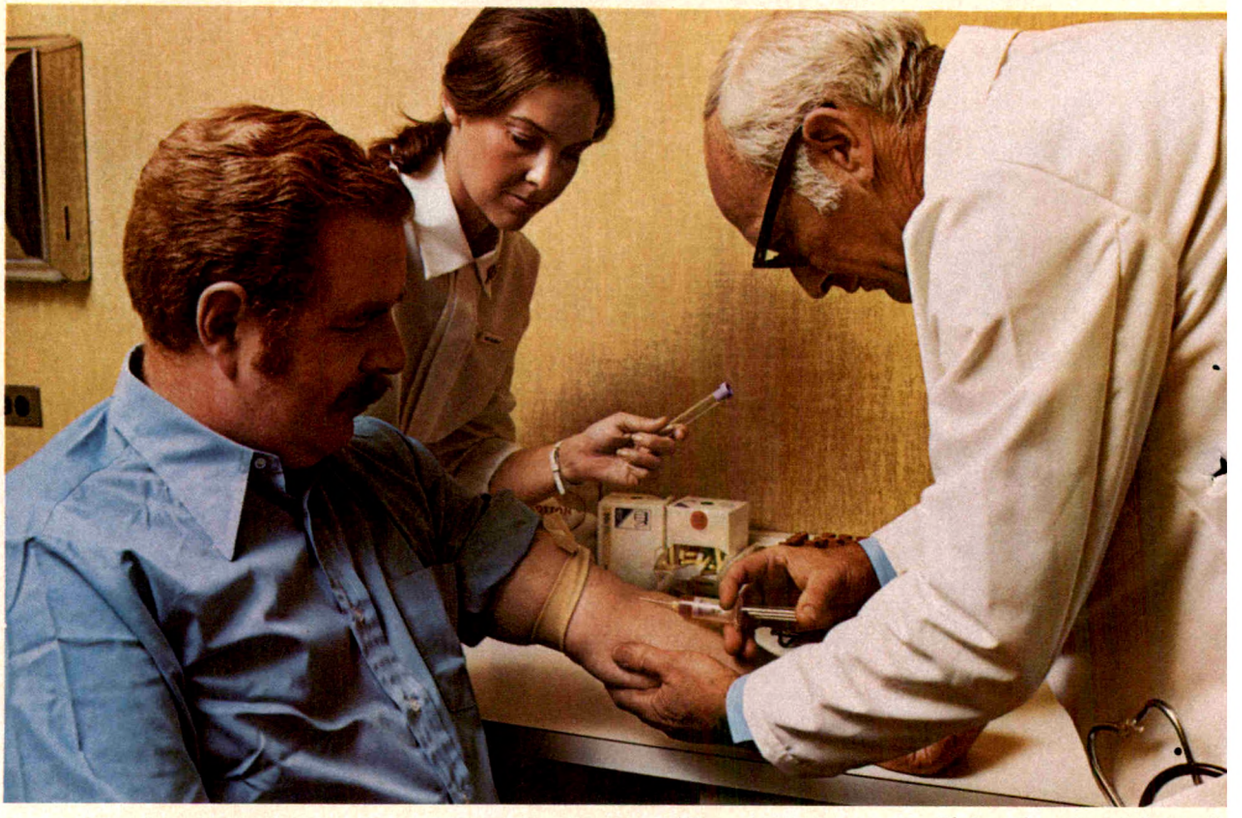
Treadmill control panel indicates speed and grade and provides manual control.

400 watt-second D.C. Defibrillator.



Seven models of clinical treadmills permit selection of the correct machine to match your requirements.

"Hyperlipidemia is one of several factors I search



(Photographs professionally posed.)

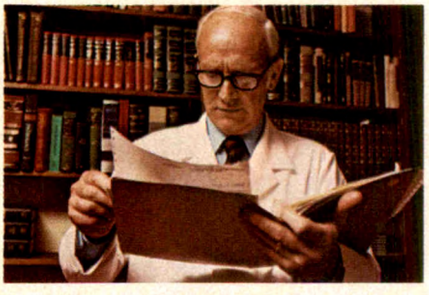
Complete lipid work-up should include both cholesterol and triglyceride determinations

Testing for both lipids—rather than just for cholesterol alone—increases the chances of detecting hyperlipidemia from 60% to over 95%.[2]

Lab results indicate pattern of lipid abnormality

When initial determinations of fasting serum cholesterol and triglyceride levels indicate the presence of hyperlipidemia, the pattern of the lipid abnormality should also be determined.[3]

When lipid elevations are confirmed, underlying disease states that may alter lipid metabolism should be ruled out through history, physical examination, and appropriate laboratory tests. Effective treatment of these pathologic conditions, if they exist, will often return the elevated lipids to a normal range. In the absence of an underlying cause, elevated lipid levels indicate a primary hyperlipidemia.



Therapy begins–but does not necessarily end–with specific dietary recommendations

Diet (specific for the lipid abnormality) is the starting point in the management of primary hyperlipidemia, and in the relatively rare Type I hyperlipoproteinemia it is the *only* therapy since currently available drugs are ineffective. But in the drug-responsive types (Types IIa, IIb, III, IV and V) diet alone may fail to lower lipids adequately.

Drug therapy is often necessary as an adjunct to diet

Convincing the asymptomatic hyperlipidemic patient to give up his favorite foods for benefits he may not feel is, at best, a difficult task. Even under carefully monitored dietary regimens, lipid reductions may be inadequate.[4] For these reasons it is often necessary to add an antilipemic agent to the dietary regimen to produce a significant reduction in serum lipids.

AN IMPORTANT NOTE: It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

for and vigorously treat."[1]

"Along with early hypertension, excessive cigarette smoking and dietary indiscretions, it is one of the few manifestations of modern society that an individual physician can attempt to control."[1]

This is how one clinician views hyperlipidemia—a condition widespread in America today. The treatment he speaks of often calls for a dietary regimen specific for the lipid abnormality *plus* an antilipemic agent. And since many hyperlipidemic patients exhibit elevations of *both* cholesterol and triglycerides, they need a drug such as ATROMID-S (clofibrate), which has the ability to lower *both* lipids.

Atromid-S significantly reduces cholesterol and triglycerides—often in patients unresponsive to diet[5]

ATROMID-S as an adjunct to diet has a proven record of effectiveness in lowering serum elevations of both cholesterol and triglycerides.[5-8]

Although most hyperlipidemic patients are asymptomatic, a small number may exhibit skin lesions or xanthomas. Regression of xanthomatous lesions with ATROMID-S visually demonstrates the efficacy of this lipid-lowering agent. In some patients xanthomas disappear completely. In others the size and number of lesions are reduced.

Continuous treatment, maintenance of daily dosage vital to long-term control

Reliable cholesterol- and triglyceride-lowering effect is usually sustained as long as ATROMID-S treatment is uninterrupted. This ability to maintain control of serum lipids for extended periods is of primary importance in treating a disorder as persistent as hyperlipidemia.

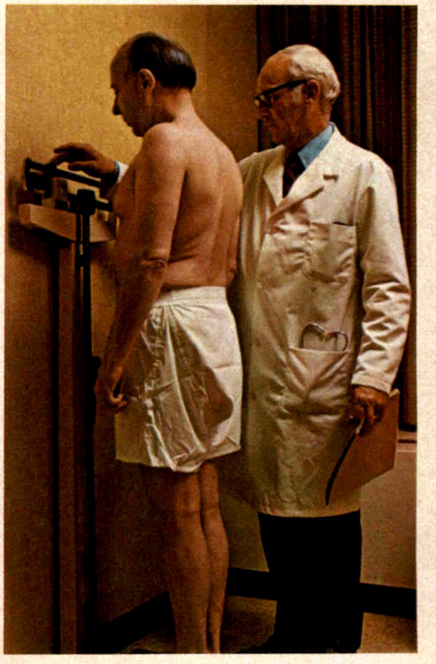
ATROMID-S is effective in a simple, well-accepted regimen that patients can stay with. Initial *and* maintenance dosage is 2 Gm. daily, in divided doses. Some patients may respond to a lower dosage. To maintain continuous control of lipid levels, therapy should be uninterrupted.

The lipid-lowering effect of ATROMID-S is usually noted during the first month of therapy. The higher the initial level, the greater the lipid reduction likely to occur.

If response is inadequate after three months of therapy, the drug should be discontinued. However, if xanthoma tuberosum is present, treatment should continue for longer periods (even up to one year) provided there is a reduction in the size and/or number of the xanthomas.

10 years of successful overall clinical experience with Atromid-S

Throughout more than ten years of widespread use, ATROMID-S has proven to be an effective and very well-tolerated drug. However, before prescribing, you should be thoroughly familiar with the possible adverse reactions as well as with the precautions and warnings described on the last page of this advertisement.



Periodic follow-up important

Once blood lipids have been stabilized at normal levels on a regimen of diet and ATROMID-S, the patient should be examined and his blood lipids tested every two to three months during the first year or so. If stabilization at such lower levels is maintained over this period, the intervals between measurements can be lengthened.

Atromid-S®

Brand of clofibrate

helps control the lipid factor in your patient's profile

Ayerst®

IF GIVEN IN CONJUNCTION WITH ANTICOAGULANTS

WARNING: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

See last page of advertisement for prescribing information.

Atromid-S® (clofibrate)
helps reduce elevated cholesterol and/or triglyceride levels — not just cholesterol alone

Initial and maintenance dosage: 2 Gm. daily (four capsules), in divided doses. Some patients may respond to a lower dosage.

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ATROMID-S® (clofibrate)

Antilipidemic agent for reduction of elevated serum lipids

INDICATIONS: ATROMID-S is indicated as adjunctive therapy to diet and other measures for the reduction of elevated serum cholesterol (especially the beta lipoprotein fraction) and/or triglycerides. Clofibrate appears to have a greater depressant effect on the very low density lipoproteins (S_f 20-400) rich in triglycerides than the low density lipoproteins (S_f 0-20) rich in cholesterol.

ATROMID-S is also indicated for treatment of patients with xanthoma tuberosum associated with hyperlipidemia. The skin lesions frequently regress with clofibrate.

It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

CONTRAINDICATIONS: Clofibrate is contraindicated in pregnant women. While teratogenic studies have not demonstrated any effect attributable to clofibrate, it is known that serum of the rabbit fetus accumulates a higher concentration of clofibrate than that found in maternal serum, and it is possible that the fetus may not have developed the enzyme system required for the excretion of clofibrate.

It is contraindicated in lactating women since it is not known if clofibrate is secreted in the milk.

It is contraindicated in patients with clinically significant hepatic or renal dysfunction.

It is contraindicated in patients with primary biliary cirrhosis since it may raise the already elevated cholesterol in these cases.

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Strict birth control procedures must be exercised by women of childbearing potential. In patients who plan to become pregnant, clofibrate should be withdrawn several months before conception. Because of the possibility of pregnancy occurring despite birth control precautions in patients taking clofibrate, the possible benefits of the drug to the patient must be weighed against possible hazards to the fetus.

PRECAUTIONS: Before instituting therapy with clofibrate, attempts should be made to control serum lipids with appropriate dietary regimens, weight loss in obese patients, control of diabetes mellitus, etc.

Because of the long term administration of a drug of this nature, adequate base line studies should be performed to determine that the patient has significantly elevated serum lipid levels. Frequent determinations of serum lipids should be obtained during the first few months of ATROMID-S administration, and periodic determinations thereafter. The drug should be withdrawn after three months if response is inadequate. However, in the case of xanthoma tuberosum, the drug should be employed for longer periods (even up to one year) provided that there is a reduction in the size and/or number of the xanthomata.

Subsequent serum lipid determinations should be done to detect a paradoxical rise in serum cholesterol or triglyceride levels. Clofibrate will not alter the seasonal variations of serum cholesterol peak elevations in midwinter and late summer and decreases in fall and spring. If the drug is discontinued, the patient should be placed on an appropriate hypolipidemic diet, and his serum lipids should be monitored until stabilized, as a rise in these values to or above the original base line may occur.

During clofibrate therapy, frequent serum transaminase determinations and other liver function tests should be performed since the drug may produce abnormalities in these parameters. These effects are usually reversible when the drug is discontinued. Hepatic biopsies are usually within normal limits. If the hepatic function tests steadily rise or show excessive abnormalities, the drug should be withdrawn. Therefore use with caution in those patients with a past history of jaundice or hepatic disease.

Clofibrate may produce "flu like" symptoms (muscular aching, soreness, cramping). The physician should differentiate this from actual viral and/or bacterial disease.

Use with caution in patients with peptic ulcer since reactivation has been reported. Whether this is drug-related is unknown.

Complete blood counts should be done periodically since anemia, and more frequently, leukopenia have been reported in patients who have been taking clofibrate.

Various cardiac arrhythmias have been reported with the use of clofibrate.

Several investigators have observed in their studies that clofibrate may produce a decrease in cholesterol linoleate but an increase in palmitoleate and oleate, the latter being considered atherogenic in experimental animals. The significance of this finding is unknown at this time.

ADVERSE REACTIONS: Of the pertinent reactions, the most common is nausea. Less frequently encountered gastrointestinal reactions are vomiting, loose stools, dyspepsia, flatulence, and abdominal distress. Reactions reported less often than gastrointestinal ones are headache, dizziness, and fatigue; muscle cramping, aching, and weakness; skin rash, urticaria, and pruritus; dry brittle hair, and alopecia.

The following reported adverse reactions are listed alphabetically by systems:

Cardiovascular
- Increased or decreased angina
- Cardiac arrhythmias
- Both swelling and phlebitis at site of xanthomas

Dermatologic
- Skin rash
- Alopecia
- Allergic reaction including urticaria
- Dry skin and dry brittle hair
- Pruritus

Gastrointestinal
- Nausea
- Diarrhea
- Gastrointestinal upset (bloating, flatulence, abdominal distress)
- Hepatomegaly (not associated with hepatotoxicity)
- Vomiting
- Stomatitis and gastritis

Genitourinary
- Impotence and decreased libido
- Findings consistent with renal dysfunction as evidenced by dysuria, hematuria, proteinuria, decreased urine output. One patient's renal biopsy suggested "allergic reaction."

Hematologic
- Leukopenia
- Potentiation of anticoagulant effect
- Anemia
- Eosinophilia

Musculoskeletal
- Myalgia (muscle cramping, aching, weakness)
- "Flu like" symptoms
- Arthralgia

Neurologic
- Fatigue, weakness, drowsiness
- Dizziness
- Headache

Miscellaneous
- Weight gain
- Polyphagia

Laboratory Findings
- Abnormal liver function tests as evidenced by increased transaminase (SGOT and SGPT), BSP retention, and increased thymol turbidity
- Proteinuria
- Increased creatine phosphokinase

Reported adverse reactions whose direct relationship with the drug has not been established: peptic ulcer, gastrointestinal hemorrhage, rheumatoid arthritis, tremors, increased perspiration, systemic lupus erythematosus, blurred vision, gynecomastia, thrombocytopenic purpura.

DOSAGE AND ADMINISTRATION: *Initial:* The recommended dosage for adults is 2 Gm. daily, in divided doses. Some patients may respond to a lower dosage. *Maintenance:* Same as for initial dosage. **Note:** In children, insufficient studies have been done to show safety and efficacy.

DRUG INTERACTIONS: Caution should be exercised when anticoagulants are given in conjunction with ATROMID-S (clofibrate). The dosage of the anticoagulant should be reduced usually by one-half (depending on the individual case) to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has been stabilized.

MANAGEMENT OF OVERDOSAGE: While there has been no reported case of overdosage, should it occur, symptomatic supportive measures should be taken.

HOW SUPPLIED: ATROMID-S—No. 243—Each capsule contains 500 mg. clofibrate, in bottles of 100.

On Reliability and a Pound of Flesh

The life's blood of an electrocardiograph is the chart that flows through it.

Assurance that the recording is totally reliable depends, in part, on the quality of the chart itself.

Charts, as provided by the instrument maker, afford this assurance to a maxima ... because they are designed as an integral part of the instrument.

Charts, as provided by others, are imitations at best. They may save a few pennies, but not without risk of shedding a "drop of reliability".

This message was prepared in the interest of better instrument performance by ...

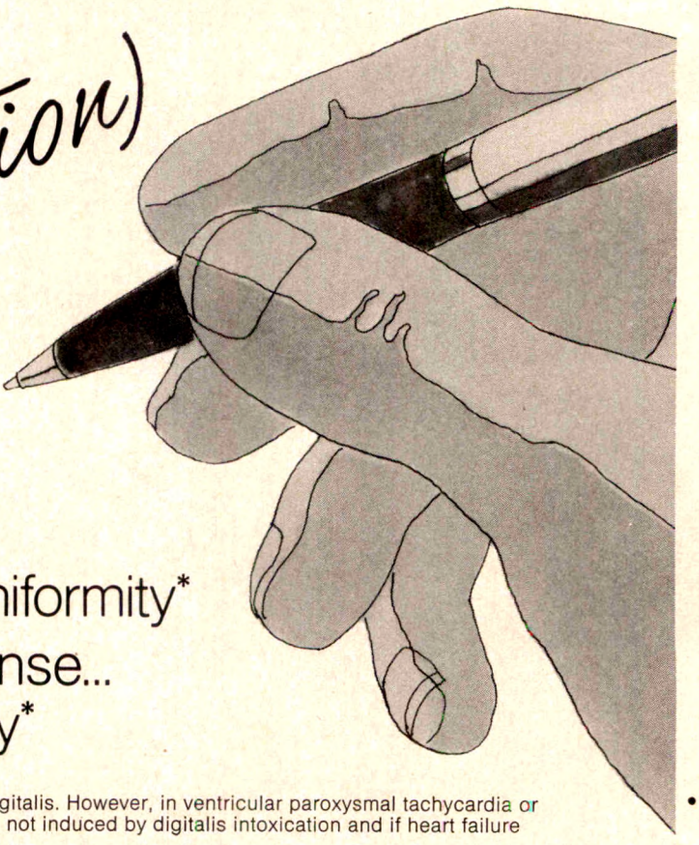
Lanoxin
[digoxin]
(no substitution)



write it

precision quality control...
- assured tablet content uniformity*

predictable patient response...
- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

CLINICAL STUDIES

Echocardiography in Acute Myocardial Infarction

BETTY C. CORYA, MD
SUSAN RASMUSSEN, RN, MSN
SUZANNE B. KNOEBEL, MD, FACC
HARVEY FEIGENBAUM, MD, FACC
with the technical assistance of
MARY JO BLACK, BA

Indianapolis, Indiana

Sixty-four patients with acute transmural myocardial infarction had daily echocardiograms while in the coronary care unit. Patients with previous infarction were excluded. The electrocardiographic site of infarction was anterior wall in 28, inferior wall in 33 and both anterior and inferior wall in 3 patients. Echocardiograms satisfactory for interpretation were obtained in 92 percent of cases. Abnormal left ventricular wall motion corresponding to the electrocardiographic site of infarction was seen in the echocardiogram in 84 percent of cases. Exaggerated normal motion in noninfarcted areas was seen in 30 percent. The left ventricular internal dimension correlated with clinical heart failure ($P < 0.005$) and was increased in 50 percent. Abnormal mitral valve closure, which reflects increased left ventricular end-diastolic pressure, was present in 33 percent. This finding did not correlate significantly with clinical heart failure. By combining the measurements of left ventricular internal dimension and mitral valve closure, it was possible to predict hospital mortality from the echocardiograms. The results indicate that echocardiography is a useful technique in the study and management of patients with acute myocardial infarction.

From the Krannert Institute of Cardiology and the Department of Medicine, Indiana University School of Medicine, Indianapolis, Ind., and the Hendricks County Hospital, Danville, Ind. This study was supported in part by the Herman C. Krannert Fund, Indianapolis, Ind.; by Grants HL-06308, HL-05363 and HL-05749 from the National Heart and Lung Institute of the National Institutes of Health, Bethesda, Md.; by the Indiana Heart Association, Indianapolis, Ind.; and by a Grant-in-Aid from the American Heart Association, Northeast Indiana Chapter, Inc., Indianapolis, Ind. Manuscript accepted December 11, 1974.

Address for reprints: Betty C. Corya, MD, Indiana University Medical Center, 1100 West Michigan St., Indianapolis, Ind. 46202.

Although present echocardiographic techniques do not permit identification of echoes from the coronary arteries and, therefore, direct assessment of the presence and severity of coronary artery disease, some of the important consequences of coronary artery disease may be indirectly evaluated by examination of the left ventricle.[1–9] Most previous studies have dealt with abnormalities of wall motion[1–3] and left ventricular volume[4–6] in patients with chronic coronary artery disease. Less information is available on the use of echocardiography in patients with acute infarction. Change in motion of the posterior left ventricular wall has been shown in animals with experimental infarction of the posterior wall.[7,8] These changes in posterior wall motion were presumed to be due to segmental left ventricular dysfunction since they were not seen in dogs with apical infarction.[8] In addition, decreased posterior wall velocity has been demonstrated in patients with inferior as opposed to anterior infarction,[9] and abnormal

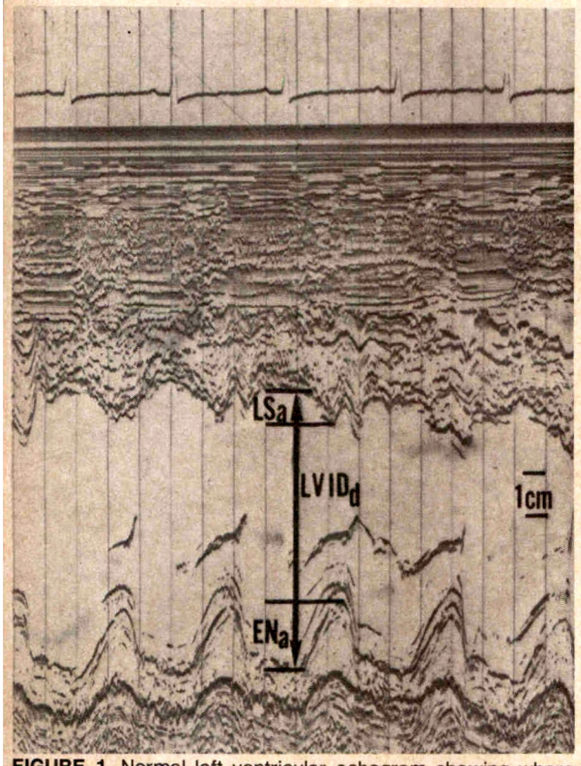

FIGURE 1. Normal left ventricular echogram showing where measurements were made. EN_a = amplitude of endocardial echocardiographic motion; LS_a = amplitude of left septal echocardiographic motion during ejection; $LVID_d$ = left ventricular internal dimension at end-diastole.

anterior left ventricular wall motion has been demonstrated in patients with transmural anterior infarction.[2] Good correlation has been reported[10] between echocardiographic and dye-dilution methods of measuring cardiac output in nine patients with acute infarction.

Because of the noninvasive nature of echocardiography and its potential usefulness in assessing both segmental and generalized left ventricular function, investigation into its use in acute infarction is indicated. Among the many questions that need to be asked are: (1) How often can technically satisfactory echocardiograms be obtained in patients with acute myocardial infarction; (2) what are the incidence rates and sites of abnormal left ventricular echocardiographic motion, and what is its relation to the electrocardiographic site of infarction; (3) how soon after infarction do abnormalities of echocardiographic motion occur; (4) what is the relation of echocardiographic findings to clinical heart failure; and (5) are echocardiographic measurements helpful in predicting mortality in acute infarction? This report deals with these questions.

Methods

Patients: Clinical and echocardiographic data were collected from 64 consecutive patients with acute transmural myocardial infarction. Patients with a history of previous myocardial infarction were excluded. All patients were examined daily by the same investigator and were included

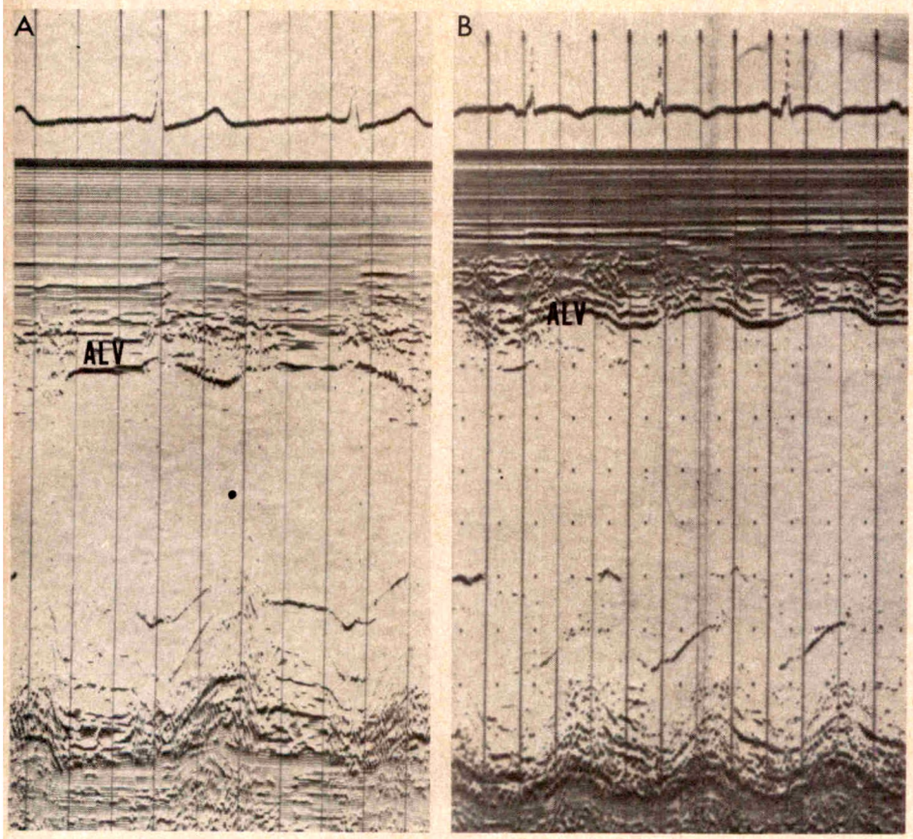

FIGURE 2. Left ventricular echograms recorded with the transducer overlying the anterior left ventricular wall (ALV). **A,** normal subject. The motion is away from the chest wall (normal) during ejection. **B,** from a patient with acute anterior wall myocardial infarction. The anterior left ventricular wall motion during ejection is paradoxical.

only if diagnostic electrocardiographic changes (Q wave greater than 0.04 second) of transmural infarction plus typical chest pain or a characteristic curve of serum enzyme activity, or both, was present. A diagnosis of congestive heart failure was made when the patient manifested bilateral basilar rales that did not clear with coughing or a third sound gallop, or both, consistent with the Killip classification.

Echocardiograms: Echocardiograms were obtained at the bedside as often as possible—in most cases daily—while the patients were in the coronary care unit. A Smith-Kline echograph with a 2.25 megahertz transducer 1.25 cm in diameter and collimated at 7.5 cm was used to obtain echoes. M mode tracings were made with a portable Honeywell Model 1856 strip chart recorder. A simultaneous electrocardiographic monitoring lead was recorded on each tracing.

Echoes were first recorded from the mitral valve. From that position a sector scan of the left ventricle from base to apex was recorded, as previously described,[11] in more than one interspace when possible. The transducer was then moved laterally 5 to 7.5 cm across the chest to record echoes from the anterior left ventricular wall. Details of this technique have previously been described.[2]

Echocardiographic measurements: The echocardiograms were interpreted without knowledge of the clinical information. Figure 1 illustrates a normal left ventricular echogram and shows where the measurements used for analysis were made. The left ventricular internal dimension at end-diastole ($LVID_d$) was taken at the peak of the R wave in the electrocardiogram at about the level of the posterior leaflet of the mitral valve. This was divided by the body surface area to obtain an $LVID_d$ index. The normal $LVID_d$ index in our laboratory is 3.2 cm/m^2 or less. The amplitude of left septal and left endocardial echocardiographic motion during ejection was measured at or just below the posterior mitral valve leaflet. Normal septal motion in our laboratory ranges from 0.3 to 0.8 cm (mean 0.6) and normal endocardial amplitude ranges from 0.8 to 1.6 cm (mean 1.3). Paradoxical septal motion was given a value of 0. Motion of both the septum and endocardium at the apex was also observed.

The anterior left ventricular wall echo was called normal if it moved away from the transducer during ejection and abnormal if it was flat or moved toward the transducer during ejection. (Fig. 2, A and B)

The period of mitral valve closure (A-C interval) was measured from the peak of the *A* wave in the mitral echogram to the point where the echoes from the anterior and posterior mitral leaflets met (Fig. 3). Abnormal mitral valve closure, which has been shown to be associated with increased left ventricular end-diastolic pressure,[12] was defined as a P-R minus duration of mitral closure (PR-AC) interval of 0.06 second or less. The duration of mitral valve closure is subtracted from the P-R interval in the electrocardiogram since the time between atrial and ventricular contraction also affects mitral valve closure.[13,14] As the mitral valve closure time increases, presumably because of increased left ventricular pressure, the PR-AC interval decreases if the P-R interval remains constant.

Statistical analysis: Data were analyzed by the Student *t* test. Chi square analysis was used to find if there was a relation between the echocardiographic measurements and congestive heart failure and to determine the ability of the following variables and combinations of variables to predict mortality on admission and at the time of the last echocardiogram (excluding admission echocardiogram): (1) elevated $LVID_d$ index; (2) abnormal mitral valve closure reflecting increased left ventricular end-diastolic pressure; (3) elevated $LVID_d$ index plus abnormal mitral valve closure; (4) $LVID_d$ index/PR-AC ratio as a volume/pressure ratio; and (5) abnormal wall motion.

Clinical variables analyzed by the same statistical methods were (1) age greater than 60 years; (2) sex; (3) serum glutamic oxaloacetic transaminase level greater than 250 units; (4) location of infarction; (5) third sound gallop; (6)

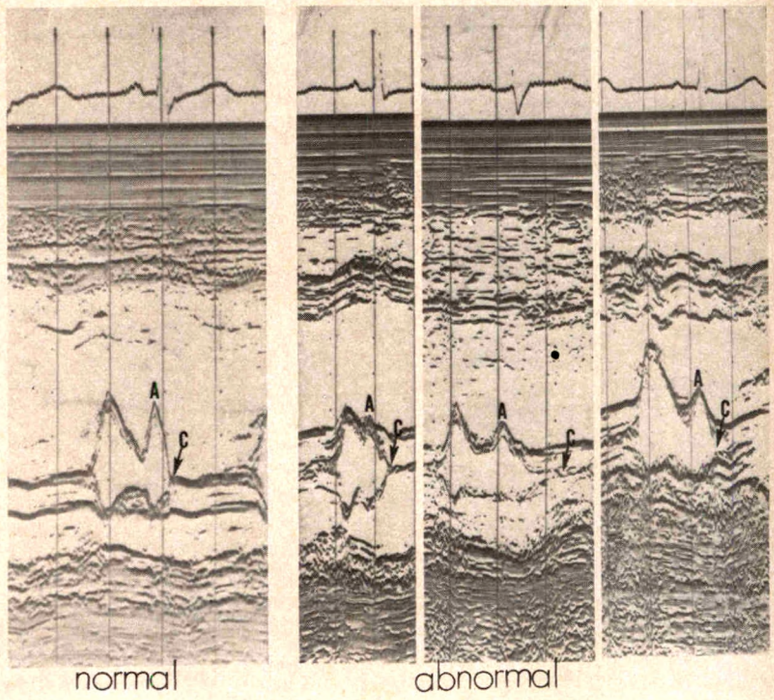

FIGURE 3. Mitral valve echograms showing abnormal mitral valve closure (P-R interval of electrocardiogram minus A-C interval = 0.06 second or less). The configuration of the A-C echo is variable. A = point at which the mitral valve begins to close; C = point of complete closure of the mitral valve.

bilateral rales; and (7) presence of heart failure on the basis of the Killip classification.

Results

Clinical Data

The 64 patients ranged in age from 31 to 85 years (mean 60) and included 36 men and 28 women. Congestive heart failure was present during the first 48 hours in 58 percent (37 of 64), and 4 patients had pulmonary edema and 2 had shock on admission. The hospital mortality rate for the entire group was 23 percent (15 of 64). The electrocardiographic site of infarction was anterior wall in 28, inferior wall in 33 and both anterior and inferior wall in 3 patients.

The group of 28 patients with anterior wall infarction included 17 men and 11 women whose ages ranged from 40 to 82 years (mean 60). Congestive heart failure was present within 48 hours of admission in 64 percent (18 of 28), and the hospital mortality rate was 32 percent (9 of 28). The 33 patients with inferior wall infarction included 16 men and 17 women whose ages ranged from 31 to 85 years (mean 59). Fifty-two percent of these patients (17 of 33) had congestive heart failure within 48 hours and the hospital mortality rate was 15 percent (5 of 33). The three patients with both anterior and inferior wall infarction were men aged 51 to 66 years (mean 58). Two had congestive heart failure, and one died in the hospital.

Echocardiographic Data

Echocardiographic data for the three groups are presented in Table I. The most obvious echocardiographic abnormalities were those of left ventricular wall motion. Decreased or paradoxical echocardiographic motion was found on admission in 84 percent of patients (54 of 64) with acute transmural infarction. The echocardiograms in Figures 4 and 5, obtained from two patients in this study, demonstrate, respectively, abnormal septal and posterior wall motion. In 73 percent of patients (47 of 64) abnormal motion was seen at the "base" of the heart where the ultrasonic beam traverses the mitral valve and where standard left ventricular echocardiographic measurements are made. In four instances the abnormality was seen only at the apex, and in three cases only the anterior left ventricular wall was abnormal. "Exaggerated normal" motion in areas not involved electrocardiographically was seen in 30 percent of this series of patients. The area of decreased or paradoxical motion corresponded to the electrocardiographic site of infarction with two exceptions. One patient with inferior wall infarction had abnormal anterior left ventricular wall motion as well as decreased endocardial motion, and another with only inferior wall infarction electrocardiographically had absence of septal motion at the base of the heart in addition to abnormal endocardial motion.

The abnormal motion associated with acute infarction was nearly always seen in the admission echocardiogram, and very little daily change was seen in subsequent tracings in the coronary care unit. Although it was not possible to quantitate the area of abnormal contraction, the changes appeared to be greater and more extensive than those we have observed in patients with chronic coronary artery disease; preliminary observations in follow-up tracings (3 to 6 months) indicate that some improvement occurred later.

Patients with anterior wall infarction: Left septal echoes were adequate for measuring amplitude of motion during ejection in 25 of the 28 patients with electrocardiographic evidence of anterior myocardial infarction. Eighty percent (20 of 25) had abnormally decreased motion (less than 0.3 cm) with a mean of 0.08 cm (range 0 to 0.6) that was significantly different from normal ($P < 0.001$). The endocardial amplitude was also measurable in 25 patients, and the group mean was not significantly different from normal. Four patients had endocardial amplitude values above the normal range (0.8 to 1.6 cm). Anteri-

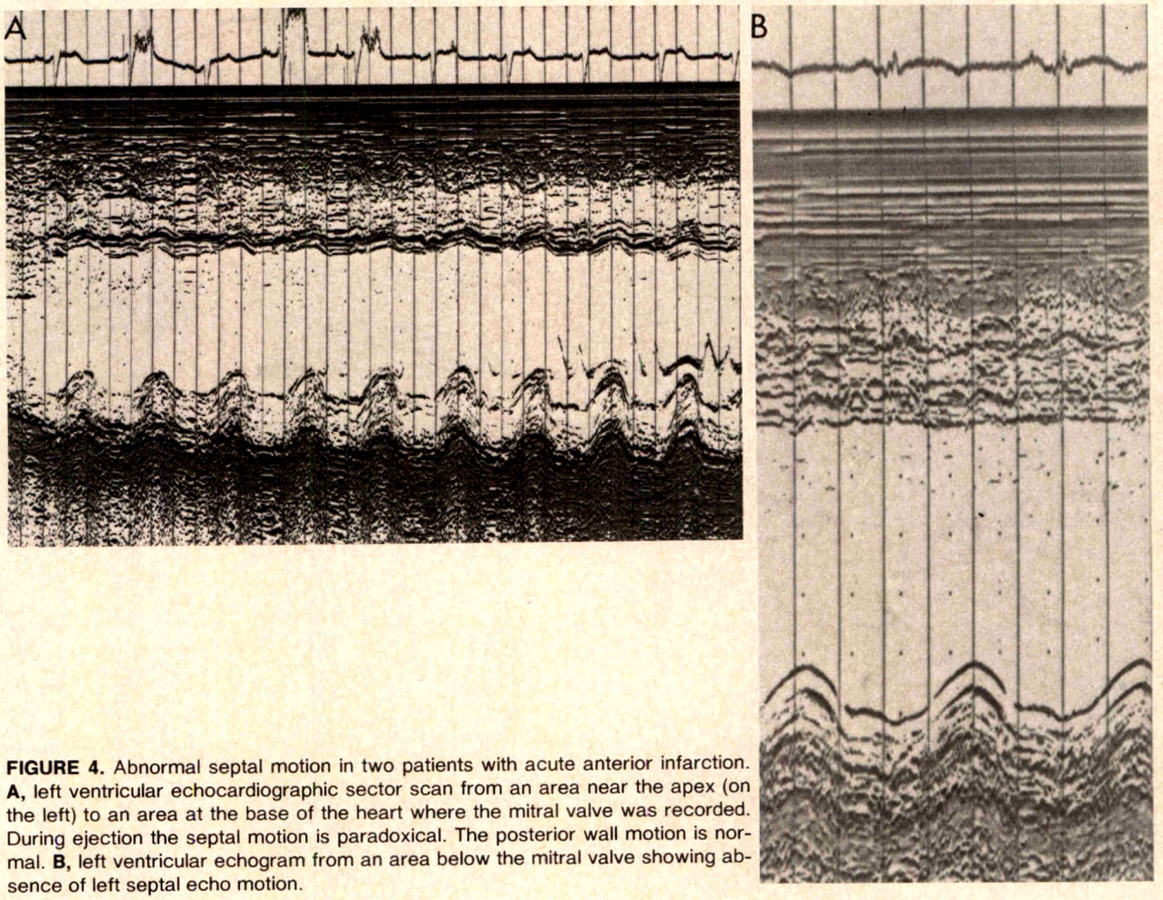

FIGURE 4. Abnormal septal motion in two patients with acute anterior infarction. **A,** left ventricular echocardiographic sector scan from an area near the apex (on the left) to an area at the base of the heart where the mitral valve was recorded. During ejection the septal motion is paradoxical. The posterior wall motion is normal. **B,** left ventricular echogram from an area below the mitral valve showing absence of left septal echo motion.

or left ventricular echocardiographic motion was abnormal in 76 percent (13 of 17) of those in whom it was recorded.

The left ventricular internal dimension at end-diastole ($LVID_d$) index was elevated in 70 percent (19 of 27) of these patients, and 50 percent (11 of 22) of them had abnormal mitral valve closure.

Patients with inferior wall infarction: Left septal echoes could be measured in 31 of 33 patients with inferior wall infarction. Values ranged from 0 to 2.0 cm (mean 0.81). The left septal amplitude was less than normal in only 1 patient and was greater than normal in 12 patients ($P < 0.025$). Endocardial amplitude ranged from 0 to 1.7 cm (mean 0.7), with 2 patients having values greater than normal and 16 having values below the normal range ($P < 0.001$). Anterior left ventricular wall motion was abnormal in 1 of the 21 patients in whom it was recorded. The left ventricular internal dimension index was elevated in 35 percent (11 of 31), and abnormal mitral valve closure was present in 41 percent (9 of 22) of these patients.

Patients with both anterior and inferior wall infarction: Measurements in the three patients with both anterior and inferior electrocardiographic changes showed septal motion increased in one and decreased in two, endocardial motion decreased in two, anterior left ventricular echo motion abnormal in three, left ventricular internal dimension index el-

evated in two and abnormal mitral valve closure in one.

Echocardiographic Measurements and Clinical Heart Failure

Figure 6 shows the significant (P <0.005) correlation between echocardiographic left ventricular size on the admission echocardiogram and clinical heart failure based on the Killip classification. However, 38 percent of patients (11 of 29) with a normal left ventricular internal dimension had clinical heart failure and 22 percent (7 of 32) with an elevated left ventricular internal dimension had no clinical evidence of failure. There was also a significant correlation between an echocardiographically dilated left ventricle and the presence of either bilateral rales (P <0.005) or a third sound gallop (P <0.025).

There was no significant correlation between abnormal mitral valve closure and clinical heart failure or the presence of rales in this series of patients. There was a significant correlation between the presence of abnormal mitral valve closure and a third sound gallop (P <0.05).

Echocardiographic Measurements and Mortality

Results of the analysis of variables showing which echocardiographic findings might predict mortality are presented in Table II.

First echocardiogram: Although an echocardiographically dilated left ventricle and abnormal mitral valve closure were more common on admission among those who subsequently died, neither finding alone was useful in predicting mortality. Only when these two abnormalities were combined were they of significant value in predicting death (Fig. 7A). The mortality rate for the group in which both measurements could be made was 20 percent (9 of 46). The mortality rate among those in whom both variables were abnormal was 55 percent (6 of 11), whereas only 9 percent (3 of 35) of patients without this combination died. This difference was significant (P <0.001). The $LVID_d$ index/PR-AC ratio was also useful in predicting mortality (P <0.005) at the time of admission (Fig. 7B). The presence of abnormal wall motion was not useful for this purpose.

Last echocardiogram in the coronary care unit: Results of analyzing the same variables using each patient's last echocardiogram obtained in the

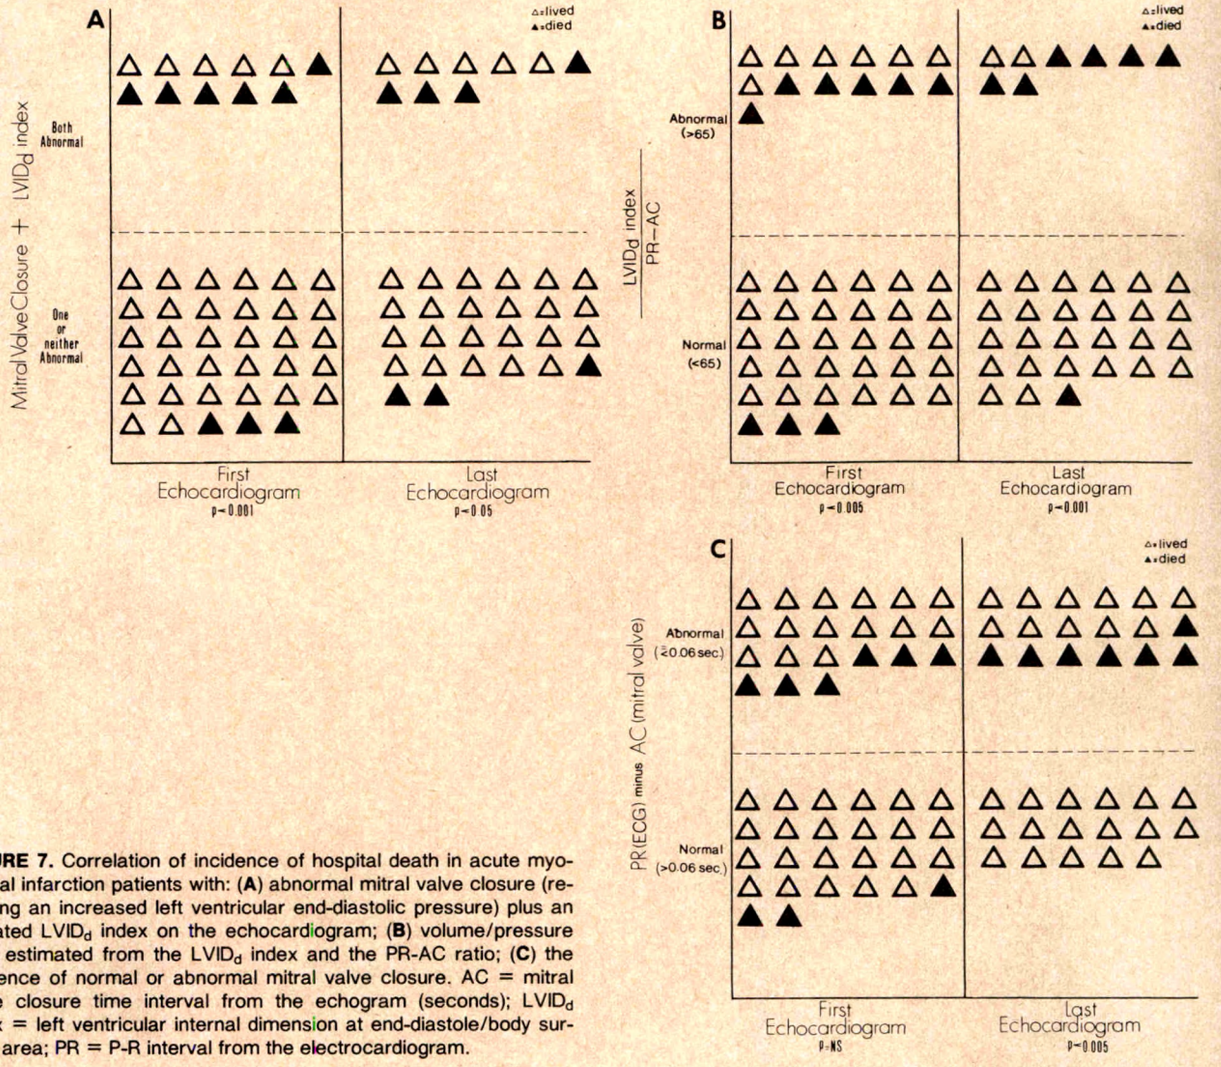

FIGURE 7. Correlation of incidence of hospital death in acute myocardial infarction patients with: (**A**) abnormal mitral valve closure (reflecting an increased left ventricular end-diastolic pressure) plus an elevated $LVID_d$ index on the echocardiogram; (**B**) volume/pressure ratio estimated from the $LVID_d$ index and the PR-AC ratio; (**C**) the presence of normal or abnormal mitral valve closure. AC = mitral valve closure time interval from the echogram (seconds); $LVID_d$ index = left ventricular internal dimension at end-diastole/body surface area; PR = P-R interval from the electrocardiogram.

coronary care unit were different. Patients who had only one echocardiogram were excluded from this analysis. When these later echocardiograms were used, the presence of abnormal mitral valve closure alone was significant (P <0.005) in predicting mortality (Fig. 7C). Most significant at this time was the $LVID_d$ index/PR-AC ratio (P <0.0001) (Fig. 7B). Only 1 of 27 patients who had a volume/pressure ratio of less than 65 on his last echocardiogram died in the hospital, whereas 6 of 8 patients with values greater than 65 died before hospital discharge. Figure 8 shows the ratios for individual patients and indicates whether or not they died in the hospital. A value of 65 seemed to provide the separation of survivors and nonsurvivors. Abnormal wall motion was still not helpful in predicting mortality.

Clinical Findings and Mortality

Results of the analysis of clinical variables in predicting mortality are presented in Table III. There was significantly increased mortality in patients more than 60 years of age (P <0.025) and in those with a third sound gallop (P <0.05), rales (P <0.05) or clinical heart failure (Killip classification) on admission (P <0.05). Forty-eight hours after admission a third sound gallop was a better predictor of mortality (P <0.001) than either rales (P <0.01) or clinical heart failure on the basis of the Killip classification (P <0.01). Mortality was significantly different between patients in Killip class I (no heart failure) and those with class II heart failure (third sound gallop or bilateral rales, or both, without overt pulmonary edema or shock) at 48 hours (P <0.01) but not on admission.

Sequential changes: Although some daily changes in both the left ventricular internal diameter at end-diastole ($LVID_d$) index and the P-R minus mitral valve closure (PR-AC) interval were observed, the most striking sequential changes related to mortality were in the $LVID_d$ index/PR-AC ratio as illustrated in Figure 9. For clarity, lines indicating change were drawn only for patients whose values went from the area of high mortality to that of low mortality or vice versa. The figure shows that abnormal echocardiographic findings preceded death by many hours or even days and were not due to sudden terminal events. There were three nonsurvivors with a "nor-

mal volume/pressure ratio" in the admission echocardiogram whose ratio became abnormal before death and six of seven survivors with an abnormal ratio on admission whose ratio became normal while they were in the coronary care unit.

Discussion

Technical feasibility: This study demonstrates that technically adequate bedside echocardiograms can be obtained routinely in patients with acute myocardial infarction. Information about left ventricular wall motion and size was obtained on 59 of 64 patients (92 percent). Although mitral valve echoes were recorded on 61 of 64 cases (95 percent), a P-R minus mitral valve closure interval could be measured in only 47 of 61 patients (77 percent) because of atrial fibrillation, heart block and sinus tachycardia in some patients and difficulty in accurately measuring the onset of the electrocardiographic P wave in others. With sinus tachycardia, the left ventricular filling period is often so short that the E and A points on the mitral valve echogram cannot be distinguished.

Left ventricular wall motion: Echocardiography was a sensitive indicator in the early detection of abnormal areas of wall motion corresponding to the electrocardiographic site of transmural infarction in this study, but it is not possible to make a diagnosis of myocardial infarction from the echocardiogram. Abnormal motion is seen with chronic coronary artery disease without evidence of infarction,[1,2] and it may be seen transiently during stress in patients who have normal echocardiographic motion at rest.[1,15] We have observed the same changes in patients with a diagnosis of preinfarction angina. The echocardiographic changes may be useful in determining whether symptoms are cardiac in origin when infarction has not taken place or before diagnostic electrocardiographic changes are present. Other conditions, including cardiomyopathy,[16] left bundle branch block,[17,18] right ventricular volume overload,[19,20] left ventricular volume overload[21] and prosthetic valve

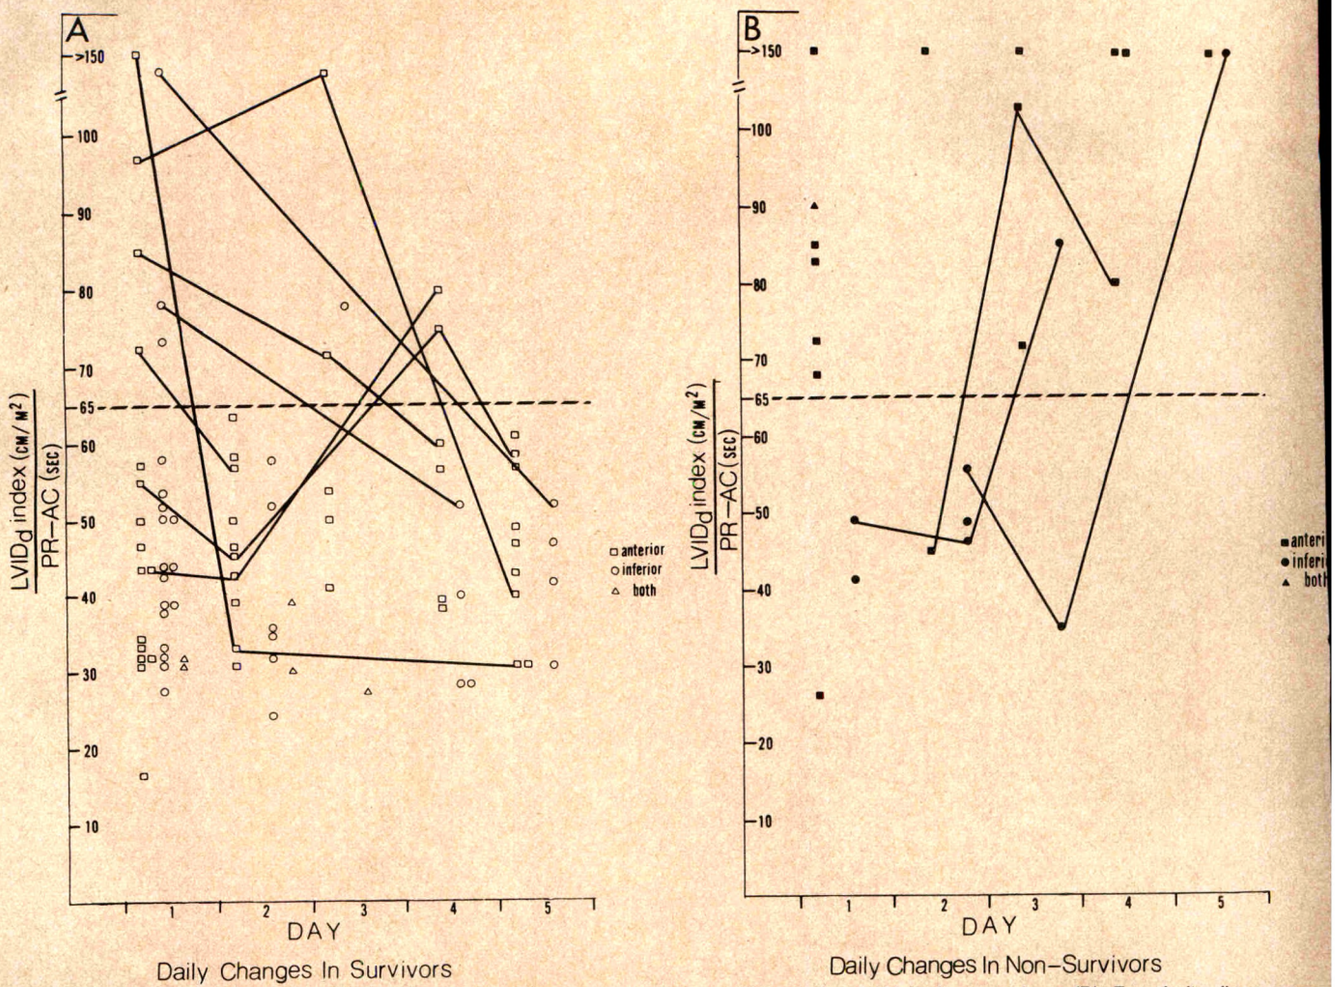

FIGURE 9. Sequential changes in the echocardiographic volume/pressure ratio in survivors (**A**) and nonsurvivors (**B**). For clarity, lines were only drawn for patients who change from areas of high mortality to low mortality, or vice versa. Abbreviations as in Figure 7.

surgery,[22] affect echocardiographic motion and must also be considered.

Left ventricular internal dimension: Because the left ventricle may be asymmetrical in coronary artery disease, especially during contraction, caution must be exercised in using echocardiographic left ventricular dimensions to estimate volumes. Studies comparing volumes derived from biplane angiograms with those derived from single echocardiographic dimensions in patients with coronary artery disease support the use of a single left ventricular diastolic dimension for estimating diastolic volume.[5] Although we found significant correlation between an increased left ventricular internal dimension and congestive heart failure, some patients with heart failure had a normal index (Fig. 6). Other investigators have also found a normal value for this dimension in patients with clinical signs of heart failure.[23,24]

Mitral valve closure: In a series of patients in whom the P-R minus mitral valve closure (PR-AC) interval was correlated with left ventricular pressure, it was found that when mitral valve closure was prolonged enough to reduce the PR-AC interval to 0.06 second or less the left ventricular end-diastolic pressure was 20 mm Hg or greater with an "atrial kick" of at least 8 mm Hg.[12] It is not certain that the correlation between valve motion and pressure demonstrated in patients with chronic disease is as reliable in patients with acute myocardial infarction and a wide range of P-R intervals.

We do not know how often decreased compliance was responsible for abnormal mitral valve closure. Presumably this was true in the patients with a left ventricle of normal size. There was no significant correlation between abnormal mitral valve closure and either increased left ventricular size or clinical heart failure based on the presence of rales or a third sound gallop, or both. However, abnormal mitral valve closure did correlate significantly with the presence of a third sound gallop. It is possible that increased left ventricular size with heart failure was also responsible for increased pressures in many cases.

Predicting mortality: Pulmonary arterial pressure, capillary wedge pressure and cardiac output have been useful in predicting mortality in patients with acute infarction.[25–27] Diamond and Forrester,[28]

using left heart catheterization, have shown a high correlation between left ventricular compliance and prognosis in such patients. Investigation of left ventricular pressure-volume relation in these patients has been limited by the lack of an acceptable means of measuring left ventricular volume in acutely ill persons. Recently Smith et al.[24] studied the volume-pressure relation ("compliance") in 14 patients with acute myocardial infarction. They used the pulmonary arterial end-diastolic pressure as the left ventricular filling pressure and echocardiographic dimensions to determine left ventricular volumes. The sequential compliance values were more useful than either left ventricular filling pressure or left ventricular volume in predicting survival in that study.

We do not know how well our echocardiographic volume/pressure ratio represents compliance but our results show that it may be useful in predicting mortality and in following a patient's clinical course. It is also unknown whether the combined presence of abnormal mitral valve closure and an increased left ventricular internal dimension at end-diastole on admission, which was highly significant in predicting mortality, represents predominantly decreased compliance or heart failure.

Clinical implications: This study does not prove that the echocardiogram accurately reflects left ventricular volume and end-diastolic pressure. These assumptions are based on previous studies in patients with chronic disease. This study does demonstrate: (1) technically adequate echocardiograms can be obtained in most patients with acute infarction. (2) Echocardiography is a sensitive method of detecting abnormalities of left ventricular wall motion corresponding to the electrocardiographic site of infarction. (3) An echocardiographically dilated left ventricle usually indicates congestive heart failure. (4) Echocardiographic measurements and their relation to each other are useful in determining prognosis in individual patients.

Echocardiography in Aortic Root Dissection and Dilatation

RICHARD W. MOOTHART, MD
RICHARD D. SPANGLER, MD, FACC
S. GILBERT BLOUNT, Jr., MD, FACC

Denver, Colorado

Six patients with aortic root dissection proved by angiography, surgery or autopsy, and six patients with aortic root dilatation were studied by echocardiography. Echocardiography was diagnostic in five of six patients with dissection and suggestive in the sixth, disclosing anterior and posterior dissection in three, anterior dissection in one and posterior dissection in one. The recording of a double echo in the aorta was the diagnostic feature. Angiography was diagnostic in four of the six patients, yielded a false negative result in one and was not performed in one. Six patients with dilatation had an enlarged aortic root by echocardiography. Left ventricular size, stroke volume, ejection fraction, aortic regurgitant flow and velocity of circumferential fiber shortening were calculated in 11 patients. Echocardiography was extremely helpful in the diagnosis, management and follow-up in patients with aortic dissection or dilatation.

Echocardiography is a noninvasive harmless bedside diagnostic technique. It is therefore especially helpful in the management of acutely ill patients and in following up those needing repeated examinations. This study reports the echocardiographic findings in 12 patients with aortic root dissection or dilatation and the associated abnormalities of aortic insufficiency, hemopericardium or abnormal ventricular function.

Material and Methods

Twelve patients, six with aortic root dissection and six with aortic root dilatation, were studied by echocardiography using a Unirad echocardiograph with a 2.5 megacycle transducer. The transducer was located in the usual position along the left sternal border and angulated to give four views: (1) the aortic root, (2) roll-off from aortic root to mitral valve, (3) the mitral valve, and (4) the left ventricular internal dimension. The study was recorded on Polaroid® prints or a strip chart recorder. The echocardiograms were evaluated by (1) examination of the echo patterns, and (2) measurements and calculations. Left ventricular volumes were calculated by the formula EDV = 59 (LVD) − 153 and ESV = 47 (LVS) − 120,[1] where EDV = end-diastolic volume, LVD = left ventricular diastolic diameter, ESV = end-systolic volume and LVS = left ventricular systolic diameter. Aortic regurgitant flow was calculated by the formula QAr = QAt − QM,[2,3] where QAr = aortic regurgitant flow, QAt = aortic valve total flow and QM = mitral valve flow. Velocity of circumferential fiber shortening was calculated by the formula (LVD-LVS)/dt/LVD,[4] where dt = duration of minor axis shortening.

Dissection was confirmed by autopsy (two cases). Angiograms were obtained in five patients at the time of the echocardiogram; in one (Case 5) an angiogram 3 months prior to the echocardiogram showed a normal ascending aorta. Three patients with dilatation had angiograms showing dilatation and aortic insufficiency. The clinical and echocardiographic data are summarized in Tables I and II.

Results

Aortic dissection: We found that a double echo recorded from the anterior or posterior aortic root was diagnostic of aortic dissection. Three patients had double echoes both anteriorly and posteriorly suggesting circumferential dissection, which was found at surgery or autopsy (Fig. 1 to 3). In one patient with a mid-aortic echo extending through systole, an anterior dissection was diagnosed angiographically and confirmed at surgery (Case 3). One patient had a posterior double echo and a posterior intimal flap by angiogram (Fig. 4). One patient with

AI = clinical aortic insufficiency (grade 0 to 4+); AML closure rate = closure rate of anterior leaflet of mitral valve (cm/sec); EDV = end-diastolic volume (cc); EF = ejection fraction; ESV = end-systolic volume (cc); LVD = left ventricular diastolic diameter (cm); LVS = left ventricular systolic diameter (cm); $\dot{Q}$AR = aortic regurgitant flow (cc); $\dot{Q}$AT = aortic valve total flow (cc); $\dot{Q}$M = mitral valve flow (cc); SV = stroke volume (cc); V_{CF} = velocity of circumferential fiber shortening (cm/sec).

aortic root dissection had an abnormal echo pattern with multiple echoes from the aorta suggesting thickening of the aortic wall and dilatation (Case 6). Dissection was not interpreted prospectively from this patient's echocardiogram because of the absence of a double echo, but it was confirmed by angiography 2 weeks later. A subsequent echocardiogram was diagnostic of pericardial effusion (hemopericardium found on pericardiocentesis). A later follow-up echocardiogram indicated healing with thickened aortic walls, confirmed by angiography. It is now clear that a thickened aortic wall is compatible with, but not diagnostic of dissection. Thickening was seen in acute dissection (Case 3), healed dissection (Case 6) and dilatation without dissection (Case 7).

Aortic dilatation: All six patients with dilatation had an enlarged aortic root diameter ranging from 4.4 to 6.2 cm (normal 3.1 to 3.9)[5] measured between the outer margins of the anterior and posterior aortic walls.

Aortic insufficiency: Five of the 12 patients had fluttering of the anterior leaflet of the mitral valve, and all 5 had aortic insufficiency. Three patients with aortic insufficiency did not have such fluttering. There was no correlation between the severity of the insufficiency and leaflet flutter.

Table II lists the measurements and calculations made in these patients. Patients with aortic insufficiency had an increased stroke volume and aortic regurgitant flow, but there was no correlation between aortic insufficiency and ejection fraction, closure rate of the anterior mitral leaflet or velocity of circumferential fiber shortening.

Discussion

Dissecting hematomas occur most frequently in the ascending aorta. More than half of the intimal tears are located within 2 cm of the aortic valve, and mortality is greatest when the tear is in this area.[6,7] There is a 3 percent incidence rate of sudden death in dissecting hematoma and an 83 percent mortality rate in 1 month if the lesion is untreated.[6] The disease can be rapidly progressive, and up to 66 percent of these hematomas may rupture into the pericardial sac.[7] Furthermore, the dissection may extend weeks to months after its onset. A diagnostic tool that can examine the aortic root repeatedly at the bedside without risk to the patient is therefore highly desirable. Echocardiography of the aortic root fulfills these criteria and we found it to be extremely helpful in the diagnosis and management of patients with aortic root abnormalities.

Echocardiography can display the following in an examination of the aortic root: (1) root diameter, (2) presence of one or more discrete walls anteriorly or posteriorly, (3) width of the aortic wall, (4) the aortic cusps. In addition, the echocardiogram visualizes changes in the anterior mitral leaflet secondary to aortic insufficiency, may demonstrate pericardial effusion and permit hemodynamic measurements to be performed to evaluate cardiac function. Our results indicate that (1) a double echo recorded from

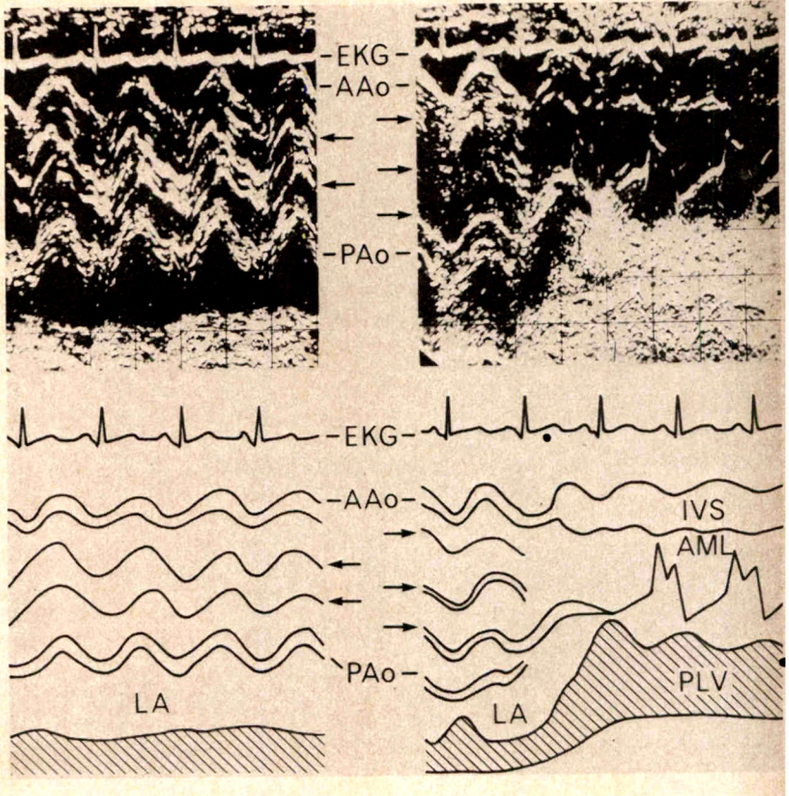

FIGURE 1. Case 1. Aortic dissection. Echocardiogram demonstrates multiple parallel discrete echoes in the aorta **(arrows).** The posterior aortic wall (PAo) is displaced posteriorly into the left atrium (LA) on the roll-off view of the aorta to the anterior leaflet of the mitral valve (AML) and is not contiguous with this leaflet. AAO = anterior aortic wall; EKG = electrocardiogram; IVS = interventricular septum; PLV = posterior left ventricular wall.

the aortic root indicates aortic dissection; (2) the diameter of the aortic root is accurately determined by echocardiography; and (3) patients with aortic insufficiency will have increased stroke volume and aortic regurgitant flow as calculated from the echocardiogram.

Validation of method and clinical implications: The validity of demonstrating the aortic root and the aortic cusps by echocardiography was shown in 1968.[8] Several investigators[9–11] have used A and B mode scanning to reveal thoracic aneurysms. Measurements obtained from suprasternal echocardiography using both A and M modes showed excellent correlation between dimensions found on echocardiography and angiography.[12] There are two reports of studies using the conventional left sternal border view of the aortic root. Millward et al.[13] reported a case of dissecting hematoma rupturing into the right atrium. The aortic root showed anterior and posterior double echoes, as seen in three of our cases. Nanda et al.[5] reported six cases of aortic root dissection. They postulated three echocardiographic findings allowing de-

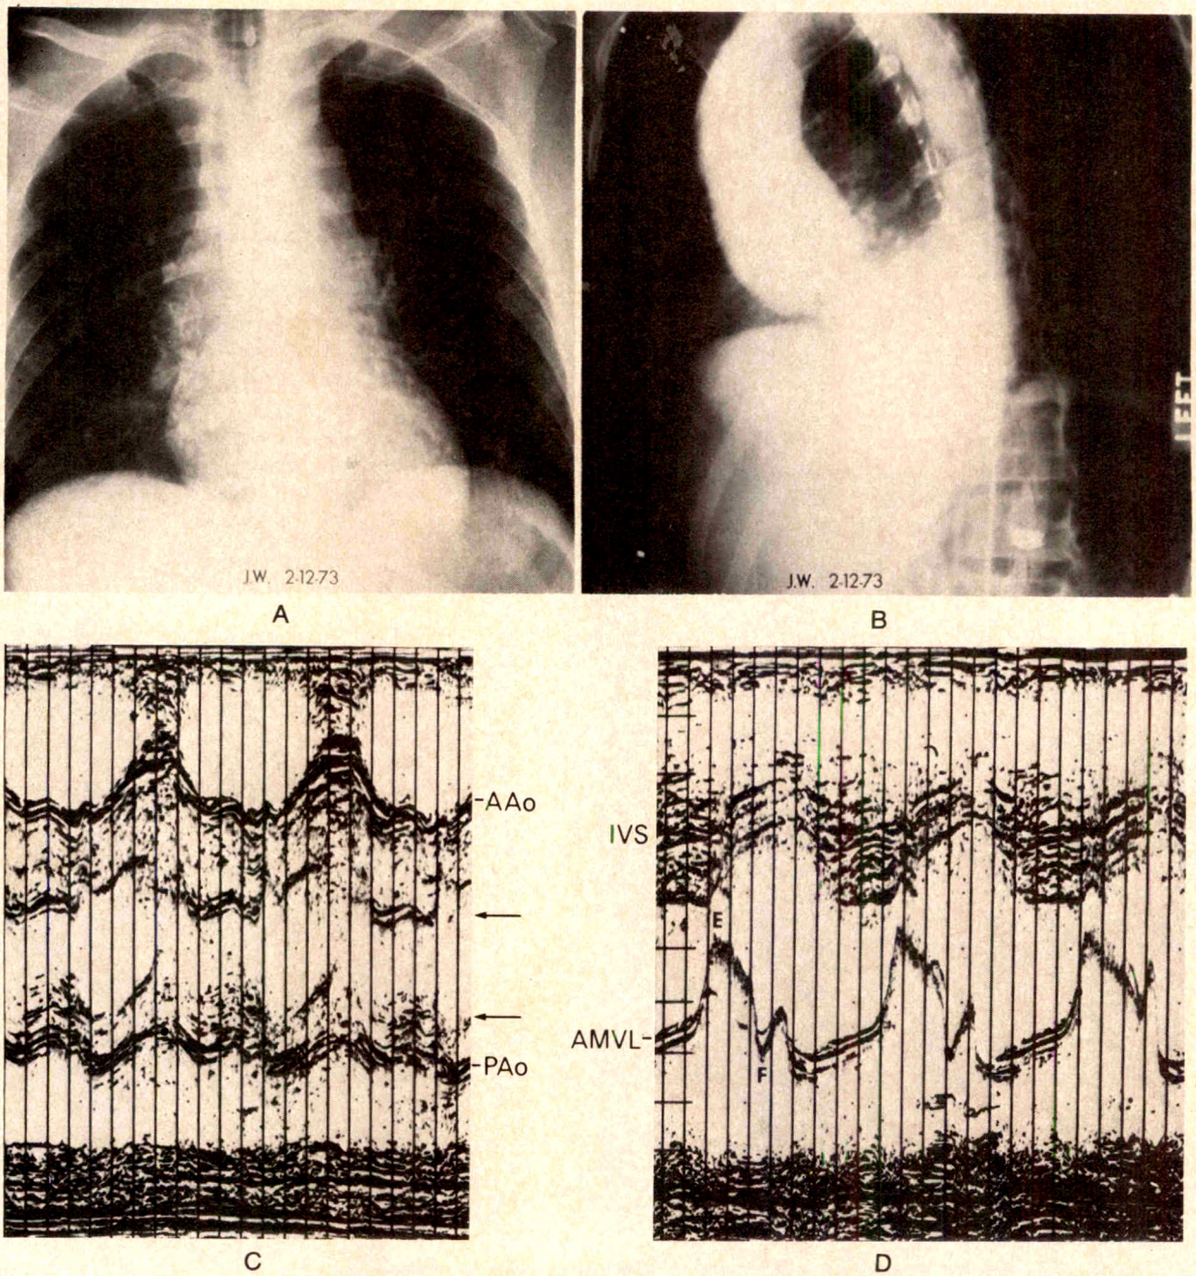

FIGURE 2. Case 2. Aortic dissection. **A,** chest film shows prominent ascending aorta. **B,** aortic angiogram shows dilated aortic root, aortic insufficiency and no evidence of dissection. **C,** echocardiogram shows a double echo both anteriorly and posteriorly **(arrows)** and reveals an enlarged aortic root (6.2 cm). **D,** echocardiogram shows flutter of the descent slope (E-F) of the anterior mitral valve leaflet (AMVL), indicating aortic insufficiency. finitive diagnosis of dissection: (1) enlargement of the aortic root, (2) widening of the anterior wall or separation of the posterior wall, and (3) maintenance of parallelism between the separated walls.

Enlargement of the aortic root was seen in all six of our patients with dilatation without dissection; widening of the aortic wall was seen in four of the six. Although parallelism of the double echoes was usually seen, it was not complete (Fig. 4). We found that only multiple discrete or double echoes arising from the anterior or posterior aortic wall, or both, are diagnostic of dissection, particularly when the double echoes are not continuous with the septum anteriorly or the mitral leaflet posteriorly (Fig. 1, 3 and 4). Double echoes may be seen in calcific aortic stenosis; however, they are usually less discrete, and normal aortic leaflets are not seen. When dissection is present, normal leaflets may be seen (Fig. 3), thus differentiating dissection from calcific aortic stenosis. We suggest that all patients suspected of having a dissecting hematoma have echocardiograms in addition to angiograms. With the increased risk of angiography (mortality 1.7 percent)[14] in this disease, echocardiography would be preferable for repeat evaluation of these patients.

Anterior mitral leaflet echoes in aortic regurgitation: As reported previously,[15] flutter of the anterior leaflet of the mitral valve was diagnostic of aortic insufficiency (Fig. 2D). However, not all patients with aortic insufficiency had flutter of the anterior mitral leaflet. Other findings reported in aortic insufficiency are an increased descent slope, premature closure and delayed opening of the anterior mitral leaflet. We found no correlation between descent slope and aortic insufficiency (Table II), and one patient (Case 9) had premature closure and one (Case

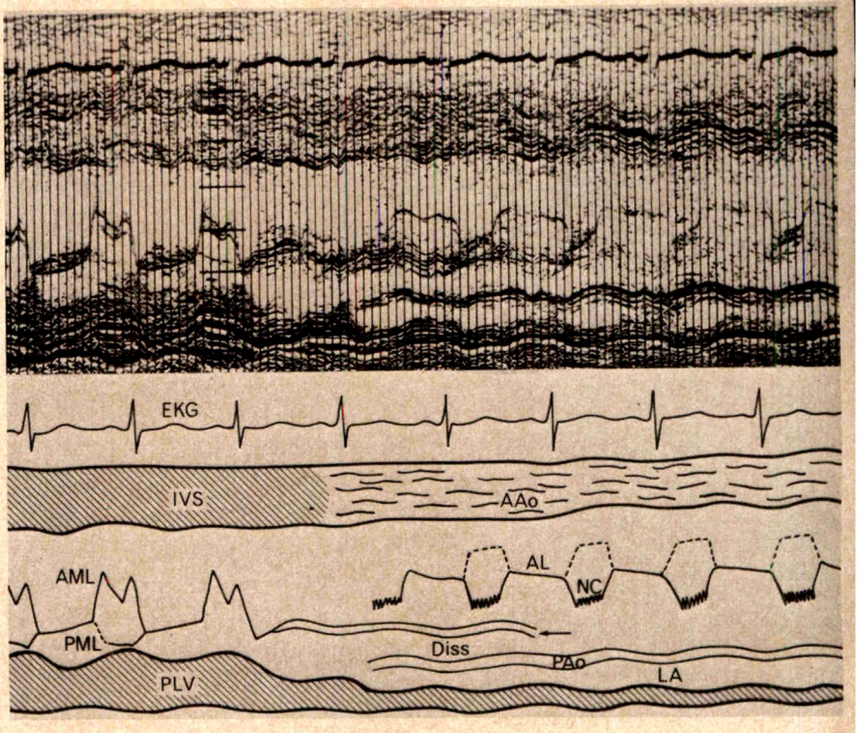

FIGURE 3. Case 3. Aortic dissection. Echocardiogram on admission. Strip chart record with roll-off from anterior mitral valve leaflet to aorta. The anterior aortic wall (AAo) is markedly thickened. The posterior aortic wall (PAo) is displaced into the left atrium (LA) with a discrete double echo not contiguous with the anterior mitral leaflet. The patient had circumferential dissection at surgery. AL = aortic leaflets; Diss = dissection; NC = noncoronary cusp; PML = posterior mitral leaflet; other abbreviations as in Figure 1.

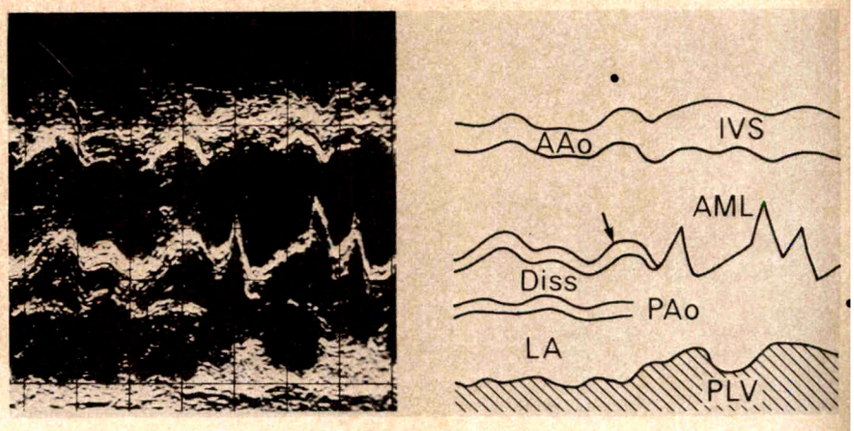

FIGURE 4. Case 5. Aortic dissection. Echocardiogram with roll-off from aorta to anterior mitral leaflet (AML). There is a double echo posteriorly demonstrating dissection, and the posterior aortic wall (PAo) is displaced into the left atrium and is not contiguous with the anterior mitral leaflet. Abbreviations as in Figures 1 and 3.

10) had delayed opening. We did find a correlation between aortic insufficiency and aortic regurgitant flow (Table II), although the degree of clinical or angiographic aortic insufficiency did not correlate with the magnitude of regurgitant flow.

In conclusion, echocardiography was diagnostic of aortic root dissection in five of six patients and suggestive in one and thus had a diagnostic accuracy equal to that of angiography. Echocardiography was diagnostic in the six patients with aortic root dilatation. It proved to be of great value in following up both groups of patients serially and in managing the associated conditions of aortic insufficiency, hemopericardium and cardiac enlargement.

Echocardiographic Criteria for Aortic Root Dissection

OWEN R. BROWN* †
RICHARD L. POPP, MD, FACC‡
FRANK E. KLOSTER, MD*

Portland, Oregon
Stanford, California

Echocardiographic findings from 10 patients without clinical indications of aortic root dissection or aortic valve disease and from 1 patient with angiographic confirmation of aortic root dissection are reported and compared. Previously reported echocardiographic findings were confirmed in the patient with aortic root dissection. These include (1) a widened posterior or anterior aortic wall, or both; (2) parallel motion of the separated margins of the aortic root walls; and (3) aortic root dilatation (42 mm or more at end-systole). However, all three findings were also noted in 5 of the 10 patients without clinical indications of aortic root dissection or aortic valve disease, and at least two of the three findings were noted in the remaining 5 patients. Echocardiographic detection of aortic root dissection appears to be most reliable when clinical indications of the anomaly are present.

Echocardiography has proved useful in detecting aortic aneurysms involving the aortic root in patients with clinical indications of this potentially lethal disease.[1–3] However, the echocardiographic pattern of aortic root dissection may be seen in patients without clinical evidence of dissection. This consideration illustrates the need for caution in diagnosing this anomaly by ultrasound unless the clinical course of the patient is consistent with this disorder.

Methods

A clinical description of the patients in this study is found in Table I.

The ultrasonic examinations were conducted utilizing either a Smith-Kline Ekoline 20 or a Picker Echoview 10 ultrasonoscope. The transducer used in all studies was an Aerotech 1.27 cm, 2.25 megacycle, 5 cm focused transducer. Continuous recordings were made on an Electronics for Medicine or Honeywell 1856 strip chart recorder.

All measurements were made by the same technique previously reported in evaluation of patients with aortic root dissection.[1] Aortic root width was measured from the most anterior echo of the anterior aortic wall to the most posterior echo of the posterior aortic wall during systole. Wall thickness was measured from the outer limit of each wall to the inner limit of the lesser components during systole (Fig. 1).

Results

Aortic root dissection: The single patient with dissection (Table II, Case 11) had aortic root dilatation (70 mm), increased posterior aortic wall thickness (15 mm) and maintenance of parallel motion between the separated margins of the aortic walls as described by Nanda et al.[1] Motion of the aortic cusps was normal. The intensity of the echoes from the outer portion of the thickened wall was greater than those from the inner portion, with the space between the inner and outer limits of the thickened wall being filled with nondescript echoes. Changes in transducer angle produced variations in aortic root and aortic wall width.

Patients without dissection: Six of the 10 patients without clinical indications of aortic root dissection (Table II) had aortic root enlargement (42 mm or more at end-systole[1]). Aortic root width ranged from 37 to 47 mm at end-systole. Marked thickening (10 mm or more)[1] of the posterior aortic wall at end-systole occurred in 9 of the 10 patients without dissection. Posterior aortic wall thickness at end-systole ranged from 8 to 11 mm. No patient had a thickened anterior aortic wall at end-systole, as previously defined in aortic root dissection (16 mm or more[1]) although in three this structure was consider-

*The echocardiogram revealed normal valve cusps in all cases.

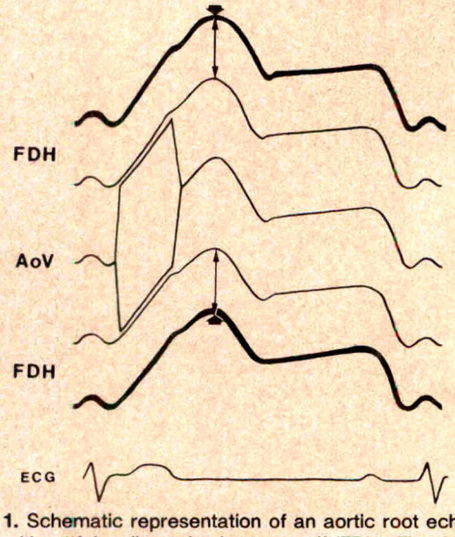

FIGURE 1. Schematic representation of an aortic root echogram in a patient with a "false dissecting hematoma" (FDH). The **thin arrows** indicate the thickness of the false hematoma, the **thick arrows** the width of the aortic root image measured at end-systole. AoV = aortic valve; ECG = electrocardiogram.

ably widened (10 mm or more[4]). Anterior aortic wall thickness at end-systole ranged from 3 to 12 mm. In all 10 patients parallelism was maintained between the inner and outer limits of the thickened wall throughout the cardiac cycle (Fig. 2). The outer portion of the thickened wall was more intense than the inner portion in all cases (Fig. 2). The space between the outer and inner limits of the thickened wall was echo-free in two cases. In the remaining eight patients this space was filled with nondescript echoes. The appearance of the aortic valve cusps was normal in all patients, as previously reported,[4] with their motion extending to the periphery of the inner lumen in systole (Fig. 2). Motion of at least one valve cusp was defined in all patients.

Changes in transducer angle also produced variations in aortic wall thickness in all 10 patients without clinical indication of aortic root dissection (Fig. 3). These changes ranged from 3 to 6 mm, with the thickness usually decreasing as the transducer was directed more superiorly and medially toward the ascending aorta. The width of the aortic root image also changed, but in more random fashion. These changes ranged from 5 to 11 mm. The more basal angulation of the transducer yielded a wider aortic root dimension in 6 of the 10 patients; in the remaining 4 patients the more basal angle produced little appreciable change in aortic root dimension.

Discussion

Recently, Nanda et al.[1] described several echocardiographic criteria for aortic root dissection including (1) enlargement of the aortic root (42 mm or more); (2) marked thickening (16 to 21 mm) of the anterior wall of the aorta at the root level or a wide separation of the posterior aortic wall (10 to 13 mm), or both; and (3) maintenance of parallelism between the separated margins of the walls. Normal motion of the aortic valve cusps was also noted in most patients with aortic root dissection.

The findings in our one patient with aortic root dissection confirm the echocardiographic criteria for

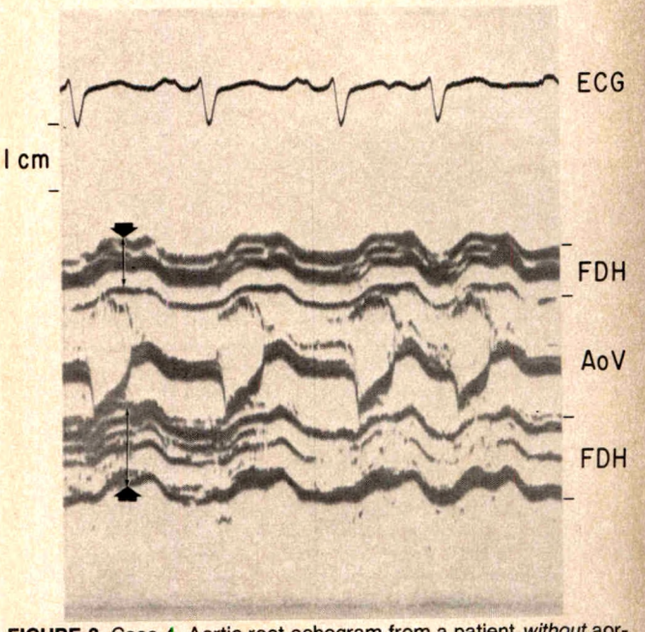

FIGURE 2. Case 4. Aortic root echogram from a patient *without* aortic root dissection illustrates two of the three previously reported criteria for this lesion. There is a parallel widening of the posterior aortic wall (10 mm or more), and the aortic valve cusps (AoV) move only to the inner border of the wall. The aortic root is not enlarged. There is also parallel thickening of the anterior aortic wall (8 mm) although this thickness is not as great as that reported in aortic root dissection. FDH = false dissecting hematoma; ECG = electrocardiogram.

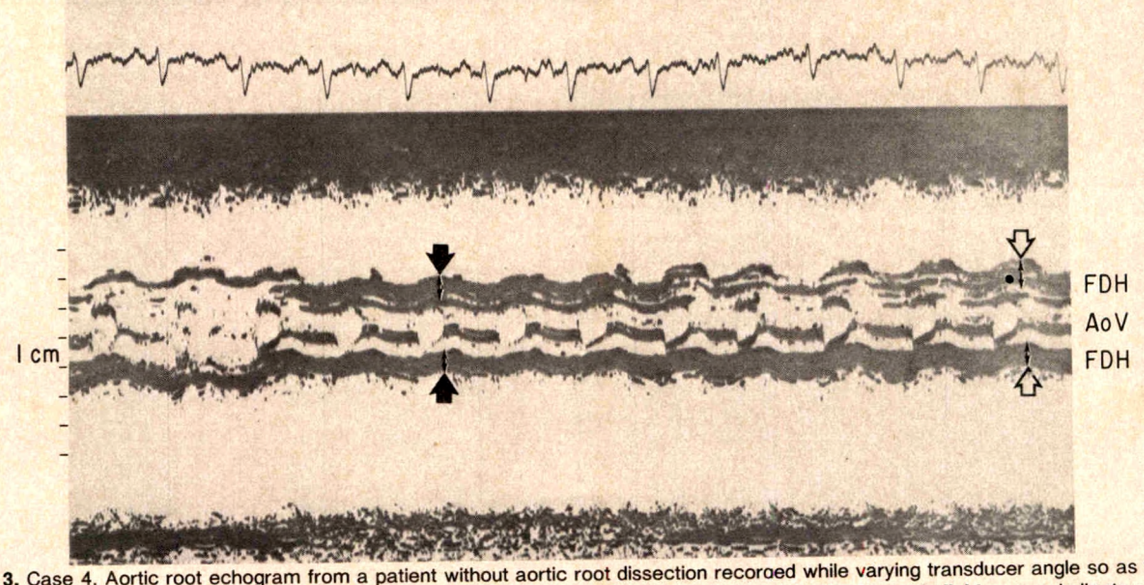

FIGURE 3. Case 4. Aortic root echogram from a patient without aortic root dissection recorded while varying transducer angle so as to sweep the aortic area. The **wide dark arrows** indicate aortic root width with the beam pointed more inferiorly. The **wide light arrows** indicate aortic root width with the beam rocked slowly in a superior and medial manner toward the ascending aorta. The **thin double-headed arrows** indicate aortic wall thickness. Note the variability in aortic root width and aortic wall thickness previously reported as consistent with a localized hematoma.

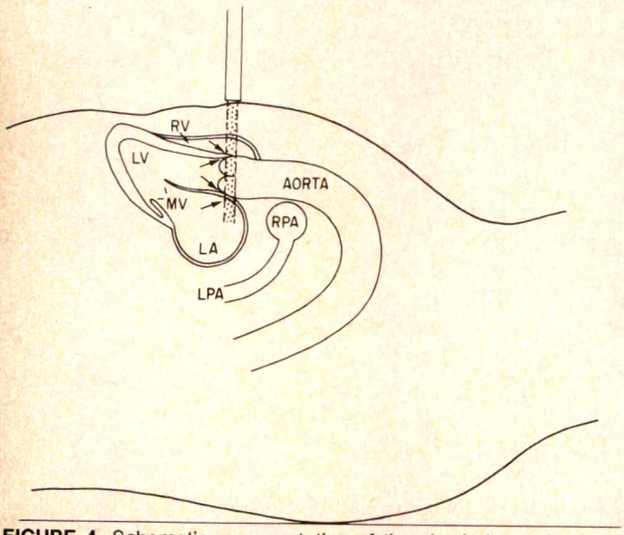

FIGURE 4. Schematic representation of theorized ultrasonic penetration through the aortic root producing the echocardiographic features of a false dissecting hematoma. The transducer position is more cephalad on the chest wall than usual. The beam passes through the fibrous aortic root-membraneous ventricular septum and fibrous aortic root-mitral (MV) junctures. Resulting echoes from the anterior and posterior sides of each of these junctures may explain the "false dissecting hematomas" described in this report. Variations in the beam angle would result in variable aortic root width as the sinuses of Valsalva and other structures were examined. LA = left atrium; LPA = left pulmonary artery; LV = left ventricle; RPA = right pulmonary artery; RV = right ventricle.

this anomaly. However, the echocardiographic pattern of aortic dissection was also noted in 5 of the 10 patients with no clinical indication of aortic root dissection. These five patients had (1) aortic root dilatation (42 mm or more at end-systole); (2) a thickened *posterior* aortic wall (10 mm or more at end-systole); and (3) maintenance of parallel motion of the separated margins of the aortic walls. The remaining five patients in our series met at least two of the three criteria for aortic root dissection. Four had a thickened posterior aortic wall and parallel motion of the separated margins of the widened walls, and one had aortic root dilatation and parallel motion of a posterior aortic wall that was a borderline indication of enlargement (8 mm at end-systole). In addition, 3 of the 10 patients studied had an abnormally thick anterior aortic wall (10 to 12 mm)[4] although in none was it as thick as in patients with aortic root dissection (16 to 21 mm)[1] (Fig. 2). As in aortic root dissection, the echocardiograms of all patients in this series revealed some variation in the width of the aortic root or aortic wall thickness, or both, with slight change in the direction of the transducer (Fig. 3).

One possible explanation for our findings lies in the angle of beam penetration through the fibrous aortic ring. As seen in Figure 4, it is easy to theorize a path of penetration in which an echo is obtained from each side of the aortic-mitral junction. An echocardiogram from this region could demonstrate a false double lumen if the movement plane of the region were almost perpendicular to the sound beam so as to allow reflected echoes from it to return to the transducer. This theory would offer some explanation for both the absence of these findings in the majority of patients and the change in aortic root width as the transducer angle is changed (Fig. 3). Angulation through various portions of the aortic ring and sinuses of Valsalva might mimic variations in aortic root thickness that occur in patients with aortic root dissection as a result of the nonuniform thickness of the dissecting hematoma.

Clinical implications: Perhaps the most useful findings previously reported in patients with aortic root dissection are a markedly thickened anterior wall (16 to 21 mm) and the presence of clinical indications of the disorder. No patient in this series without aortic root dissection had an anterior aortic wall thickness as great as that found in aortic root dissection, whereas 9 of the 10 patients without clinical indication of this disorder had a thickened posterior aortic wall. Echocardiographic patterns mimicking aortic root dissection were found in only 1 to 2 percent of the patients studied in this laboratory without clinical indication of the disorder. When there is a clinical indication of dissection, echocardiography is probably a very helpful means of detecting the aortic root dissection if (1) the *anterior* aortic wall is at least 16 mm thick, (2) parallel motion between the inner and outer borders of the thickened wall is maintained throughout the cardiac cycle, (3) the aortic root is dilated (42 mm or more), and (4) the clinical course of the patient is consistent with aortic root dissection.

When aortic root dissection is present, we believe that echocardiography is a useful tool in detecting it. However, the echocardiographic pattern of aortic root dissection is sometimes seen when there is no clinical indication of the disorder. Therefore, those performing ultrasonic studies should be wary of making the diagnosis on the basis of the echocardiographic pattern unless the clinical history is suggestive of dissection. This caution could prevent unnecessary invasive studies in some cases.

Echocardiographic Differentiation of Infundibular from Valvular Pulmonary Stenosis

ARTHUR E. WEYMAN, MD
JAMES C. DILLON, MD
HARVEY FEIGENBAUM, MD, FACC
SONIA CHANG, BA

Indianapolis, Indiana

Echocardiographic tracings of the pulmonary valve were examined in 24 normal subjects, 16 patients with valvular pulmonary stenosis and 3 patients with infundibular pulmonary stenosis. In normal subjects, atrial contraction produced a slight posterior or opening motion of the pulmonary valve leaflet (*a* wave). This presystolic opening motion (*a* wave) varied with respiration, and maximal *a* wave depth recorded during quiet inspiration (*A*max) averaged 3.7 ± 1.2 (standard error of the mean) mm (range 2 to 7 mm). In the 10 cases with moderate or severe valvular pulmonary stenosis, increased force of right atrial contraction and elevated right ventricular end-diastolic pressure resulted in an increased posterior or opening motion of the pulmonary valve leaflet, and *A*max averaged 9.6 ± 2.0 mm (range 8 to 13 mm, $P < 0.001$ versus normal). When both anterior and posterior leaflets were recorded, presystolic opening or doming of the valve was observed. In six cases of mild valvular pulmonary stenosis, *A*max averaged 4 ± 2.5 mm (not significant). In patients with infundibular pulmonary stenosis, marked chaotic systolic fluttering of the valve leaflet, which lies in the turbulent stream of blood distal to the obstruction, was recorded. This finding was never seen with valvular pulmonary stenosis. In two cases of mild infundibular pulmonary stenosis, the amplitude of presystolic opening motion was within the normal range of 3 and 7 mm. In one case of severe infundibular pulmonary stenosis, no presystolic opening motion was recorded, thus suggesting that the small pressure changes produced by atrial systole failed to reach the valve leaflets. Echocardiography, therefore, should be of use in differentiating valvular from infundibular pulmonary stenosis.

Obstruction to right ventricular outflow may occur at the valvular, infundibular or subinfundibular level.[1] Valvular pulmonary stenosis is characterized by conical or dome-like fusion of the pulmonary valve cusps with a central perforation at the apex. Infundibular pulmonary stenosis may result from either a discrete fibrous band at the entrance to the right ventricular outflow tract with post-stenotic dilatation of the infundibular chamber or more generalized hypertrophy of the infundibular musculature with resultant obstruction.[2] Subinfundibular stenosis is a relatively rare variety of right ventricular outflow obstruction caused by hypertrophic muscle bundles within the right ventricular cavity that tend to separate the inflow from the outflow portions of the ventricle.[3,4]

The diagnostic value of the echocardiographic motion of the pulmonary valve has been suggested in several recent reports.[5,6] We have been interested in examining the pulmonary valve for the diagnosis of valvular pulmonary stenosis.[7] While examining a large group of patients with clinically suspected pulmonary stenosis, we observed three in whom the pattern of pulmonary valve echocardiographic motion differed markedly from that which we had previously observed

in valvular pulmonary stenosis. In each of these three cases the obstruction to right ventricular outflow was determined to be at the infundibular level. This report describes the pattern of pulmonary valve motion seen with infundibular pulmonary stenosis and compares it with the pattern observed in valvular pulmonary stenosis.

Materials and Methods

Echocardiographic tracings of the pulmonary valve were examined in three female patients with infundibular pulmonary stenosis. Their ages were 10, 18 and 19 years, respectively. The diagnosis of infundibular pulmonary stenosis was made on the basis of a pressure gradient across the right ventricular outflow tract with no gradient at the valvular level and the typical appearance of the lesion on cineangiograms. In Case 1, the peak systolic gradient was 48 mm Hg. In this case the infundibular obstruction was associated with a small muscular ventricular septal defect with a 1.2:1 left to right shunt that was not considered hemodynamically significant. In Case 2, a catheter could not be passed beyond the infundibular obstruction and the diagnosis was made on the basis of the angiographic demonstration of an area of narrowing of the right ventricular outflow tract proximal to the pulmonary valve with normal mobility of the valve itself, and a right ventricular systolic pressure of 43 mm Hg. In Case 3, the peak systolic gradient was 113 mm Hg. In no case was associated valvular pulmonary stenosis believed to be present. The pattern of pulmonary valve motion observed in these 3 patients was then compared with the valve motion observed in 24 normal patients and 16 patients with valvular pulmonary stenosis. Of the latter 16 patients, 6 had mild stenosis (gradient less than 50 mm Hg), 6 had moderate stenosis (gradient 50 to 100 mm Hg) and 4 had severe stenosis (gradient more than 100 mm Hg).

The echocardiographic examination was performed with an Ekoline 20A echograph combined with either a Honeywell model 1856 fiberoptic strip chart recorder or an Electronics for Medicine recorder. A 2.25 megahertz transducer with an outer diameter of 1.25 cm focused at 7.5 cm was used. Several techniques for examining the pulmonary valve have previously been described. The first approach, described by Gramiak et al.,[5] is to locate the aortic valve and then, either by angling the transducer cephalad or by moving the transducer one interspace higher, to locate the supravalvular portion of the aorta. From this high left parasternal position, the beam is angled in a lateral and cephalad direction. As the image of the aortic wall disappears, the pulmonary artery becomes visible as an echo-free space anterior to the aorta with its anterior border within 1 to 2 cm of the lower margin of the chest. The posterior margin of the pulmonary artery is characteristically visualized as a wide band of echoes that may lie 2 to 4 cm behind the anterior margin of the artery. The pulmonary valve cusps appear as thin lines that move within the margin of the pulmonary artery.

The second approach[7] is to locate the mitral valve, then tilt the transducer superiorly and slightly toward the throat, but not far enough to record the aorta. As the ultrasonic beam leaves the left ventricular cavity, a dense mass of echoes will be recorded from the region of the right ventricular outflow tract and the potential space between the pulmonary artery and the left atrium. Continuing cephalad, the echo-free pulmonary artery again will appear 1 to 2 cm below the anterior chest wall. The valve leaflets are then located by gentle scanning within the pulmonary artery. Finally, we have noted that, in patients in whom a pulmonary arterial impulse can be palpated along the left sternal border, placing the transducer directly over this impulse permits ready detection of the pulmonary valve.[8] In each of the three cases of infundibular stenosis a complete echocardiographic examination including a recording of the tricuspid valve was performed in addition to the pulmonary valve study. The posterior pulmonary and anterior tricuspid leaflets were clearly recorded in each case. Respiration was timed by an independent observer and the tracing marked for the duration of inspiration.[9]

Because only one pulmonary valve leaflet is usually recorded, the exact duration of right ventricular ejection cannot be determined from the pulmonary valve echo alone. Since tricuspid valve opening represents the onset of right ventricular diastole and follows the termination of right ventricular ejection and normal pulmonary valve closure, we attempted to relate the point of tricuspid valve opening to the pulmonary valve echo to determine the expected limit of right ventricular ejection. To do this, the duration from the onset of tricuspid valve opening to the Q wave of the following QRS complex of the electrocardiogram was measured. This measurement was then used to determine the point of tricuspid valve opening in pulmonary valve complexes of similar cycle length. This point slightly overestimates the point of pulmonary valve closure since it fails to allow for isometric relaxation. However, any motion of the leaflet continuing beyond this point will obviously extend into the diastolic period of the right ventricle.

Results

The Normal Pulmonary Valve

Figure 1A illustrates a normal posterior pulmonary valve leaflet recorded throughout several cardiac cycles. Because of the position of the pulmonary valve in the chest and its plane of motion relative to the ultrasonic beam, the echocardiogram usually records only one posterior pulmonary valve leaflet. The lettering in this figure is similar to that previously described.[7] The *a* wave that follows the P wave of the electrocardiogram reflects the effect of atrial contraction on the pulmonary valve leaflet. That this wave is due to atrial contraction has been confirmed by its constant relation to the P wave in complete heart block and its disappearance with atrial fibrillation. In normal patients the *a* wave depth increases during inspiration. In 24 normal subjects, the maximal depth of the *a* wave recorded during quiet respiration (*A*max) was 3.7 ± 1.2 (standard error of the mean) mm (range 2 to 7 mm).

After atrial contraction, the leaflet normally returns to an initial or closed position (point b) prior to the onset of ventricular ejection. In patients with deep inspiratory *a* waves, particularly when the P-R interval is short, ventricular ejection may occur with the leaflet still partially open. From point b, (the position of the valve at the onset of ventricular ejection), the leaflet moves rapidly to a fully open position (point c).

During systole there is a gradual anterior movement of the leaflet (c-d) followed by rapid diastolic closure of the valve (d-e). During diastole, the leaflet moves gradually posteriorly to point f, which precedes the onset of atrial systole. The anterior systolic

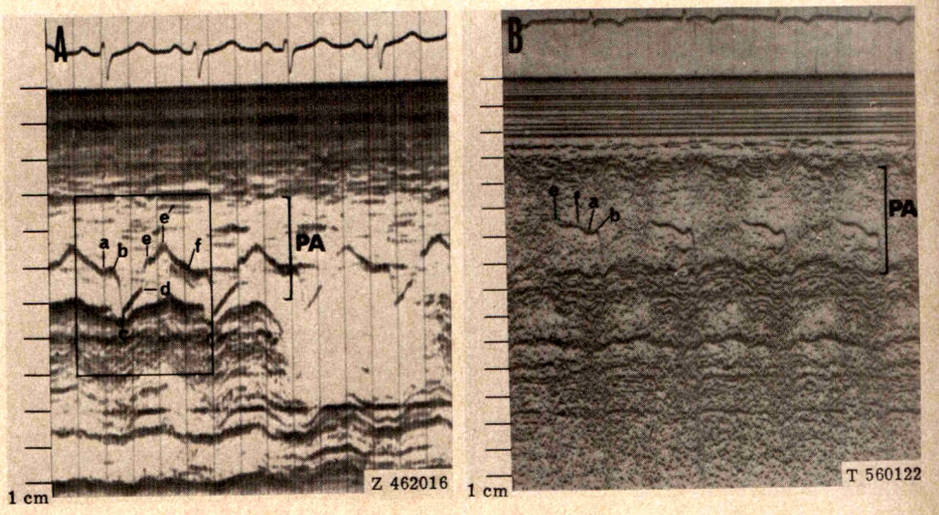

FIGURE 1. Normal. **A,** a normal posterior pulmonary valve leaflet recorded throughout several cardiac cycles. The *a* wave that follows the P wave of the electrocardiogram reflects the effect of atrial contraction of the pulmonary valve leaflet. Point b = the position of the leaflet at the onset of ventricular ejection; b-c = rapid systolic opening of the leaflet; c-d = the leaflet in the open position during systole; d-e = diastolic closure; e-f = leaflets in the closed position during diastole; e-e′ is a variable finding and probably represents transmitted pulsations from the aorta. **B,** a more characteristic normal recording. See text. PA = pulmonary artery.

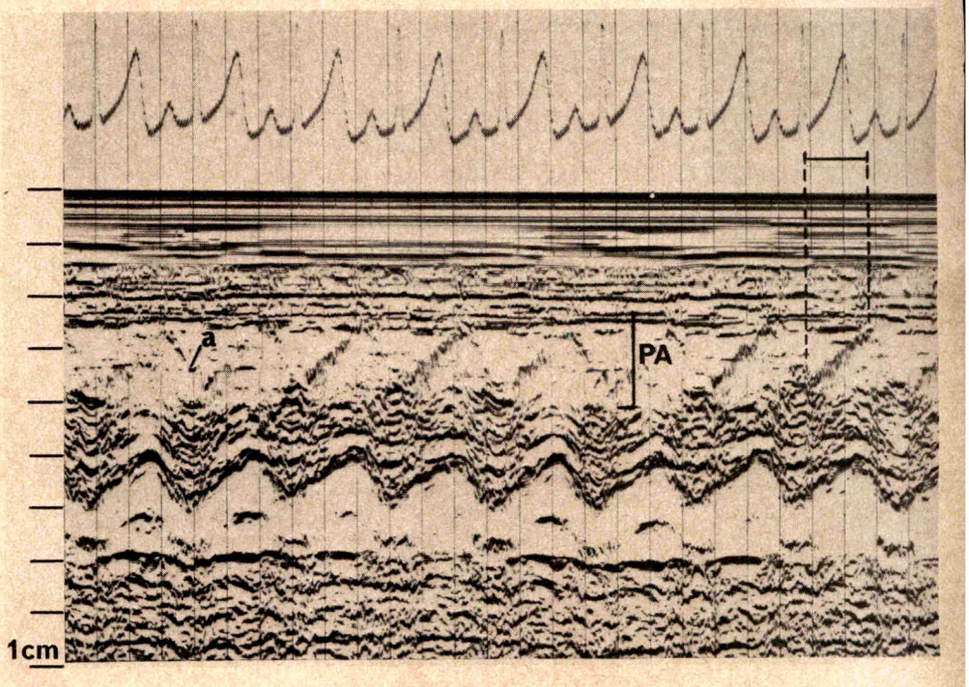

FIGURE 2. Case 1. Mild pulmonary infundibular stenosis. See text.

(c-d) and posterior diastolic (e-f) slopes of the leaflet probably represent pulsatile movement of the pulmonary artery and valve apparatus. In Figure 1A there is further anterior motion from point e-e′. This is a variable finding and may represent transmitted pulsations from the aorta.

Whereas in Figure 1A the leaflet is recorded throughout the cardiac cycle, Figure 1B represents the more characteristic normal recording. In this tracing, the e-f slope, *a* wave and b point are clearly seen. However, as the leaflet approaches the fully open position (point c) it is lost in the dense mass of echoes recorded from behind the pulmonary artery. In these cases, point c, together with the c-d slope and diastolic closure (d-e), is not appreciated. When the leaflet is recorded during systole in normal subjects, the c-d segment is straight. In two of these normal subjects, very fine fluttering of this segment was observed.

Infundibular Pulmonary Stenosis

In the three cases of infundibular pulmonary stenosis, a characteristic pattern of pulmonary valve motion was observed during systole. In each case, the posterior pulmonary valve leaflet opened normally with the onset of ventricular ejection. However, immediately upon reaching the fully open position, the leaflet began a gross high-frequency fluttering that continued throughout systole and into diastole. In each case, cycles occurred where this fluttering was interrupted only by the next atrial contraction.

The magnitude of the *a* wave reflecting the effect of atrial systole on the pulmonary valve was also examined in these cases. In Cases 1 and 2 (mild steno-

sis), *A*max, or the maximal depth of the *a* wave recorded during normal inspiration, was within the normal range of 2 to 7 mm (7 and 3 mm, respectively). In Case 3 (severe stenosis), no *a* wave was recorded.

Figure 2 illustrates a posterior pulmonary valve leaflet recorded from Case 1 (mild infundibular pulmonary stenosis). On the left of the tracing a normal *a* wave (7 mm) is recorded. After the *a* wave, the valve opens rapidly with systolic ejection. Immediately upon reaching a fully open position, the leaflet begins a high-frequency fluttering that continues throughout systole and into diastole, being terminated only by the next *a* wave (atrial contraction). The duration of fluttering in relation to the electrocardiogram is shown between the interrupted lines in the last complex. In this case, we were unable to record the leaflet throughout the cardiac cycle from one transducer position. In this figure, the duration and amplitude of the systolic fluttering are clearly seen; however, the *a* wave and systolic opening of the valve are poorly recorded. In Figure 3, from the same patient, the *a* wave and systolic opening of the leaflet can be clearly seen. In addition, the normal respiratory variation in *a* wave depth is apparent. However, in this recording, the leaflet is lost in the latter part of systole and the extension of the fluttering into diastole is not appreciated.

Figure 4 is a recording from Case 2 (mild infundibular stenosis). A normal *a* wave (3 mm) and high-frequency, very coarse fluttering of the posterior pulmonary valve leaflet are again seen.

Figure 5 is a recording from Case 3 (severe infundibular stenosis). No *a* wave is present and, again, coarse systolic fluttering extending well into diastole is observed. The fluttering in this case is of a similar amplitude, but lower frequency than that seen with mild stenosis. As in the other two cases, this fluttering was frequently observed to continue into diastole.

Valvular Pulmonary Stenosis

In the six cases with mild valvular pulmonary stenosis (gradient less than 50 mm Hg), *A*max averaged 4 mm (range 1 to 8 mm) (difference not significant from normal). In patients with moderate and severe pulmonary stenosis, a marked increase in *a* wave depth was observed. In these 10 cases *A*max averaged 9.6 ± 2 mm (range 8 to 13 mm) ($P < 0.001$). In none of these cases was the systolic c-d segment or diastolic closure (d-e) of the posterior leaflet recorded.

Discussion

Systolic fluttering of the pulmonary leaflet in infundibular stenosis: The characteristic finding in the three patients with infundibular pulmonary stenosis was a high-frequency, coarse systolic fluttering of the pulmonary valve leaflet. This fluttering very likely results from the turbulent stream of blood distal to the infundibular obstruction striking the pulmonary valve. Whereas turbulence distal to a point of obstruction will induce vibration in any mobile structure exposed to it, this vibration is especially prominent in poorly supported structures such as valve leaflets. In patients with discrete membranous subaortic stenosis a similar situation occurs. In these

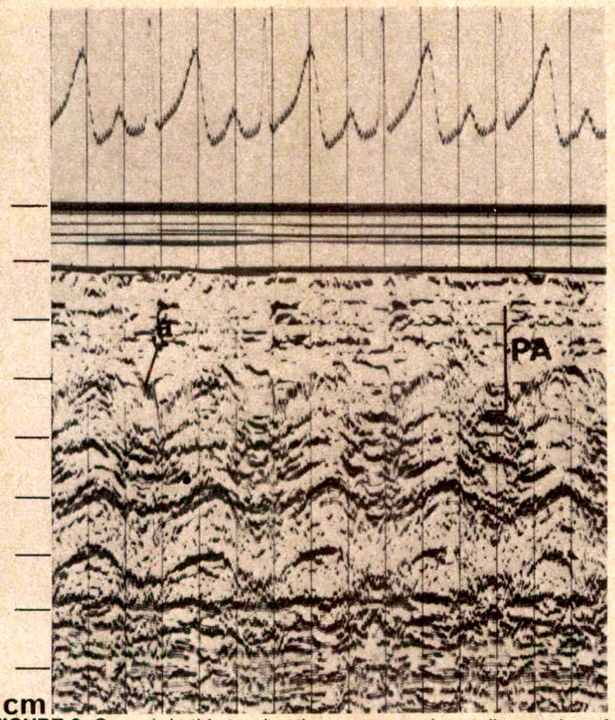

FIGURE 3. Case 1. In this tracing the *a* wave and systolic opening of the leaflet are more clearly seen and the normal respiratory variation in *a* wave depth is apparent. In the first complex on the left, obtained during inspiration, a 5 mm *a* wave is recorded. Fluttering of the leaflet during atrial contraction is also apparent, implying turbulent flow of blood distal to the infundibular obstruction during atrial systole.

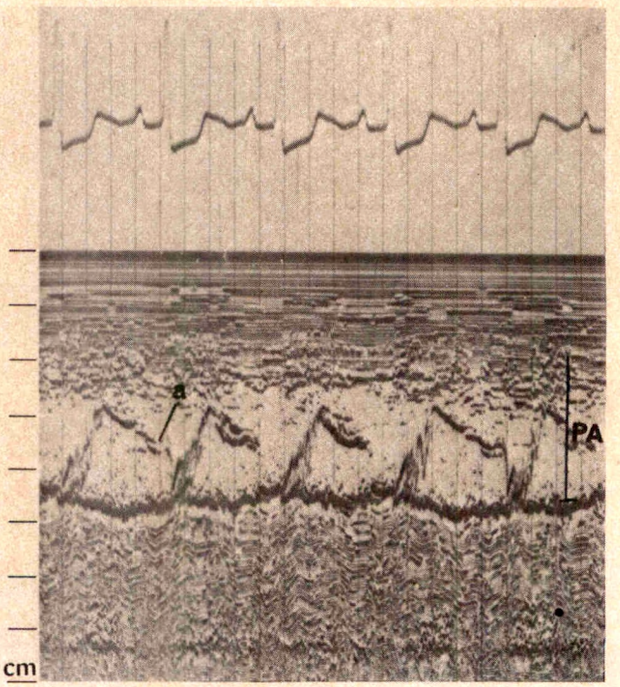

FIGURE 4. Case 2. Mild infundibular stenosis. See text.

cases the aortic leaflets lie within the turbulent stream of blood distal to the area of obstruction, and systolic vibrations or fluttering of these leaflets has been described.[10] In left-sided lesions this vibration or fluttering is limited to the period of systolic ejection and terminates with valve closure.[10] In each of the three cases of infundibular pulmonary stenosis, the fluttering appeared to extend well beyond the expected end of ventricular ejection. Since both pulmonary valve leaflets are ordinarily not recorded, we were unable to determine the end of ventricular ejection directly from the point of pulmonary valve closure. However, by determining the point of tricuspid valve opening at similar cycle lengths, we were able to establish end-systole or beginning diastole in the right ventricular chamber. When this point was related to the duration of fluttering, it was evident that fluttering continued well into diastole in each case, frequently being interrupted by the atrial contraction of the next cycle. The exact duration of fluttering beyond the termination of right ventricular systole could not be determined because of the lack of a precise point at which fluttering terminates and the failure of our method to allow for isometric contraction and relaxation.

Hemodynamic basis for pulmonary leaflet fluttering: If fluttering is due to turbulent blood flow and this fluttering continues into diastole, then con-

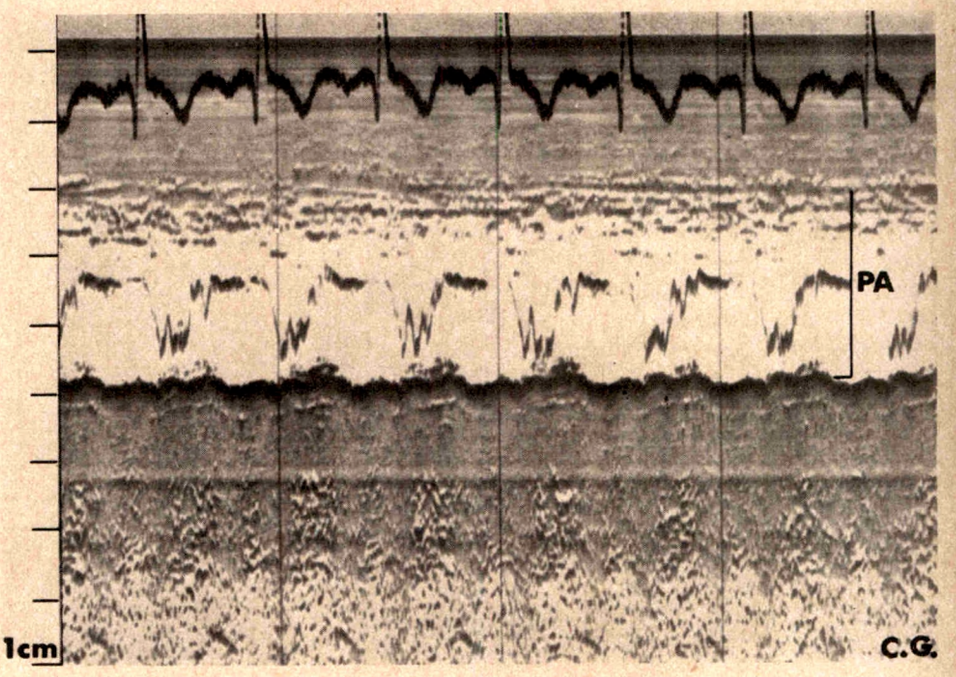

FIGURE 5. Case 3. Severe infundibular stenosis. See text.

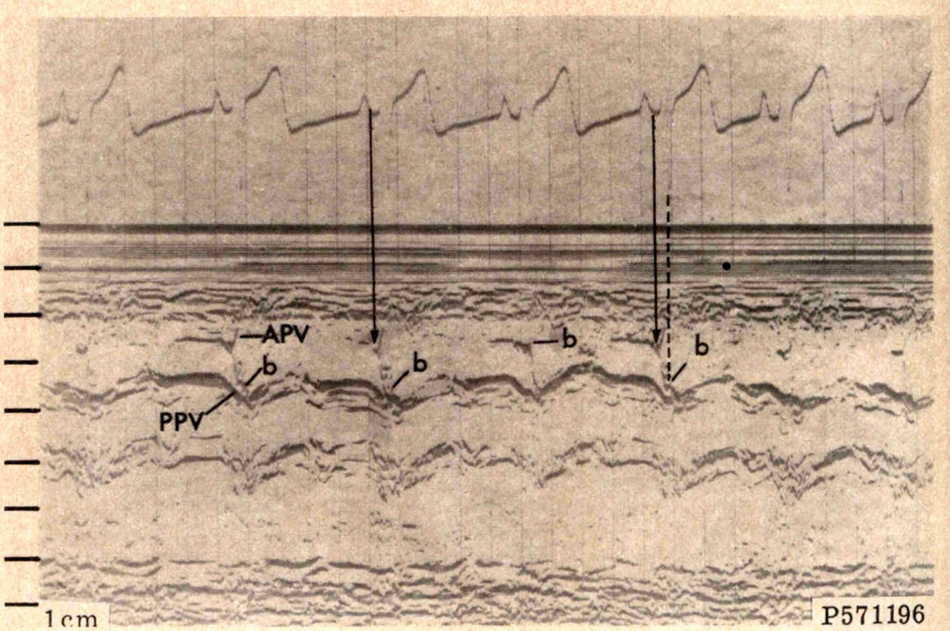

FIGURE 6. Case with valvular pulmonary stenosis. Large inspiratory *a* waves can be appreciated after atrial systole (**solid vertical arrows**) in the first, second and fourth complexes from the left. In these three complexes ventricular systole (interrupted line, fourth complex) occurs with the leaflets in an almost fully open position (point b). In addition, the anterior pulmonary valve leaflet (APV) can be seen to separate from the posterior leaflet and move anteriorly after atrial systole, indicating that the large *a* waves do reflect opening or doming of the valve. In the third complex recorded during expiration, a normal *a* wave is present, and ventricular systole occurs with the valve in a closed position (point b). APV = anterior pulmonary valve; PPV = posterior pulmonary valve; point b = position of the valve at the onset of ventricular systole.

tinued diastolic flow from the infundibular chamber into the pulmonary artery might be implied. In these cases, the leaflets did return to an initial and presumably closed or nearly closed position during diastole, thus suggesting that if there was continued flow across the valve it was of small volume. In addition, the amplitude of fluttering decreased during this period. Vogelpoel and Schrire[11] demonstrated that pulmonary valve closure occurred later in patients with infundibular pulmonary stenosis than in patients with valvular pulmonary stenosis with similar gradients. They recorded a duration from aortic to pulmonary valve closure of up to 0.14 second in patients with severe infundibular stenosis. By comparing pressure curves from the right ventricular and infundibular cavities in patients with tetralogy of Fallot, these authors[12] also demonstrated that systole continued for a longer period in the infundibular chamber than in the body of the right ventricle. They postulated that the prolongation of right ventricular systole as measured by the delayed closure of the pulmonary valve was in fact due to late contraction of the infundibular chamber. Since the infundibular chamber empties into the low pressure pulmonary arterial system, the occurrence of some diastolic flow with resultant fluttering or vibration of the leaflet would not be surprising. Alternatively it is possible that the high-frequency vibrations in the valve leaflets during systole are poorly damped by the low pulmonary arterial pressures distal to the valve and continue well into diastole.

Differentiation from valvular pulmonary stenosis: The pattern of pulmonary valve motion observed in infundibular pulmonary stenosis is sufficiently different from that observed in valvular pulmonary stenosis to permit ready differentiation of the two lesions. In valvular pulmonary stenosis, the characteristic changes are related to the magnitude or depth of the *a* wave of the posterior pulmonary valve leaflet. The *a* wave has been shown to be caused by right atrial contraction, and its depth is thought to be related to the simultaneous pressures existent across the pulmonary valve at peak right ventricular end-diastolic pressure after atrial contraction. In mild valvular pulmonary stenosis, a normal *a* wave has been observed (average 4 mm). In moderate and severe valvular pulmonary stenosis, the increased force of right atrial contraction and increase in right ventricular end-diastolic pressure occurring with a normal or low pulmonary arterial pressure frequently produce a positive end-diastolic gradient across the valve that results in marked augmentation in *a* wave depth (average 9.6 mm). When both anterior and posterior leaflets are recorded simultaneously after atrial systole, the anterior leaflet separates from the posterior leaflet and moves anteriorly. This indicates that these large *a* waves represent presystolic opening or "doming" of the valve (Fig. 6). In addition, we have observed no fluttering of the leaflet during systole in patients with valvular pulmonary stenosis. This absence of fluttering is to be expected since in valvular pulmonary stenosis the turbulent stream occurs distal to the obstruction and should not affect the valve itself.

***A* wave in infundibular versus valvular stenosis:** In the two cases of mild infundibular stenosis, a normal *a* wave was recorded. This is similar to our findings in mild valvular stenosis and we believe that it represents the lack of significant hemodynamic changes produced by mild lesions. However, in the case with severe infundibular stenosis, no *a* wave was recorded. This is the exact opposite of the situation with severe valvular stenosis and may imply that the severe obstruction below the valve prevents the relatively small pressure change caused by atrial contraction from reaching the valve with enough force to produce movement of the leaflets. This suggests then that, whereas the *a* wave in valvular pulmonary stenosis grows increasingly larger as the lesion becomes more severe, the opposite may occur in infundibular stenosis, with the *a* wave becoming smaller and finally disappearing as the degree of obstruction increases. In addition, although normal *a* waves are seen in both mild valvular and mild infundibular stenosis, chaotic systolic fluttering of the valve leaflet extending into diastole is seen only with infundibular stenosis. Therefore, when pulmonary stenosis is suspected clinically, these echocardiographic findings should serve to distinguish the two lesions.

Acknowledgment

We thank Dr. Charles Wunsch and Community Hospital, Indianapolis, Ind. for the data on the patient with severe infundibular pulmonary stenosis.

Radiographic Appearance of the Thorax in Systolic Click-Late Systolic Murmur Syndrome

CARL P. BON TEMPO, MD
JAMES A. RONAN, Jr., MD, FACC*
ANTONIO C. de LEON, Jr., MD, FACC
HOMER L. TWIGG, MD

Washington, D.C.

The posteroanterior and lateral chest X-ray films of 64 consecutive patients with an isolated systolic click (55 patients) or a systolic click with a late systolic murmur (9 patients) showed a striking frequency of thoracic skeletal abnormalities. There were 50 female and 14 male subjects. The average age of the female subjects was 36.7 years (range 13 to 67), that of the male subjects 39.7 years (range 17 to 56). Seventy-two percent of the female and 78 percent of the male subjects had an anteroposterior/transverse thoracic ratio less than the mean ratio in a normal population. Bony abnormalities such as pectus excavatum, straight thoracic spine and scoliosis occurred alone or in combination in 31 of the 50 female patients (62 percent) and in 8 of the 14 male patients (57 percent). Overall, 39 of the 64 patients (61 percent) had at least one of the skeletal abnormalities. Scoliosis occurred in 25 subjects (39 percent) and was mild in 19. A "straight back" was found in 15 (23 percent) and pectus excavatum in 7 patients (11 percent). The explanation for these findings is not apparent. Thoracic cage abnormalities should be included as one of the nonauscultatory features of the systolic click-late systolic murmur syndrome.

Patients with an apical isolated systolic click or a systolic click together with a late systolic murmur have many clinical features in common. In addition to the auscultatory characteristics (clicks and murmurs), certain nonauscultatory features occur with such frequency that they collectively constitute a distinct syndrome. These features are unusual forms of chest pain; palpitations; anxiety; lightheadedness; dyspnea; atrial or ventricular arrhythmias, or both; electrocardiographic T wave changes and, occasionally, Q waves in the inferior leads; occasional familial incidence; and a tendency to occur more commonly in young women.[1–10] We have observed[11] still other common characteristics in this group: a tendency to narrow anteroposterior dimensions of the chest and a high frequency of mild thoracic scoliosis, pectus excavatum or a loss of normal dorsal kyphosis of the thoracic spine. This study reports these patterns of chest configuration as seen in X-ray films of the chest.

Material

Sixty-four consecutive outpatients, referred for evaluation of a systolic click or a click with a late systolic murmur, had a complete history, physical examination, 12 lead electrocardiogram, phonocardiogram and X-ray examination of the chest in posteroanterior and lateral projections.

The films were reviewed for the presence of thoracic scoliosis and pectus excavatum and for the decrease or absence of normal thoracic kyphosis ("straight back"). Internal dimensions of the chest were recorded in the lateral view, from the anterior surface of the body of the eighth thoracic vertebra along a perpendicular line to the posterior cortex of the sternum; in the posteroanterior view, the transthoracic diameter was measured at the level of the diaphragm. The ratio of the anteroposterior to the transthoracic dimen-

sion was obtained. Thoracic cage dimensions in 100 normal subjects, 50 men and 50 women of similar age, have previously been reported and were used for comparison.[12]

Results

Of the 64 subjects studied, 55 had an isolated systolic click, and 9 had a click with a late systolic murmur. In 24 (44 percent) of the 55 patients with an isolated click, a late systolic apical murmur did develop with provocative maneuvers, such as standing erect, exercise, the Valsalva maneuver or the infusion of a vasopressor. There were 50 female and 14 male subjects.

The 50 female subjects ranged in age from 13 to 67

Any of above	31	62	8	57	39	61

years (average 36.7) (Table I). In these subjects, the chest X-ray films revealed the following prevalence of the three specific chest configurations: scoliosis in 20 subjects (40 percent), "straight back" in 11 (22 percent) and pectus excavatum in 7 (14 percent). At least one of the three findings occurred in 31 of these subjects (62 percent). The average ratio of the anteroposterior dimension to the transverse dimension of the chest was 43 percent. Thirty-six female subjects (72 percent) had a ratio less than the mean ratio for normal women (45.7 percent) (Table II).

The 14 male patients ranged in age from 17 to 56 years (average 39.7) (Table I). Scoliosis was present in 5 (36 percent), "straight back" in 4 (29 percent) and pectus excavatum in none. The average anteroposterior/transverse ratio was 43 percent, and in 11 men (78 percent) this ratio was less than the mean ratio for normal men (47 percent) (Table II).

In the entire group of 64 subjects, 39 (61 percent) had at least one of the thoracic skeletal abnormalities; scoliosis was the most common defect, occurring in 25 subjects (39 percent) (Table I). It was moderate to severe (Fig. 1) in 6, and mild (Fig. 2) in 19. "Straight back" was observed in 15 patients (23 percent) (Fig. 3) and pectus excavatum in 7 (11 percent) (Fig. 4). Forty-seven subjects (73 percent) had an anteroposterior/transverse ratio less than the normal mean ratio for persons of their sex (Table II). Eight of the 64 patients (12.5 percent) had two of the bony thoracic abnormalities. None had the musculoskeletal or ocular manifestations typical of the Marfan syndrome.

Discussion

Prevalence of thoracic cage abnormalities: Abnormalities of the bony thorax are relatively common in the adult population. Although their presence does not imply associated cardiac disease,[13,14] some thoracic abnormalities, notably scoliosis and kyphosis, have been associated with other congenital anomalies, such as hiatus hernia.[15,16]

Narrow anteroposterior dimensions of the chest in mitral regurgitation have been previously noted, women with mild mitral regurgitation having been said to be "short, thin, and flat-chested."[16] The 73 percent rate of reduced anteroposterior/transverse thoracic ratios in our cases substantiates the typical "flatness" of the thorax in this population. Although measurements of body height and weight were not made, it has been our distinct impression that young patients with a systolic click and late systolic murmur are usually of slender build.

Thoracic abnormalities have been a point of interest in patients with a systolic click because these clicks were originally thought to be extracardiac in origin.[18–20] It was proposed that thoracic deformities might cause external compression of the heart, creating a clicking sound as the heart contracted and rotated during systole. However, the mitral valve origin of the clicks has been convincingly demonstrated by angiography,[21,22] echocardiography[23,24] and intracardiac phonocardiography,[25,26] and there is little evidence to substantiate their extracardiac origin.

Our data indicate that certain patterns of thoracic configuration are commonly seen in the systolic click-late systolic murmur syndrome. Twenty-five patients (39 percent) had scoliosis, and it was mild in 19. Fifteen subjects (23 percent) had lost the normal dorsal kyphosis of the thoracic spine and were said to have a "straight back." Seven patients (11 percent) had a pectus excavatum. Thirty-nine (61 percent) had at least one of these defects, and eight (12.5 percent) had two of the defects. None had a severe thoracic lesion. Despite the narrow internal anteroposterior dimension of the thorax, the heart was not "trapped" between the sternum and the spine in any case because there was adequate space either anterior or posterior to the heart. In no case did the thoracic configuration appear to be causing an extracardiac click.

The patients in this study were taken consecutively as they were referred for evaluation and thus represent a random sample of patients with the systolic click-late systolic murmur syndrome. They were predominantly young and female, as has been reported by others.[5,6] However, the male patients manifested all the thoracic abnormalities of the female patients, with the exception of pectus excavatum.

Embryologic basis for association of systolic click and thoracic abnormalities: The explanation for the correlation between the auscultatory findings in the syndrome and these types of thoracic configuration is not known. It has been suggested that patients with myxomatous changes in the mitral valve, some of whom had pectus excavatum or scoliosis, actually are manifesting a forme fruste of the Marfan syndrome, having a basic connective tissue disorder that leads to myxomatous changes in the mitral valve and skeletal abnormalities.[27,28] On the other hand, there may be an embryologic explanation for this coincidence of findings because the primordia of the mitral valve undergoes differentiation to its final form between the 35th and 42nd day of fetal development, at the time that the vertebral column and thoracic cage are beginning their chondrification and ossification.[28,29] Any influence on growth patterns at that stage of development might affect both the mitral valve and the bony thorax.

The nonauscultatory features that should be added to the findings commonly seen in the systolic click-late systolic murmur syndrome are a chest configuration with a narrowed anteroposterior dimension and the frequent occurrence of scoliosis, "straight back" and pectus excavatum.

Acknowledgment

We thank Miss Claudia Robichek for her help in the preparation of this manuscript.

Thoracic Skeletal Abnormalities in Idiopathic Mitral Valve Prolapse

JOSEPH SALOMON, MD
PRAVIN M. SHAH, MD, FACC
ROBERT A. HEINLE, MD, FACC

Rochester, New York

Idiopathic prolapse of the mitral valve is a common disorder, but many cases are clinically subtle. Thoracic skeletal abnormalities, reported recently to accompany the syndrome, may serve as an easily identifiable clinical indicator. The prevalence of these abnormalities was defined in 24 patients with proved prolapse of the mitral valve. The valvular syndrome was defined clinically, by echocardiography and, in seven cases, by left ventricular angiography. The skeletal deformities were defined clinically and radiographically. Pectus excavatum was present in 62 percent of the patients, "straight back" in 17 percent and severe scoliosis in 8 percent. Eighteen of the 24 patients (75 percent) had a definite thoracic skeletal deformity. The association of idiopathic prolapse of the mitral valve with these skeletal deformities may represent a forme fruste of Marfan's syndrome. Patients with "straight back" and pectus excavatum should be examined clinically and perhaps by echocardiography to exclude idiopathic prolapse of the mitral valve; when murmurs are present, a diagnosis of "pseudoheart disease" should not be made before mitral valve prolapse has been excluded.

Since the earlier reports of Barlow et al.[1,2] describing a new syndrome of prolapse of the mitral valve, numerous communications have described its clinical,[3–5] pathologic,[6,7] echocardiographic[8,9] and angiographic[10–12] characteristics. The syndrome is now recognized with increasing frequency and is probably a very common disorder. The classic case presenting with nonejection click and late systolic murmur is readily identified. However, many cases are more subtle, and a high level of suspicion and various clinical maneuvers[4] are required to detect the click and the murmur, which may be variable[13] and evanescent. An easily identifiable clinical indicator is needed to suggest which patients may have mitral valve prolapse so that a more careful and complete examination is conducted. Thoracic skeletal abnormalities, which were reported recently to accompany mitral valve prolapse,[14,15] can serve as such an indicator. This report defines the prevalence of these skeletal abnormalities in our patients with prolapse of the mitral valve.

Material and Methods

The records were reviewed of all patients in the cardiology units of Strong Memorial Hospital and Rochester General Hospital from 1970 through 1972 who were found to have prolapse of the mitral valve. Patients with prolapse of known origin (Marfan's syndrome, rheumatic heart disease, coronary artery disease and chest trauma) were excluded. Twenty-four patients were found to have idiopathic prolapse of the mitral valve. Fourteen patients were female and 10 were male. The average age was 34 years (range 6 to 72). Clinical evaluation included assessment of the thoracic habitus (pectus excavatum, kyphoscoliosis, loss of the physiologic thoracic kyphosis, shallow chest) and auscultation in the supine and upright positions and during the Valsalva

maneuver. Phonocardiograms were recorded in 21 patients. Standard posteroanterior and lateral chest X-ray films were obtained in each case. Anteroposterior diameter of the chest at the level of the eighth thoracic vertebra and transverse diameter at the level of the dome of the diaphragm were measured, and the ratio of the anteroposterior and transverse diameters was calculated. The presence of pectus excavatum was determined from the chest X-ray films and the condition was quantitated as either mild or severe. "Straight back" was defined by the following criteria: (1) loss of the physiologic thoracic kyphosis, and (2) anteroposterior diameter of the chest and anteroposterior

transverse diameter ratio smaller than 2 standard deviations from the normal mean as reported by Twigg et al.[16] Echocardiograms, recorded in 21 patients, were reviewed for mitral valve prolapse, utilizing previously published criteria.[8] Left ventricular angiography was performed in the right anterior oblique projection in seven patients, and the description of prolapse of the mitral valve as discussed by Jeresaty[11] and Ranganathan et al.[12] was used to define this abnormality.

Results

All 24 patients had the characteristic auscultatory features of mitral valve prolapse—mid-late systolic click or late systolic apical murmur, or both—and the findings were confirmed by phonocardiography in 21 (Fig. 1). Echocardiographic confirmation was obtained in all 21 patients studied by this technique (Fig. 2). Prolapse of the mitral valve with mild to moderate mitral regurgitation was demonstrated by left ventricular angiography in all seven patients who underwent cardiac catheterization (Table I, Fig. 3).

Pectus excavatum (Fig. 2 and 3) was observed radiographically in 15 of 24 patients (62 percent). "Straight back" (Fig. 1) was present in four patients (17 percent). Two additional patients (8 percent) had severe scoliosis. Three patients had a combination of two abnormalities. Six patients (25 percent) had no definite chest deformity; two of these and a third patient with pectus excavatum had clinical features of "straight back," but their condition did not meet the strict radiographic criteria. Therefore, 18 of the 24 patients (75 percent) manifested a definite thoracic skeletal deformity and 2 had a probable deformity (Table II). The mean anteroposterior diameter of the chest and the mean anteroposterior transverse diameter ratio of these 24 patients were decreased as compared with normal standards (Table III), but the differences were not statistically significant.

Discussion

At least 75 percent of the patients in our series had skeletal thoracic deformities, thereby confirming the initial observations of DeLeon and Ronan,[14] who reported a similar prevalence rate of 78 percent. A more recent communication mentioned a lower though still significant prevalence rate of 47 percent.[15] We found pectus excavatum to be the most common deformity (62 percent) followed by "straight back" (17 percent) and scoliosis (8 percent). There

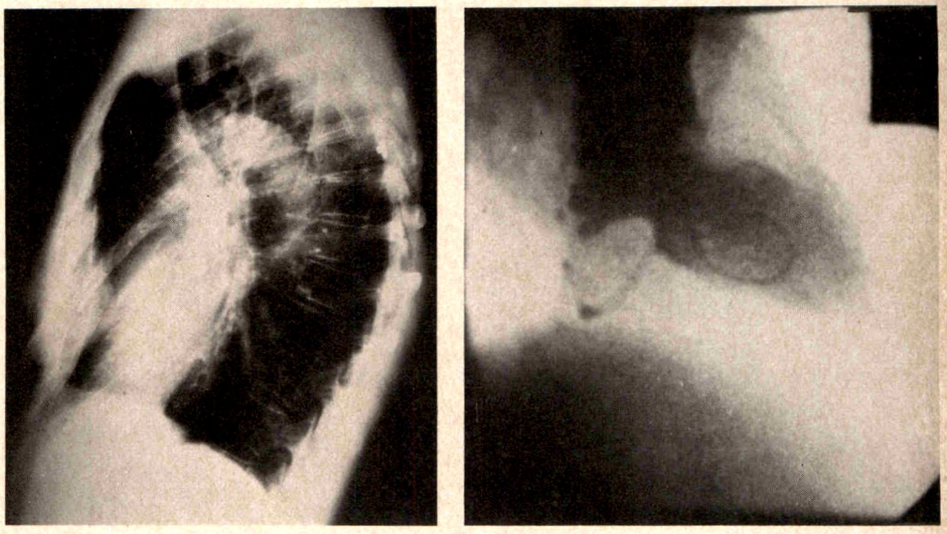

FIGURE 3. Case 4. **Left,** lateral chest X-ray film demonstrates marked pectus excavatum. **Right,** frame from the left ventricular angiogram shows the ventricle in late systole in the right anterior oblique view. The scalloped appearance of the mitral valve prolapsing into the left atrium is readily seen.

was no significant difference between the female and male patients.

Even though mitral valve prolapse occurs in patients with normal body build, it seems to be more frequently associated with asthenic habitus, pectus excavatum, "straight back" and, occasionally, kyphoscoliosis. These skeletal deformities may provide the easily identifiable clinical indicator that is necessary to arouse suspicion of mitral valve deformity and lead to more accurate definition of the disease.

These abnormalities are reminiscent of Marfan's syndrome, in which there is frequently prolapse of the mitral valve[17,18] as well as pectus excavatum and kyphoscoliosis.[19] Moreover, the mucoid degenerative changes described in patients with mitral valve prolapse and Marfan's syndrome are very similar.[6,7,20] One is tempted to postulate that the same mesenchymal heredity that determines the skeletal habitus also affects the mitral valve, resulting in weakening and stretching of the chordae tendineae, loss of leaflet support and eventual development of prolapse of the valve leaflets.

Patients with pectus excavatum or "straight back" occasionally manifest right ventricular hemodynamic restrictive phenomena,[21,22] probably as a result of "pancaking" of the heart within the shallow chest. Mechanical pressure on the heart could account for mitral valve distortion in only a small number of patients with an extremely shallow chest and is probably not a significant factor in the etiology of mitral valve prolapse.

Both "straight back" and pectus excavatum have been shown to be associated with "pseudoheart disease." The murmurs of the "straight back" syndrome are of basal and pulmonary location,[22] whereas in pectus excavatum murmurs can also be heard at the apex[21] and could be confused with those of mitral valve prolapse. Since these rather rare skeletal abnormalities are very prevalent in patients with prolapse of the mitral valve, patients should not be diagnosed as having "pseudoheart disease" until valve prolapse has been excluded.

Clinical implications: It is apparent that many patients (75 percent in our series) with mitral valve prolapse have easily recognizable chest wall and thoracic spine abnormalities that should alert the physician to consider mitral valve disease. Careful auscultation of the heart will almost invariably reveal the correct diagnosis, which can be substantiated by phonocardiography, echocardiography and, in selected cases, angiocardiography. The identification of these patients is extremely important since they tend to have potentially fatal ventricular arrhythmias[23–25] and are predisposed to bacterial endocarditis.[26,27]

Termination of Ventricular Fibrillation in Dogs by Depolarizing a Critical Amount of Myocardium

DOUGLAS P. ZIPES, MD, FACC
JOHN FISCHER, MD
ROBERT M. KING, MD
ANN deB. NICOLL, RN
WALTER W. JOLLY, MD

Indianapolis, Indiana

The role of a critical myocardial mass required to maintain ventricular fibrillation initiated by rapid ventricular pacing was studied by two methods in dogs placed on total cardiopulmonary bypass. In the first method, depolarization of a limited myocardial mass was accomplished by injecting potassium chloride into one or two coronary arteries. Injection of potassium chloride simultaneously into the left circumflex and left anterior descending coronary arteries abolished ventricular fibrillation more often than did injection into any other single or combination of two coronary arteries ($P < 0.0001$). Ventricular fibrillation could not be reinitiated as long as the left ventricle remained inexcitable. Immersing the heart in a solution of potassium chloride or injecting the solution into the right and left ventricular cavities failed to terminate ventricular fibrillation. The second method evaluated the amount of current necessary to terminate ventricular fibrillation when the current was passed between two right ventricular electrodes, between two left ventricular electrodes and between one right ventricular and one left ventricular electrode. Electrical shocks of equal magnitude terminated ventricular fibrillation most often when those shocks were delivered between an electrode located at the right ventricular apex and an electrode located at the posterior base of the left ventricle, and least often when the shock was delivered between two right ventricular electrodes. Successful defibrillation results when a critical amount of myocardium becomes depolarized by either potassium chloride or electrical discharge; depolarization of every cell in both ventricles is not necessary to terminate ventricular fibrillation in the entire heart.

Although the explanation for the pathogenesis of self-sustained fibrillation remains divided between the ectopic focus and reentry theories,[1–3] much evidence exists to substantiate the need for a critical myocardial mass to maintain self-sustained fibrillation. A critical mass represents the amount of myocardium that must be present and excitable for fibrillation to continue spontaneously. In the late 1800's, McWilliam[4] and Porter[5] noted that ventricular fibrillation was more easily supported in larger hearts and, in 1914, Garrey[6] demonstrated that when pieces of ventricular muscle with a surface area of less than 4 cm^2 were shaved from the wall of the fibrillating left ventricle, these pieces stopped fibrillating. The remaining portion of the ventricle continued to fibrillate until three fourths of the ventricular mass had been removed. In other experiments, after appropriate cuts divided the fibrillating heart into the right ventricle, interventricular septum and left ventricle, the right ventricle stopped fibrillating while fibrillation in the larger masses continued.

The purpose of this study was to test whether ventricular fibrillation can be terminated in the intact heart in situ by depolarizing only a limited population of cells. If ventricular fibrillation can be termi-

nated in such a fashion, it indicates that the remaining excitable cells represent a critical mass that is insufficient to maintain self-supported ventricular fibrillation. Such a concept has been suggested to explain observations recorded during defibrillation studies in dogs using an intracavitary catheter electrode.[7] The results of our study provide direct proof in support of this concept.

Two types of experiments were devised. In one group of dogs we employed a solution of potassium chloride to depolarize a limited mass of myocardium by bolus injection of the solution into the right, left anterior descending or circumflex coronary artery. In the second group of dogs, we determined the amount of current and voltage necessary to terminate ventricular fibrillation in the entire heart when the current was passed in the form of a trapezoidal wave between two electrodes sewn on the right ventricle, between two electrodes sewn on the left ventricle and between various combinations of one right ventricular and one left ventricular electrode.

Methods

Healthy mongrel dogs of either sex weighing 15 to 30 kg were anesthetized with secobarbital (30 mg/kg body weight), intubated and ventilated with a Harvard respirator at a rate and tidal volume predicted from a nomogram. The chest was opened in the midline, and the pericardium was incised and retracted to cradle the heart.

Total cardiopulmonary bypass was achieved in both groups of animals. After ligation of the azygous vein and administration of heparin (3 mg/kg intravenously), large bore catheters to collect venous blood were inserted into the superior and inferior venae cavae through a right atriotomy and secured by purse-string sutures. Umbilical tapes, placed loosely around the venae cavae, were later tightened to direct all venous blood returning in the venae cavae into the venous catheters. Blood was also collected from a suction catheter placed in the chest cavity and from a left ventricular vent catheter and pumped (Sigma motor model T65, Leland Electric) into a filtered cardiotomy reservoir (model Q120, Bentley Laboratory) that emptied into the venous return line. Venous blood was drained by gravity into a disposable blood oxygenator (pediatric size Temptrol, model Q110, Bentley Laboratory), primed with saline and Ringer's lactate solution through which 100 percent oxygen was bubbled. The blood, warmed and oxygenated in the Temptrol oxygenator, was pumped by a finger pump (Sigma motor model TM1, Leland Electric) into a large arterial perfusion catheter that had been placed in the abdominal aorta by way of the femoral artery. Arterial flow rates were kept between 2 and 3 liters/min.

Systemic blood pressure was monitored on an oscilloscope by means of a strain gauge transducer (Statham 23BD) that was connected to an indwelling catheter placed in the carotid artery. Mean systolic blood pressure was maintained between 45 and 65 mm Hg by adjusting venous return, altering arterial flow rate or by infusing normal saline solution; vasopressors were not used. The body temperature of the dogs was kept between 98 and 101° F. Periodic blood gas and electrolyte determinations during the experiments revealed that partial pressure of oxygen was always greater than 100 mm Hg. Initial hypokalemia in some animals, possibly related to hyperventilation before institution of cardiopulmonary bypass, was gradually corrected. In the group of dogs that received intraarterial injections of potassium chloride, serum potassium concentrations slowly rose and reached levels of 5 to 7 mEq/liter by the end of the experiment. In the second group of animals, serum potassium levels gradually rose toward normal but rarely exceeded 4 mEq/liter. Plasma levels of sodium and chloride became elevated as a result of saline infusion. Arterial pH was kept above 7.25 with periodic infusion of sodium bicarbonate. The hematocrit level fell in most dogs as a result of blood loss, pump-induced hemolysis and dilution with saline infusion. However, the experimental results we obtained cannot be ascribed to metabolic or hematologic imbalances since comparisons were made between interventions performed in the same animal within limited time periods, during which abnormal metabolic or hematologic status would be expected to affect the entire heart more or less equally.

Electrical activity was recorded with bipolar J-shaped electrodes that were hooked into the epicardium of the right or left atrium, or both, and in the following epicardial ventricular sites: high right ventricle near the outflow tract, low right ventricle along the inferior border, posterobasal left ventricle, in the lateral free wall of the left ventricle adjacent to the interventricular septum, and apex of the left ventricle. The latter two left ventricular electrodes were placed to reflect distribution of the left anterior descending coronary artery, whereas the posterobasal electrode reflected distribution of the circumflex artery. Bipolar electrical activity was filtered between 40 and 500 hertz, displayed along with lead II of the electrocardiogram on a switched beam oscilloscope (DR8, Electronics for Medicine), and recorded on photographic paper at speeds of 50 and 100 mm/sec.

After the animal was placed on total cardiopulmonary bypass, we initiated ventricular fibrillation by rapidly stimulating either the right or left ventricle at rates of 20 to 100 times/sec for 5 to 30 seconds. Stimuli, obtained from a pulse generator through an isolation transformer (Digipulser, model 830; Isopulser, model 850, WP Instrument, Inc.), were rectangular pulses of 2 msec duration delivered over bipolar electrodes at an intensity of 1 1/2 to 2 times the diastolic threshold. In the potassium studies, stimuli of 30 volts and 5 milliamperes were sometimes used.

Ventricular fibrillation was considered present when totally disorganized ventricular activity continued spontaneously for a minimum of 15 to 30 seconds after cessation of ventricular stimulation. Ventricular fibrillation was considered terminated when either organized electrical activity or complete absence of all electrical activity replaced ventricular fibrillation for more than 5 seconds, simultaneously in all five of the epicardial ventricular leads and lead II.

Potassium Studies

In the initial group of eight dogs treated with potassium chloride infusion, polyethylene tubing (22 gauge, Deseret) was inserted by way of a small arteriotomy into the right coronary artery near its origin and into the midportion of the left anterior descending coronary artery. The tip of the tubing in the latter vessel was advanced in retrograde manner to the bifurcation of the main left coronary artery, where a single potassium chloride injection depolarized ventricular muscle located in areas perfused by both the circumflex and left anterior descending coronary arteries. Brief occlusion at the origin of the right coronary artery during retrograde infusion into the left anterior descending

artery prevented reflux of potassium chloride into the former vessel, so that the solution perfused primarily the left ventricle. If only the anterior or posterior left ventricular recording, but not both, was affected by the potassium chloride, the infusion was considered a single vessel infusion made into either the left anterior descending or circumflex coronary artery, respectively. In order to perfuse these vessels separately, in the final group of six animals subjected to potassium chloride infusion, the origins of the right, left anterior descending and circumflex coronary arteries were dissected free from the epicardium and each vessel was cannulated individually. The tips of the tubing, located within 1 to 2 cm of the origin of each coronary artery, were directed "downstream" and secured in place with epicardial or purse-string sutures. The small diameter of the polyethylene tubing allowed unimpeded coronary blood flow.

To determine whether depolarization of a limited myocardial mass could result in termination of ventricular fibrillation in the remaining myocardium, a fixed total amount of potassium chloride was injected into a single coronary artery, or equal portions of the total amount of potassium chloride were injected into two coronary arteries simultaneously. Thus, the distribution of the particular coronary artery or combination of coronary arteries perfused with potassium chloride determined the amount of myocardium that was depolarized. Although anastomoses between coronary arteries permitted a certain amount of cross circulation, the major portion of the ventricle not directly perfused remained unaffected by infusion of potassium chloride into the contralateral side, as judged by the epicardial recordings. In each experiment, we compared the efficacy of equal total amounts of potassium chloride in terminating fibrillation when the solution was injected into one or two coronary arteries.

Finally, in another group of animals, potassium chloride (25 to 50 ml, 1 mEq/ml) was injected into the cavity of the left or right ventricle, or both, or the entire heart in situ was immersed in a polyethylene "bag" filled with 160 ml of potassium chloride (1 mEq/ml) for 30 seconds.

Electrical Defibrillation Studies

In the group of 11 animals electrically shocked, pairs of circular electrodes (3.14 cm^2) were sewn on the right and left ventricular epicardium, in a plane parallel to the interventricular septum. The electrodes were cut from copper sheets and coated with a layer of solder; the copper did not come into direct contact with the myocardium. On the right ventricle, the electrodes were sewn close to the atrial border near the outflow tract (RV_{Base}, RV_B) and near the inferior margin of the right ventricular apex (RV_{Apex}, RV_A). On the left ventricle, they were sewn in the posterobasal area between the origins of the left anterior descending and circumflex coronary arteries (LV_{Base}, LV_B), and near the left ventricular apex (LV_{Apex}, LV_A). The current and voltage wave forms were recorded on a calibrated storage beam oscilloscope (Tektronix model D11) from which the amplitude was measured. All electrical grounds, including the right leg electrode for the electrocardiogram, were removed from the animal. The shock was delivered after ventricular fibrillation had been initiated and was present spontaneously for at least 30 seconds. We determined the current and voltage required to terminate ventricular fibrillation in the entire heart when the shock was delivered between the following pairs of electrode combinations: RV_B-RV_A, LV_B-LV_A, RV_B-LV_B, RV_A-LV_A, RV_B-LV_A and RV_A-LV_B. In addition, each electrode of each pair served as the "hot" electrode; that is, the current and voltage required to terminate fibrillation was determined separately for current flowing in each direction between two electrodes. The distance between each of the electrode pairs was measured and, at the conclusion of each experiment, the heart was removed and weighed.

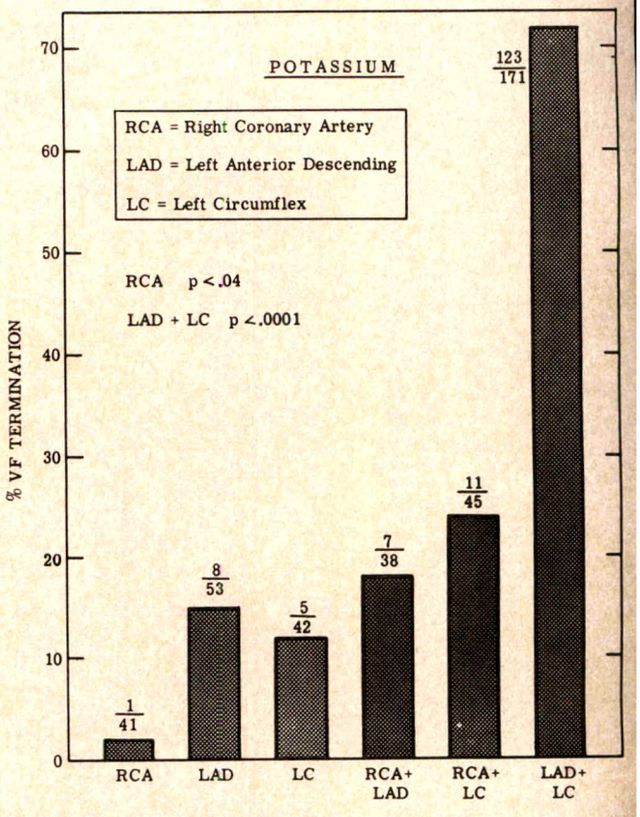

FIGURE 1. Graph indicating the percent of potassium chloride injections that successfully terminated ventricular fibrillation (Y axis) according to the single or combination of coronary arteries into which the solution was injected (X axis). Figures above the bars show the number of injections that terminated ventricular fibrillation (numerator) and the number of total injections (denominator). VF = ventricular fibrillation.

The electrical impulse used was a truncated exponential ("trapezoidal pulse") impulse delivered from a capacitor (800 μfarad at 600 volts direct current) that had been charged to a selected voltage with a variable regulated power supply. The length of the pulse (24 msec) was controlled by a variable integrated circuit timer that operated a silicon-controlled rectifier circuit.*

Results

Potassium Studies

The results from the entire group of 14 dogs were combined and are presented in Figure 1. Injections into the right coronary artery resulted in significantly fewer terminations than injections at any other site ($P < 0.04$), whereas the 72 percent rate of termination during simultaneous injection into the left anterior descending and circumflex coronary arteries was sig-

* The electrical circuitry was designed and built by Medical Electronics Consulting Associates, Indianapolis, Ind.

nificantly greater than terminations produced by any other injections ($P < 0.0001$). Simultaneous infusion of potassium chloride into the left anterior descending and circumflex coronary arteries naturally represents perfusion of the largest amount of ventricular myocardial mass. The success rate for defibrillation diminished in the other combinations, approximately in direct relation to the amount of ventricular myocardial mass perfused. Anastomotic circulation may have minimized these differences to a degree.

An example illustrating the termination of ventricular fibrillation by selective potassium chloride infusion is displayed in Figure 2. Potassium chloride injections (1 ml, 1 mEq/ml) into the right, left anterior descending or circumflex coronary artery, individually, depolarized limited portions of the ventricle supplied by these vessels but did not terminate ventricular fibrillation (not shown). Selective potassium chloride infusions terminated ventricular fibrillation within 5 to 6 seconds (Fig. 2, B and C) when the potassium chloride was injected simultaneously into either the right plus the circumflex coronary artery or the left anterior descending plus the circumflex coronary artery. Therefore, the remaining number of excitable cells represented a critical mass insufficient to maintain fibrillation. Infusion of potassium chloride into only one coronary artery or simultaneously into the right and left anterior descending coronary arteries failed to terminate ventricular fibrillation, presumably because the remaining excitable mass was large enough to support continued fibrillation. In this particular example, the high right ventricle and left atrium were not affected by infusions of potassium chloride into the right and circumflex coronary artery, respectively, because these areas were supplied by branches close to the origin of each coronary artery and were not perfused by the potassium chloride solution.

When ventricular fibrillation terminated after infusion of potassium chloride into the left coronary artery, the refractory period and diastolic stimulation threshold for the right ventricle remained at prefibrillation control values. However, rapid right ventricular stimulation failed to initiate ventricular fi-

brillation as long as the left ventricle remained depolarized by the effects of the potassium chloride (Fig. 3, A and B). After the return of left ventricular activity, fibrillation could be promptly restarted (Fig. 3C). Right ventricular inexcitability after infusion of potassium into the right coronary artery did not prevent precipitation of left ventricular fibrillation (not shown).

Ventricular fibrillation could not be terminated when potassium chloride (25 to 50 ml, 1 mEq/ml) was injected into the cavity of the right or left ventricle and confined there for 15 to 30 seconds. Similarly, ventricular fibrillation could not be terminated by immersing the entire heart into a plastic bag with a potassium chloride solution (160 ml, 1 mEq/ml) (not shown).

Electrical Defibrillation Studies

The combination of electrodes, the distance between electrodes and the heart weight were all major factors affecting the ability of the electroshock to defibrillate. The percent termination of ventricular fibrillation in 1,170 shocks for three current and voltage ranges is presented in Figure 4, in which each curve represents one of the electrode combinations. The rate of termination of ventricular fibrillation is significantly different among the six electrode combinations at each range for both voltage and amperes (overall P value <0.001 for each voltage and amperage range). Termination of ventricular fibrillation also occurred at less than 100 volts and less than 1.00 amperes, but the incidence was not large enough to analyze. The direction of current flow did not statistically influence the rate of termination.

Curves (Fig. 4) that decrease at 3.00 to 3.99 amperes and 300 to 399 volts can be explained by trials in which only one or two shocks were attempted at the lower two energy levels because the shocks failed to defibrillate the myocardium, and a large number of shocks—also unsuccessful—were attempted at the highest settings. This naturally reduced the percent of successful shocks at 3.00 to 3.99 amperes and 300 to 399 volts, while only minimally affecting the percentages at the lower two energy levels.

Heart weight was an important variable; it required significantly more volts (P <0.001) and amperes (P <0.001) to terminate ventricular fibrillation in heavier hearts, whether weights were analyzed for the right ventricle alone, the left ventricle alone (free wall of the left ventricle plus the interventricular septum) or total ventricular weight.

Increasing the distance between the LV_B and LV_A electrodes from 3 to 5 cm increased the rate of termination of ventricular fibrillation from 38.9 to 65 percent (P <0.05). However, increasing the distance between the RV_B and RV_A electrodes from 3 to 5 cm did not significantly increase the termination rate.

The relative importance of distance versus electrode combination could be assessed for two combinations by analyzing the data obtained with the RV_B-RV_A and LV_B-LV_A electrodes. In each experiment, the distance between RV_B and RV_A equaled the distance between LV_B and LV_A (3 to 5 cm). However, the LV_B-LV_A electrode combination yielded a higher percent of defibrillations for electroshocks of equal magnitude than did the RV_B-RV_A combination (P <0.001 except at 200 to 299 volts and 3.0 to 3.99 amperes). We conclude that, at least for these two electrode combinations, electrode position rather than interelectrode distance, was more important.

Subthreshold shocks were often followed by transient organization of recorded ventricular activity[7] but, presumably because an insufficient amount of myocardium was depolarized, fibrillation continued (Fig. 5A). Threshold shocks sometimes evoked short bursts of repetitive ventricular discharge (Fig. 5B) but were most often followed by abrupt termination of fibrillation.

Discussion

Critical ventricular mass required to maintain ventricular fibrillation: The data from the potassium infusion studies clearly establish for the intact dog heart in situ the importance of a critical ventricular mass to maintain self-supported ventricular fibrillation, which was initiated by rapid electrical stimulation. Ventricular fibrillation was terminated when potassium infusion reduced the remaining amount of excitable myocardium to a value less than that of the critical mass. Therefore, depolarization of every cell in both ventricles is not necessary to terminate ventricular fibrillation in the entire heart. The amount of this critical mass cannot be accurately quantified from our protocol, since we did not correlate combinations of potassium chloride injections that terminated fibrillation with the exact amount of myocardial mass perfused. This might be accomplished by injecting different dye markers into the right, left anterior descending and circumflex coronary arteries after completion of the potassium infusions. However, if we assume from Figure 1 that the entire left ventricle and interventricular septum, or a comparable amount of myocardium, must be depolarized to reduce the remaining excitable myocardium to a value insufficient to maintain ventricular fibrillation, then the critical mass necessary for ventricular fibrillation to continue in 13 dogs studied represents 28 percent of the total ventricular myocardium, a percentage remarkably similar to that found by Garrey.[6] This value is at best only an estimate for the dog heart because of the problems generated by cross circulation, our inability to perfuse branches arising very close to the origin of the coronary artery, and the fact the potassium chloride very probably did not uniformly depolarize the entire ventricular mass with which it made contact. This percentage may not necessarily be extrapolated directly to the patient with heart disease because the tendency to perpetuate fibrillation in the latter situation might be affected by many variables.

Support of concept of critical myocardial mass: The data from the electroshock studies provide indi-

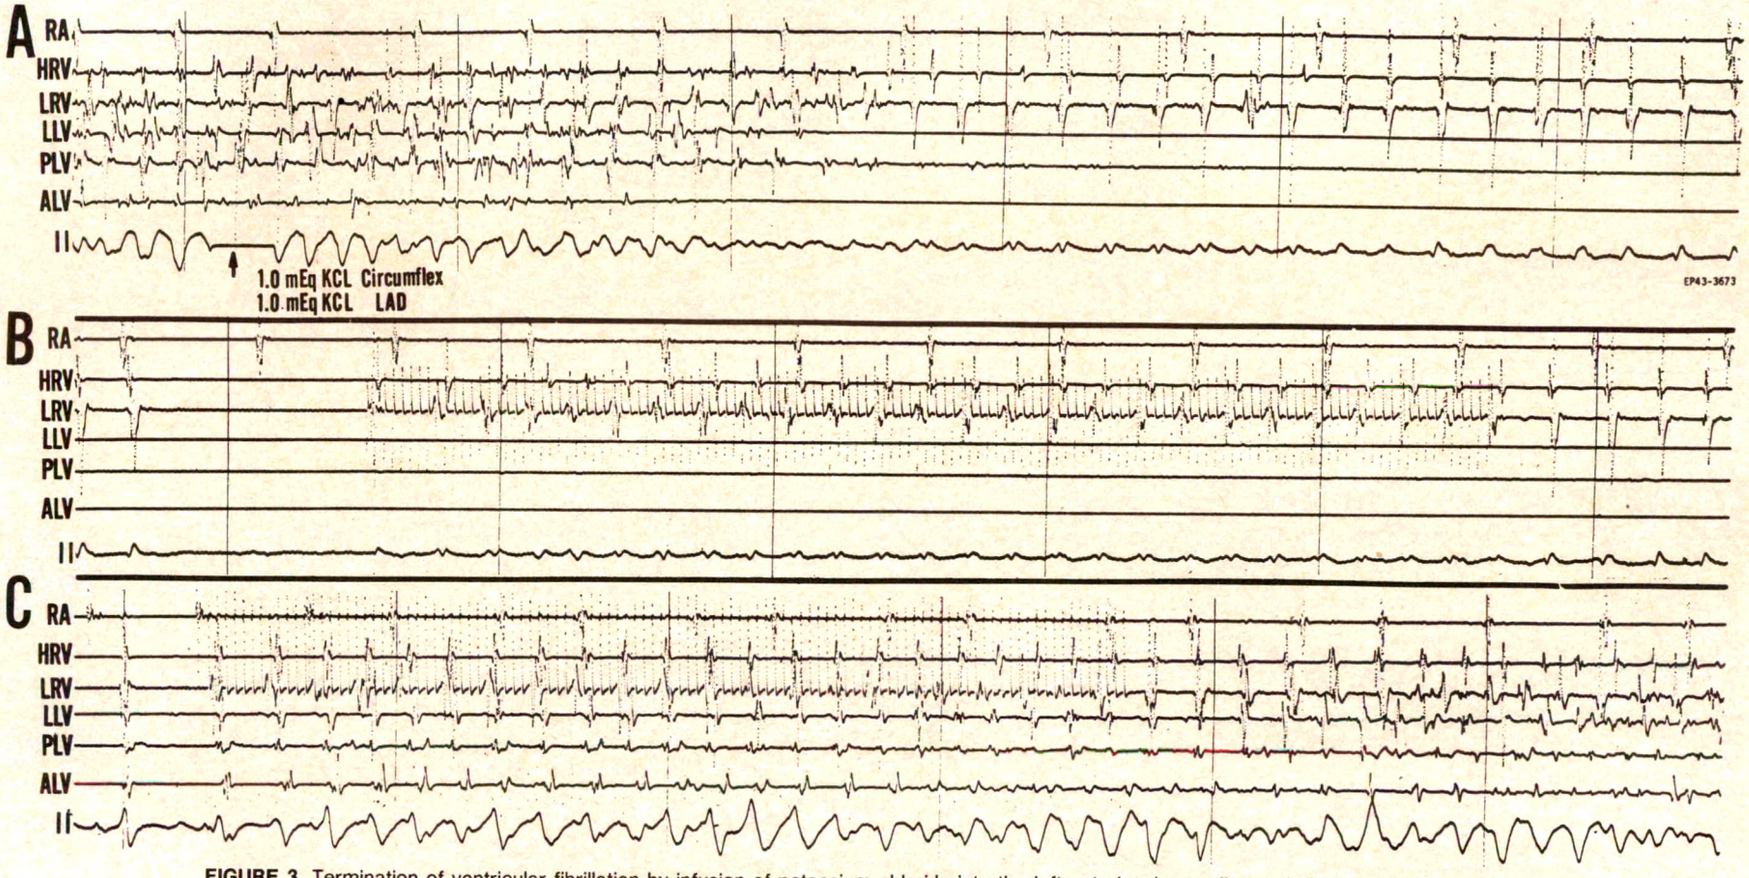

FIGURE 3. Termination of ventricular fibrillation by infusion of potassium chloride into the left anterior descending and circumflex arteries with failure to initiate ventricular fibrillation while the left ventricle remained inexcitable. Panels **A** and **B** are a continuous recording with the terminal two complexes in panel **A** repeated as the first two complexes in panel **B**. Potassium chloride (1 mEq/ml, 1 ml) was injected simultaneously into the left anterior descending and circumflex coronary arteries at **arrow.** Electrical activity recorded at the LLV, PLV and ALV electrodes became suppressed and an organized ventricular rhythm replaced ventricular fibrillation in the right ventricle. **B,** rapid right ventricular pacing (30/sec for about 4 seconds) failed to initiate ventricular fibrillation. **C,** after recovery of left ventricular excitability, right ventricular pacing (30/sec for about 3 1/2 seconds) promptly initiated ventricular fibrillation. rect evidence supporting the concept of a critical myocardial mass. Those data indicate that electrical shocks of equal magnitude terminated ventricular fibrillation most often when the shocks were delivered between the RV_A-LV_B electrodes and least often when they were delivered between the RV_B-RV_A electrodes. LV_B-LV_A and the remaining electrode combinations resulted in intermediate values. If these observations are explained in terms of the critical myocardial mass concept, then we would postulate that current flowing between two right ventricular electrodes (RV_B-RV_A) encountered, and therefore depolarized, the least number of cells, and resulted in the lowest rate of cardioversions. Current traveling between the right ventricular apex and posterobasal left ventricle (RV_A-LV_B) encountered, and therefore depolarized, the largest number of cells and resulted in the highest rate of cardioversions. Differences between the remaining electrode combinations may have been less great in terms of mass bounded by the two electrodes and resulted in intermediate values with a fair amount of overlap.

Distance between electrodes played a role in terminating fibrillation because interelectrode distance influenced the amount of mass through which the current flowed. However, the electrode combination seemed more important. The distance between RV_B-RV_A and LV_B-LV_A was equal in each experiment. Nevertheless, a higher percentage of terminations occurred with the LV_B-LV_A combination, presumably because of the larger mass bounded by the two left ventricular electrodes. The RV_A-LV_B electrode combination most successfully terminated ventricular fibrillation for two reasons. First, the combination spanned virtually the entire left ventricle and, second, its interelectrode distance was generally the largest.

Clinical implications: Speculations about the events that occur during clinical direct-current electroshock are consistent with the concepts advanced in this report. For example, during electrical defibrillation, the shock cannot discharge many cells that have just been depolarized spontaneously (by the fibrillating rhythm) and are absolutely refractory at the moment the shock is delivered. These cells naturally repolarize in advance of cells that are discharged at a slightly later time by electroshock, but, during a successful cardioversion, they represent a mass of cells insufficient to perpetuate the fibrillation. Continued fibrillation indicates failure to depolarize a sufficient number of cells. Administering a continuous series of shocks has been suggested to terminate refractory ventricular fibrillation.[8,9] It is possible that each successive shock depolarizes more muscle mass until finally a sufficient amount of myocardium becomes depolarized and fibrillation stops. Heart weight also has been important during defibrillated studies performed in man. The heavier the heart, the greater the energy required for defibrillation.[10]

This concept of critical mass may also explain the success of intracavitary catheter defibrillation in man and animals,[7,10] because depolarization of the entire heart is not necessary to terminate fibrillation. From our data, however, we would predict that energy requirements for defibrillation with a catheter electrode in or behind (coronary sinus) the left ventricle might be less than for a catheter electrode in the right ventricle. Such comparisons have not been performed by Mirowski and Mower.[12]

Influence of Sympathetic Tone on Ventricular Fibrillation Threshold During Experimental Coronary Occlusion

BERNARD R. KLIKS, MD
MARY JO BURGESS, MD*
J. A. ABILDSKOV, MD, FACC

Salt Lake City, Utah

The effects of increased and decreased cardiac sympathetic tone and coronary occlusion on ventricular fibrillation threshold were determined in 14 open chest dogs anesthetized with sodium pentobarbital. Heart rate was kept constant by pacing the right atrium at cycle lengths of 500 msec. Ventricular fibrillation threshold was measured by delivering 350 msec trains of constant current stimuli with a frequency of 100 hertz and 2 msec duration. The minimal current of the train that induced fibrillation was taken as the ventricular fibrillation threshold. In seven animals, the effects of stellate stimulation were studied. Ventricular fibrillation threshold was measured during control periods, after 2 minutes of coronary occlusion, after 2 minutes of stellate stimulation and after 2 minutes of stellate stimulation and coronary occlusion. Coronary occlusion alone decreased ventricular fibrillation threshold an average of 35 percent of control values and stellate stimulation alone decreased the threshold an average of 42 percent of control values. The combination of both these interventions decreased ventricular fibrillation threshold an average of 63 percent of control values.

The effects of stellate ablation were studied in seven animals. Ventricular fibrillation threshold was measured during control periods, and during coronary occlusion before and after stellate ganglionectomy. Stellectomy increased the threshold an average of 31 percent above control values. After stellectomy, coronary occlusion decreased ventricular fibrillation threshold by only 11 percent of control values, a value 26 percent higher than the threshold during coronary occlusion before stellectomy. These findings may have therapeutic implications for the management of arrhythmias in patients with acute myocardial infarction or some forms of central nervous system disease.

The high mortality rate during the early phases of acute myocar infarction is mainly due to the high incidence of ventricular arrhy mias during this period. The mechanism of these arrhythmias has been completely defined; they may be due to enhanced automatic a reentrant mechanism, or both. Whatever the mechanism of th arrhythmias, many investigators have demonstrated that manipu tion of autonomic tone during experimental coronary occlusion in ences their incidence and severity.[1–10] In previous studies heart r has not been controlled, and it is therefore difficult to tell if the sults are due to the difference in heart rate before and after mani lation of autonomic tone or to the level of autonomic tone itself addition, previous studies have been concerned with the incidenc arrhythmias rather than with a quantitative measure of vulnerab to fibrillation independent of its initiating mechanism.

This study was conducted to determine the influence of ca sympathetic stimulation or surgical removal of the stellate and thoracic ganglia on fibrillation threshold during acute coronary

sion. Heart rate was controlled, and fibrillation threshold was determined in dogs in a control state, during coronary occlusion, during stellate stimulation, during coronary occlusion and stellate ganglion stimulation, after surgical removal of the stellates and upper thoracic ganglia and during coronary occlusion after ganglionectomy.

Methods

Experiments were performed in 14 mongrel dogs anesthetized with sodium pentobarbital (30 mg/kg body weight) and ventilated with a fixed volume pump respirator. The chest was opened with a sternal splitting incision and the heart suspended in a pericardial cradle. The vagi were divided in the neck. The sinus node was crushed, a bipolar electrode placed on the right atrial appendage, and the heart paced at cycle lengths of 500 msec. The left anterior descending coronary artery or one of its major branches was isolated. Umbilical tape was passed around the artery and subsequently used to occlude it temporarily. A vertical lead body surface electrocardiogram and a bipolar electrogram from the lateral surface of the right ventricle were recorded.

To measure fibrillation threshold, 350 msec trains of constant current stimuli with a frequency of 100 hertz and a duration of 2 msec were delivered to the ventricle after every ninth basic driving cycle. The timing of the train with respect to a body surface electrocardiogram and a right ventricular electrogram are shown in Figure 1. In panel A the train stimulus intensity is subthreshold, and in panel B the intensity has been increased sufficiently so that it produces one propagated ventricular response. The trains of stimuli were delivered to two stainless steel hook electrodes. The anode was placed on the surface of the right ventricle in the region of the pulmonary conus, and the cathode was placed on the left ventricle near the border of the area that became cyanotic during temporary occlusion. The intensity of the train was increased in 0.5 milliampere increments until fibrillation was induced. The animals were defibrillated within 10 seconds of the onset of fibrillation, and repeat measurements were not made for 5 to 10 minutes after defibrillation.

Fibrillation threshold was measured in a control state, within 2 to 5 minutes of acute coronary occlusion and during alteration of sympathetic tone before and during coronary occlusion. The occlusion of the coronary artery was released as soon as fibrillation threshold was measured. In one dog repeated measurements of fibrillation threshold were made during control states and after 2 minutes of coronary occlusion. This was done to establish the reproducibility of the method. In another animal, the effects of both stellate stimulation and stellectomy on fibrillation threshold before and during coronary occlusion were determined.

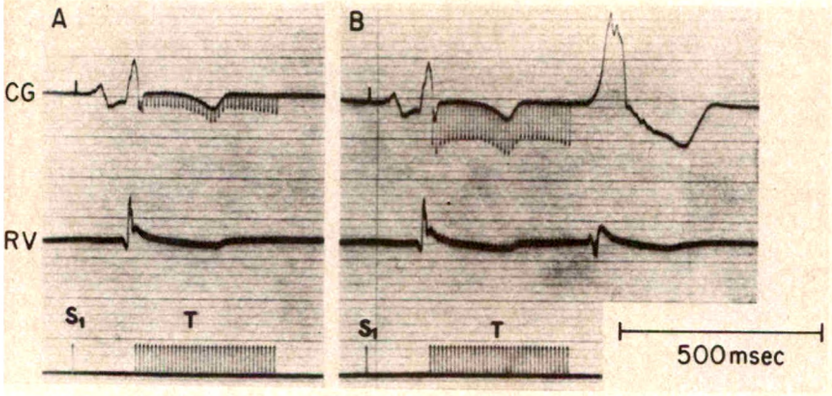

FIGURE 1. Vertical lead body surface electrocardiogram (ECG), a right ventricular (RV) electrogram, and stimulus pulses of the basic drive (S_1) and of the train (T) used to induce ventricular fibrillation. In **A** the intensity of the train is subthreshold and it does not induce a ventricular response. In **B** the intensity of the train has been increased sufficiently to induce one ventricular response.

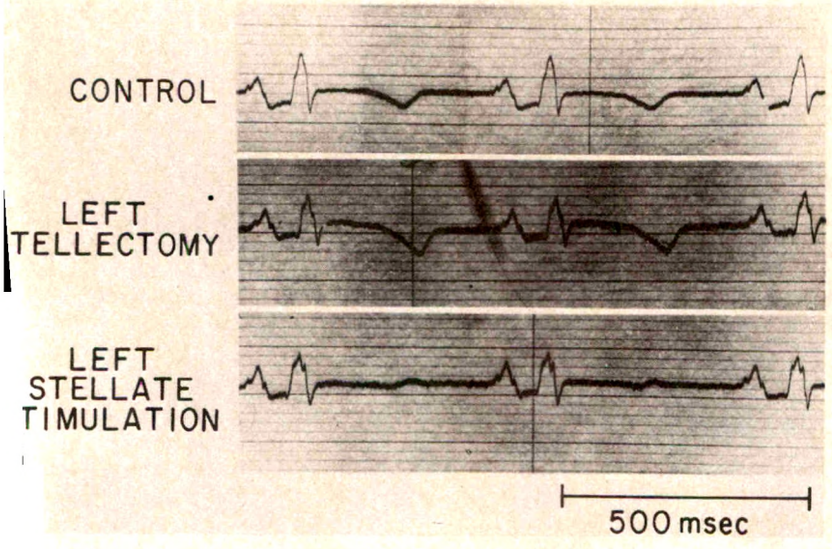

FIGURE 2. Vertical lead electrocardiograms of a dog taken during a control period **(top tracing)**, after left stellectomy **(middle tracing)** and during stimulation of the distal ends of the ansae subclaviae **(bottom tracing).**

The results from this animal are included with the results from animals in which only the effects of stimulation or stellate ablation were studied. The effects of sympathetic stimulation were studied in six additional dogs. In these animals the left stellate ganglion or the left dorsal and ventral ansae were isolated and stimulated with trains of pulses with a frequency of 12 hertz, a duration of 4 msec and an intensity of 5 to 16 volts. Change in T wave form in a vertical lead body surface electrocardiogram was taken as evidence of change in sympathetic tone. The effects of left stellate stimulation and removal on one dog's electrocardiogram are shown in Figure 2. Stimulation of the stellate ganglia was started 2 minutes before measurement of fibrillation threshold and continued during coronary occlusion. Measurements of threshold during sympathetic stimulation alone were alternated with measurements of sympathetic stimulation during coronary occlusion. In each animal 3 to 5 measurements were made under each condition. In six other dogs, the effects of sympathetic ablation were studied. Fibrillation thresholds were determined during a control state and after 2 minutes of coronary occlusion. Either the left stellate ganglion (two dogs) or both the left and right stellate ganglia (four dogs) were then excised together with the upper three or four thoracic ganglia. After ganglionectomy, 30 minutes was allowed to elapse and fibrillation threshold measurements with coronary occlusion were alternated with measurements without occlusion. In each animal two to five measurements were made under each of the two conditions.

Results

The ranges of time required to measure fibrillation threshold after 2 minutes of coronary occlusion alone were almost identical to those required to measure fibrillation threshold after 2 minutes of coronary occlusion in animals with stellate stimulation or stellectomy. With coronary occlusion alone, measurement of fibrillation threshold was started 2 minutes after occlusion of the artery and was completed an average of 82 ± 39 (standard deviation) seconds later. With stellate stimulation and coronary occlusion, measurement of fibrillation threshold was started 2 minutes after occlusion and the onset of stimulation and completed an average of 78 ± 47 seconds later. With stellectomy and coronary occlusion, measurement of fibrillation threshold was started 2 minutes after occlusion and completed an average of 82 ± 40 seconds later. Spontaneous arrhythmias rarely occurred and, if they did, a smaller vessel was occluded. If spontaneous arrhythmias persisted, the animal was excluded from the study. Fibrillation after release of the coronary artery did not occur in the animals studied.

Figure 3 is a bar graph of repeated measurements of fibrillation threshold made in one dog during control periods and after 2 minutes of coronary occlusion. In this animal, fibrillation threshold averaged 7 ± 1 (standard deviation) milliamperes in the control periods and 4 ± 1 milliamperes during coronary occlusion. Although the threshold in the control periods ranged from 6 to 9 milliamperes, there was no overlap in measurements made in control periods with those made during occlusion.

The effects of both stellate stimulation and stellectomy on fibrillation threshold before and during coronary occlusion usually could not be determined in the same animals because of the time required to complete all measurements. The determination of the effects of all these interventions in the same animal was successfully carried out in one dog (Fig. 4). One hour after left stellectomy alone, fibrillation threshold increased. After stellectomy, threshold decreased less during coronary occlusion than it had be-

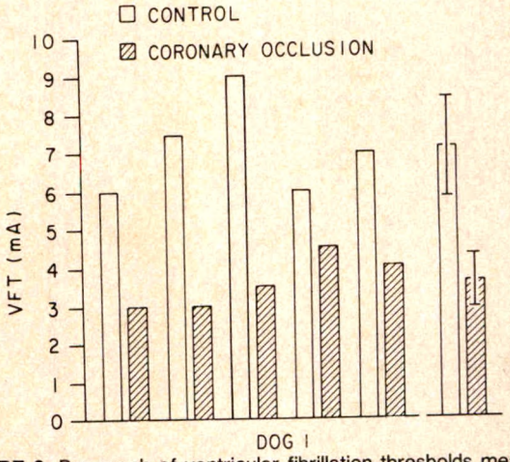

FIGURE 3. Bar graph of ventricular fibrillation thresholds measured during five control periods and five periods of temporary coronary occlusion. Fibrillation threshold is shown in milliamperes (mA). The last two bars on the graph show the averages and standard deviations of the control and coronary occlusion thresholds. VFT = ventricular fibrillation threshold.

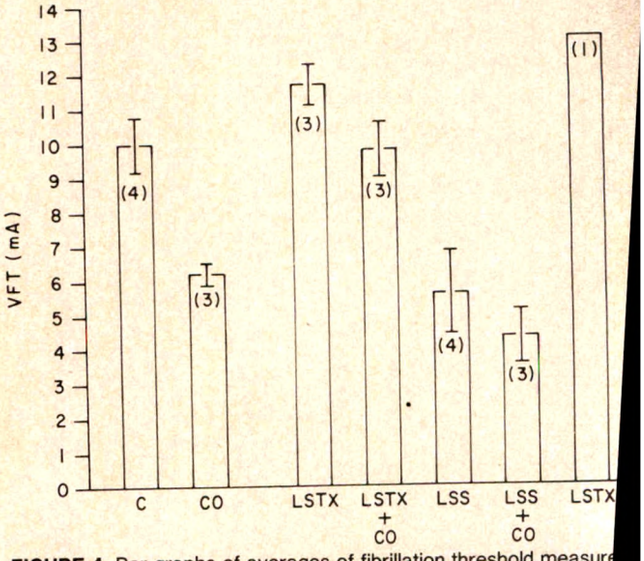

FIGURE 4. Bar graphs of averages of fibrillation threshold measure in milliamperes of one dog during control periods (C), during temp rary coronary occlusion (CO), after left stellectomy (LSTX), duri coronary occlusion after stellectomy, during stimulation of the dis ends of the left stellate (LSS) and during coronary occlusion and l stellate stimulation. The numbers in parentheses indicate the numb of measurements included in the averages. VFT = ventricular fib lation threshold.

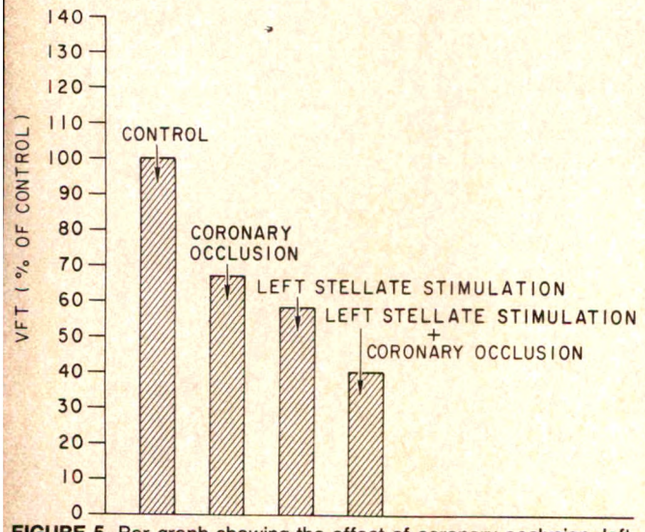

FIGURE 5. Bar graph showing the effect of coronary occlusion, left stellate stimulation and left stellate stimulation and coronary occlusion on fibrillation threshold. Fibrillation threshold is expressed as a percent of control level, and the graph is compiled from the average findings in seven dogs. VFT = ventricular fibrillation threshold.

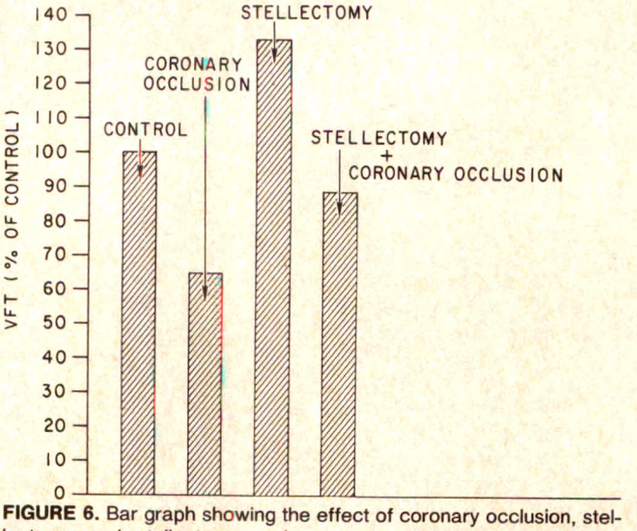

FIGURE 6. Bar graph showing the effect of coronary occlusion, stellectomy and stellectomy and coronary occlusion on fibrillation threshold. Fibrillation threshold is expressed as a percent of control level, and the graph is compiled from the average findings in seven dogs. VFT = ventricular fibrillation threshold.

fore stellectomy. Stimulation of the distal ansae subclaviae decreased fibrillation threshold more than coronary occlusion alone, and there was a further decrease in the threshold when the coronary artery was occluded during stellate stimulation. After these measurements were made, 1 hour was allowed to elapse and threshold was again measured. This measurement is shown as the last bar on the graph and is only 1 milliampere higher than the measurements of fibrillation threshold made 1 hour after stellectomy. This indicates that the preparation was stable. The results from this dog are included in the results of experiments in animals in which only the effects of stellate stimulation or stellectomy were studied.

Sympathetic stimulation and coronary occlusion: The effect of sympathetic stimulation on fibrillation threshold before and during coronary occlusion was studied in seven dogs, and the results of these experiments are summarized in Figure 5. In these animals, after coronary occlusion alone, fibrillation threshold decreased by an average of 35 percent from control values. Stimulation of the left stellate ganglion alone decreased fibrillation threshold by an average of 42 percent from control values. This decrease was comparable to that seen with coronary occlusion alone. The combination of sympathetic stimulation and coronary occlusion produced a further decrease in fibrillation threshold. With the combination of these two interventions, threshold to fibrillation fell by an average of 63 percent of control values, a level 27 percent lower than the threshold with coronary occlusion alone.

Stellectomy and coronary occlusion: The effect of stellectomy on fibrillation threshold before and during coronary occlusion was studied in seven dogs (Fig. 6). In these dogs, before stellectomy, coronary occlusion decreased fibrillation threshold by an average of 37 percent from control values. Stellectomy alone increased fibrillation threshold to an average of 31 percent above control values. After stellectomy, coronary occlusion decreased fibrillation threshold but, when compared with levels before stellectomy, threshold was decreased by an average of only 11 percent from control levels, a level 26 percent higher than fibrillation threshold during coronary occlusion before stellectomy.

Discussion

As early as 1936 the study of Cox and Robertson[1] implicated an increase in sympathetic tone as a contributory factor in the occurrence of arrhythmias after coronary occlusion; they observed a lower mortality rate in dogs with acute coronary occlusion and prior ganglionectomy than in dogs with intact cardiac sympathetic nerves. Similar findings have been reported by others.[2–5]

The study of Schaal et al.[5] was performed in unanesthetized dogs with chronic cardiac denervation. Maling and Moran[6] demonstrated an increased incidence of arrhythmias in unanesthetized dogs with coronary occlusion during infusion of catecholamines, and Harris et al.[10] showed that stimulation of the cardiac sympathetic nerves in anesthetized dogs with coronary occlusion also increased ectopic ventricular activity. None of the previous studies measured fibrillation threshold and none controlled heart rate. The failure to control heart rate in previous studies makes interpretation of results difficult. Han et al.[11] reported that temporal dispersion of refractory periods was greater and fibrillation threshold lower with slow than with fast heart rates. More recently, how-

ever, Kent et al.[12] found that in the setting of acute coronary occlusion, fibrillation threshold is reduced by tachycardia.

Clinical implication: In our study, heart rate was maintained constant during all interventions and was therefore not a factor in the observed changes in vulnerability to fibrillation. Stimulation of the left stellate during acute coronary occlusion decreased fibrillation threshold more than either intervention alone, and stellectomy had a protective effect. The results of this study indicate that, in addition to the role the sympathetic nerves may have in the incidence of arrhythmias in the setting of coronary occlusion, increased levels of sympathetic tone may sometimes lead to lethal arrhythmias in patients with some forms of neurologic disease.

Effect of Manganese Chloride and Verapamil on Automaticity of Digitalized Purkinje Fibers

WARREN W. TSE, PhD
JAOK HAN, MD, PhD, FACC

Albany, New York

The effects of manganese chloride ($MnCl_2$) and verapamil on automaticity of digitalized Purkinje fibers were studied using conventional microelectrode techniques. The studies were made in isolated, spontaneously beating Purkinje preparations. Ouabain alone consistently increased the automatic rate, whereas no such increase was observed when the preparations were superfused with a mixture of ouabain and $MnCl_2$. $MnCl_2$ was also shown to be effective in suppressing the enhanced automaticity induced by ouabain. $MnCl_2$ alone did not have a significant effect on the spontaneous rate of Purkinje fibers. The effect of verapamil was similar to that of $MnCl_2$ in preventing and suppressing the ouabain-induced increase in automaticity. $MnCl_2$ and verapamil have been shown to inhibit the slow inward calcium current of cardiac fibers. The results therefore suggest that an inward calcium ion current may play a role in the development of digitalis-induced increase in the slope of phase 4 depolarization in Purkinje fibers.

Ventricular arrhythmias accompanying digitalis intoxication have usually been attributed to enhanced phase 4 depolarization of Purkinje fibers.[1,2] Recently, Ferrier and Moe[3] examined the effects of calcium ions and acetylstrophanthidin on canine Purkinje fibers and observed the development of transient depolarization after a series of driven responses. Such transient depolarization could occasionally reach threshold potentials and cause spontaneous responses. They suggested that the transient depolarization rather than "true" phase 4 depolarization is responsible for ventricular ectopic beats induced by digitalis. In their experiments the production of transient depolarizations could be prevented by the addition of manganese chloride to the perfusing Tyrode solution. Since $MnCl_2$ has been shown to block a slow inward calcium ion current associated with cardiac action potentials,[4–6] they concluded that the transient depolarization may be due to an influx of calcium ions.

Many ventricular ectopic beats resulting from digitalis intoxication are still believed to be due to an increase in the slope of "true" phase 4 depolarization of Purkinje fibers. This study was therefore undertaken to determine whether the ouabain-induced increase in the slope of phase 4 depolarization can also be prevented by manganese ions and verapamil. The enhanced automaticity could indeed be prevented by these agents, suggesting that an influx of calcium ion may also play a role in increasing the slope of phase 4 depolarization in digitalized Purkinje fibers.

Methods

Hearts were excised from dogs anesthetized with an intravenous injection of pentobarbital sodium, 30 mg/kg body weight. Papillary muscle with attached false tendon was dissected from the right or left ventricle and stored in oxygenated Tyrode solution. The preparation was then pinned under slight tension to a paraffin block in a tissue bath. Modified Tyrode solution

rom the Department of Medicine (Cardiology), lbany Medical College of Union University, and e Electrocardiography Laboratory, Albany edical Center Hospital, Albany, N. Y. This udy was supported by Contract NHLI-72-2974 m the National Institutes of Health, Bethesda, ., a grant from the Heart Association of East- New York, Albany, N. Y. and institutional nt GRS-FR-5394 from Albany Medical Col- e. Manuscript accepted November 20, 1974. Address for reprints: Jaok Han, MD, Department of Medicine, Albany Medical College, Albany, N. Y. 12208.

equilibrated in a reservoir with 95 percent oxygen and 5 percent carbon dioxide was infused into the bath at a rate of 5 ml/min. The temperature in the bath was maintained at 37° to 38° C and remained constant during any experiment. The composition of the Tyrode solution in millimoles was sodium chloride, 137; dextrose, 5.5; potassium chloride, 2.7; calcium chloride, 2.7; magnesium chloride, 0.5; sodium phosphate, 0.9; and sodium bicarbonate, 24.0. Transmembrane potentials of Purkinje fibers were recorded with conventional microelectrode techniques. Glass microelectrodes were filled with 2.7 molar potassium chloride, and the resistance of these electrodes ranged from 20 to 30 megohms. A silver wire indifferent electrode was in contact with the Tyrode solution in the bath. Action potentials were continuously monitored on an oscilloscope and photographed using a Grass camera. A series of Tektronix wave form and pulse generators were used to deliver pacing stimuli to a pair of bipolar electrodes attached to the preparation. Some of the preparations were driven by applying suprathreshold rectangular pulses at a cycle length of 630 msec.

Ouabain octahydrate was dissolved in 0.9 percent saline solution to make a stock solution in a concentration of 1 mg/ml. The working solution in a concentration of 2.0×10^{-7} M was prepared by diluting the stock solution with Tyrode solution. Manganese chloride ($MnCl_2$) and verapamil were dissolved in distilled water to make stock solutions of 4 and 1 mg/ml, respectively. The working solutions of $MnCl_2$ in a concentration of 4.0×10^{-4} M and verapamil in a concentration of 2.0×10^{-6} M were then prepared by diluting the stock solutions with the Tyrode solution. In this study, the effects of ouabain and $MnCl_2$ were analyzed from the results of those experiments in which the microelectrodes remained in the same cell throughout the experiment.

Results

Effect of Ouabain Alone

In these experiments only those preparations with a spontaneous rate of 15 to 75 beats/min were used. The effect of ouabain alone on the Purkinje fiber automaticity was first studied in seven preparations. Ouabain consistently increased the rate of spontaneous discharge in all seven preparations; the results of a typical experiment are depicted in Figure 1. Record A shows transmembrane potentials of a spontaneously beating Purkinje fiber at a rate of 18 beats/min. At the arrow labeled O, superfusion of the preparation with ouabain was begun. In records B to D, the rate increased steadily to 36, 72 and 140 beats/min at 15, 24 and 31 minutes, respectively, after the start of ouabain superfusion. The increase in automaticity was largely due to an increase in the slope of phase 4 depolarization. In four experiments the amplitude of the action potentials decreased with the increase in automaticity. In the remaining three experiments a biphasic change with an initial slight increase before the decrease in the action potential amplitude was observed. These variations were mainly due to corresponding changes in the maximal diastolic potential.

Effect of $MnCl_2$

Ouabain plus $MnCl_2$: The effect of $MnCl_2$ on the spontaneous rate of digitalized Purkinje fibers was studied with two different types of experimental design. In the first type of experiment, six preparations were superfused with Tyrode solution containing ouabain and $MnCl_2$ throughout the experiment. In all six preparations, a mild decrease in the spontaneous rate occurred in the presence of $MnCl_2$. The important observation was that no increase in the spontaneous rate was observed in these preparations in contrast to findings in preparations treated with ouabain alone. Figure 2 illustrates the results of one of these experiments. Record A shows transmembrane potentials of a spontaneously beating Purkinje fiber at a rate of 36 beats/min. At the arrow labeled O + MN, superfusion of the preparation with ouabain and $MnCl_2$ was begun. In record B, 15 minutes after the beginning of superfusion with the mixture, the spontaneous rate of the preparation decreased to 26 beats/min. In record C, 24 minutes after the start of superfusion, the spontaneous rate further slowed to 20 beats/min.

Ouabain followed by ouabain-$MnCl_2$ mixture: In the second type of experiment, four preparations were first superfused with ouabain until the sponta-

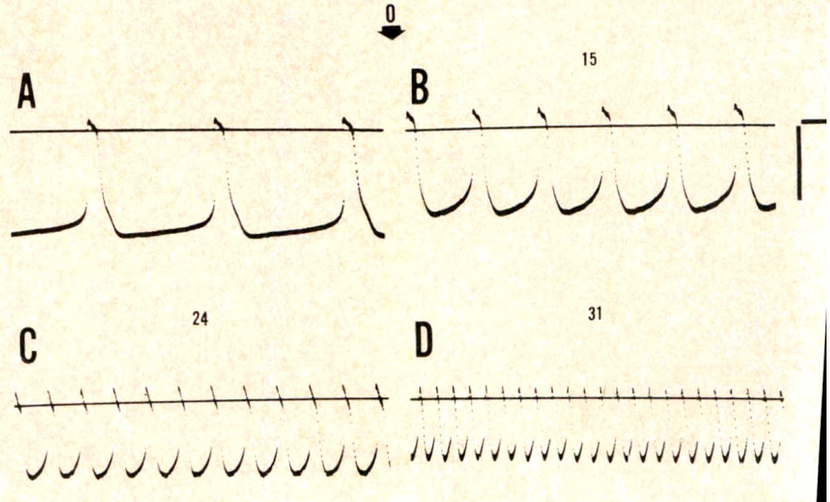

FIGURE 1. Effect of ouabain on the rate of a spontaneously beating Purkinje fiber. O = ouabain. The number at the top of each panel indicates the time in minutes after the beginning of superfusion of ouabain. Calibration: horizontal line = 1 second; vertical line = 50 mv. See text.

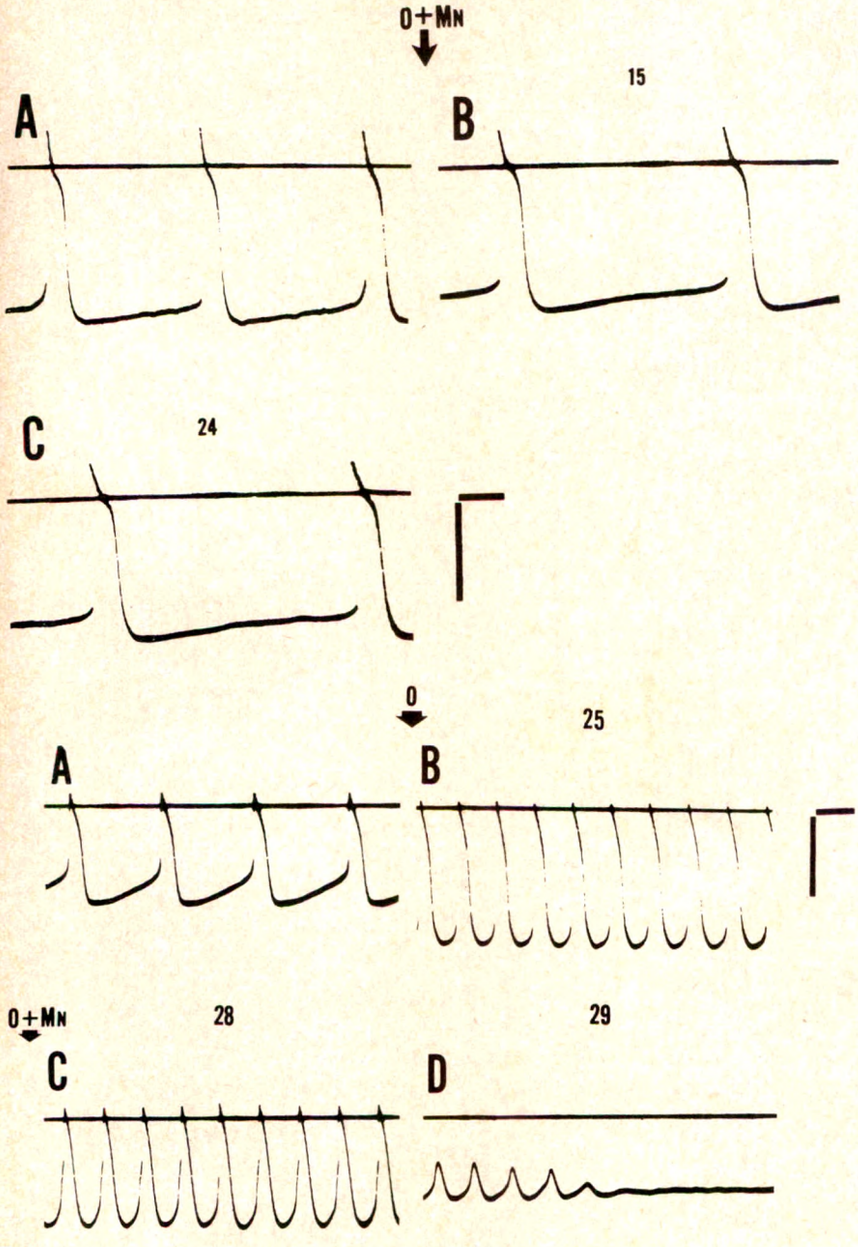

FIGURE 2. Effect of a mixture of ouabain and $MnCl_2$ on the spontaneous rate of a Purkinje fiber. O + MN = ouabain + $MnCl_2$. Other conventions as in Figure 1. Calibration: horizontal line = 500 msec; vertical line = 50 mv. See text.

FIGURE 3. Inhibitory effect of $MnCl_2$ on the ouabain-induced increase in automaticity of a Purkinje fiber. Conventions as in Figures 1 and 2. Calibration: horizontal line = 500 msec; vertical line = 50 mv. See text.

neous rate of the preparation was greatly increased, and the mixture of ouabain and $MnCl_2$ was then superfused to the preparation. Manganese chloride was able to reverse the increased automaticity induced by ouabain in all four experiments, and the results of one of these experiments are depicted in Figure 3. Record A shows transmembrane potentials of a spontaneously beating Purkinje fiber at a rate of 48 beats/min. At the arrow labeled O, ouabain was superfused to the preparation. In record B, 25 minutes after the beginning of ouabain superfusion, the spontaneous rate increased to 120 beats/min. At the arrow labeled O + MN, the mixture of ouabain and $MnCl_2$ was superfused to the preparation. In record C, 28 minutes after the beginning of ouabain superfusion and about 3 minutes after the start of superfusion with the mixture of ouabain and $MnCl_2$, a further increase in the spontaneous rate was interrupted and the rate actually began to decrease slightly. In record D, 1 minute later, the amplitude of the action potentials abruptly decreased, followed by cessation of the spontaneous activity.

$MnCl_2$ alone: In six experiments $MnCl_2$ alone was superfused to the preparations. The results of five experiments showed a mild decrease in the spontaneous rate 5 to 10 minutes after the beginning of the superfusion. Figure 4 illustrates the results of one of these experiments. Record A shows the transmembrane potentials of a spontaneously beating Purkinje fiber at a rate of 18 beats/min. At the arrow labeled MN, $MnCl_2$ was superfused to the preparation. As shown in records B and C, the spontaneous rate of

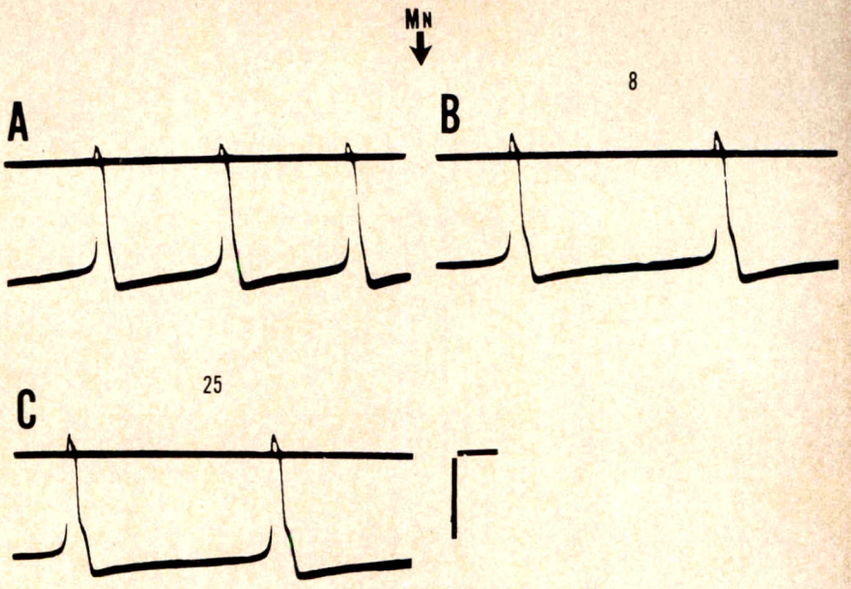

FIGURE 4. Effect of $MnCl_2$ alone on a spontaneously beating Purkinje fiber. MN = $MnCl_2$; other conventions as in Figure 1. Calibration: horizontal line = 1 second; vertical line = 50 mv. See text.

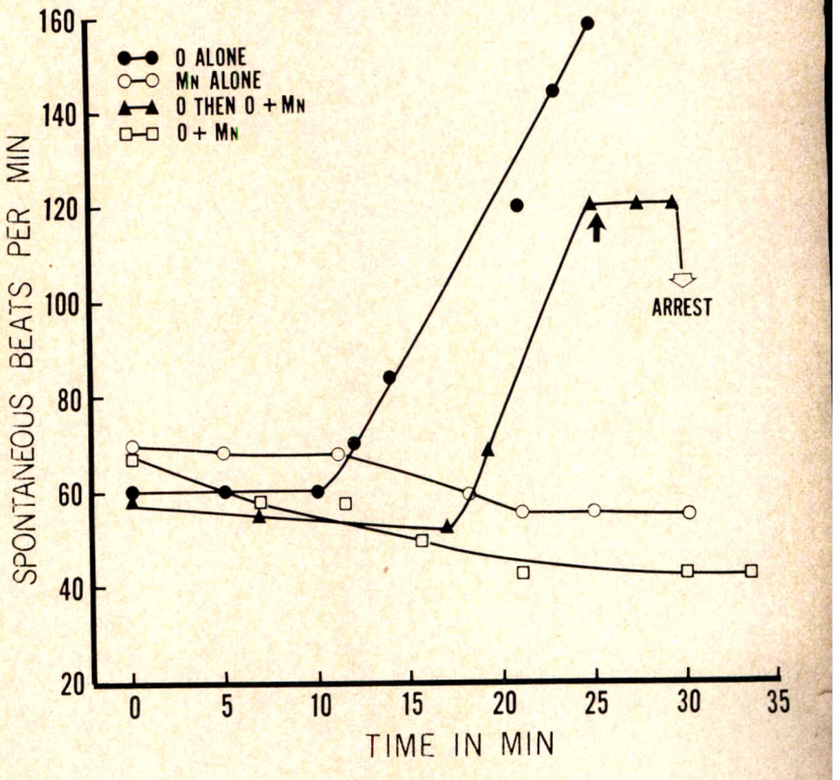

FIGURE 5. Comparison of various effects of $MnCl_2$ (MN) on the rate of spontaneously beating Purkinje fibers under different conditions. O = ouabain. See text.

the preparation then decreased slightly to 12 beats/min at 8 minutes and remained about the same for the remaining 25 minutes of the experiment. In the sixth experiment, a very slight increase in rate was observed during superfusion with $MnCl_2$ alone.

Figure 5 summarizes the effect of $MnCl_2$ on the spontaneous rates of Purkinje fibers under various conditions, presenting the results of a representative experiment of each of the four types. The Purkinje fiber preparation superfused with ouabain alone was characterized by a rapid and steady increase in the spontaneous rate beginning about 10 minutes after start of the ouabain superfusion. In the preparation superfused with both ouabain and $MnCl_2$, a mild decrease in the spontaneous rate was observed. In the experiment in which the spontaneous rate was first increased by ouabain, the addition of $MnCl_2$ (indicated by a solid arrow) prevented further increases in the rate, followed by arrest or cessation of spontaneous activity. The spontaneous rate of Purkinje tissue exposed to $MnCl_2$ alone showed no obvious change for the first 10 minutes and then decreased slightly.

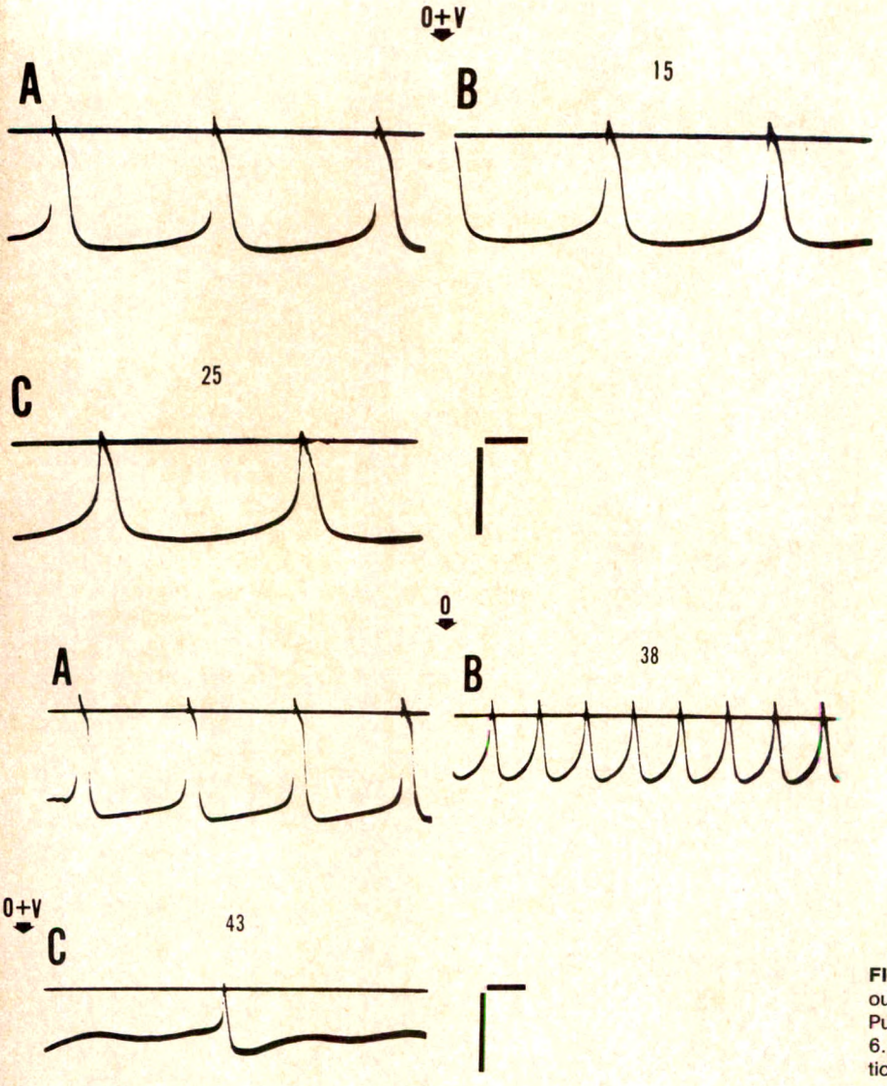

FIGURE 6. Effect of a mixture of ouabain and verapamil on the spontaneous rate of a Purkinje fiber. O + V = ouabain + verapamil. Other conventions as in Figure 1. Calibration: horizontal line = 500 msec; vertical line = 50 mv. See text.

FIGURE 7. Inhibitory effect of verapamil on the ouabain-induced increase in automaticity of a Purkinje fiber. Conventions as in Figures 1 and 6. Calibrations: horizontal line = 1 second; vertical line = 50 mv. See text.

Comparison of these results clearly indicates that $MnCl_2$ is effective in preventing the increase in automaticity of Purkinje fibers induced by ouabain.

Effect of Verapamil

The observed effect of $MnCl_2$ suggested that the increase in phase 4 depolarization induced by ouabain is related to an increase in calcium conductance. Since verapamil is also known to block a slow calcium current, some experiments were performed to test whether the effect of ouabain can be similarly prevented by verapamil.

The effect of verapamil on automaticity of digitalized Purkinje fibers was studied in six experiments in a manner similar to that of $MnCl_2$. All of these experiments demonstrated that verapamil, like $MnCl_2$, could prevent the enhanced automaticity induced by ouabain. Figure 6 shows the results of one of these experiments. Record A shows the control spontaneous rate of the preparation at about 36 beats/min. At the arrow labeled O + V, the preparation was superfused with a mixture of verapamil in a concentration of 2.0×10^{-6} M and ouabain in a concentration of 2.0×10^{-7} M. In the course of 25 minutes of superfusion, a slight decrease in the spontaneous rate (to about 24 beats/min) and the amplitude of the action potential was observed. In three other experiments, verapamil was also able to reverse a ouabain-induced increase in automaticity. Figure 7 shows the results of a representative experiment. Record A shows the control spontaneous rate of the preparation at about 24 beats/min. The preparation was first superfused with ouabain in a concentration of 2.0×10^{-7} M, and record B shows that the spontaneous rate increased to about 48 beats/min 38 minutes after the beginning of this superfusion. The preparation was then superfused with the mixture of ouabain and verapamil. In record C, about 5 minutes after this superfusion, the spontaneous rate decreased to about 10 beats/min.

Discussion

In this study, the effect of $MnCl_2$ on automaticity of digitalized Purkinje fibers was studied in spontaneously beating preparations. Ouabain alone consis-

tently enhanced the spontaneous rate to four or more times its control value. This increase was primarily due to an increase in the slope of phase 4 depolarization. These results are in accord with those obtained from earlier experiments by others[7,8] in intact dog hearts. When $MnCl_2$ was applied with ouabain to the preparation, the spontaneous rate was not generally altered except for a few preparations in which a slight decrease in the rate was observed. Manganese chloride was also effective in suppressing the increased spontaneous activity induced by ouabain. Verapamil was similarly effective in preventing and reversing the ouabain-induced increase in automaticity of the Purkinje tissue.

Manganese, verapamil and calcium currents: Ample evidence is available to support the view that manganese ions and verapamil inhibit the inward calcium current of cardiac cells.[4–6,9] Various studies with the voltage clamp technique[10–12] demonstrated that the slow inward current occurring during the plateau of cardiac action potentials is related to an influx of calcium ion. Manganese chloride and verapamil were shown to prevent such an inward current in cardiac fibers.[4–6,9] Our observations that $MnCl_2$ and verapamil prevent or reverse the ouabain-induced increase in automaticity suggest that the effect of ouabain on phase 4 depolarization is, in part, related to an influx of calcium ion. Manganese chloride alone had no appreciable effect on the automaticity of nondigitalized Purkinje fibers. This suggests that calcium conductance plays an insignificant role during phase 4 of normal Purkinje fibers. This is in keeping with the well accepted view that phase 4 depolarization of normal Purkinje fibers is primarily due to a progressive decrease in potassium conductance and a gradual increase in sodium conductance during diastole.[13,14]

Clinical implication: The slow calcium inward current that is present during the plateau of cardiac action potentials is speculated to be linked to the excitation-contraction coupling of cardiac fibers.[12,15] Therefore, an increase in calcium ion influx induced by digitalis in ventricular myocardial fibers could possibly manifest itself as positive inotropism, whereas in Purkinje fibers it could result in an increase in the slope of phase 4 depolarization and enhanced automaticity. The ability of $MnCl_2$ and verapamil to prevent the development of enhanced automaticity in digitalized Purkinje fibers may imply that they could be used as antiarrhythmic agents for digitalis-induced arrhythmias. However, their use in patients with digitalis toxicity may not be practical because they may inhibit the inward calcium current in myocardial fibers and decrease contractility of the ventricular myocardium.

Los Angeles, California

A new balloon-tipped flotation catheter equipped with two pairs of electrodes has been developed for simultaneous monitoring of cardiac rhythm and hemodynamics as well as for temporary emergency atrial, ventricular and atrioventricular sequential pacing. Experience in 43 patients demonstrates the following: (1) The catheter can be passed and positioned with the tip in the pulmonary artery or its branches at the bedside without the use of fluoroscopy as easily as the standard (Swan-Ganz) catheters. (2) With the catheter in the proper position and with the use of appropriate filters (proximal, 50 to 300 hertz; distal, 15 to 300 hertz), the intracavitary electrograms recorded from the proximal and distal pair of electrodes provide characteristic high right atrial and right ventricular signals, virtually free of noise artifact, baseline drift and respiratory variation, that are particularly suitable for automated on-line monitoring of cardiac rhythm. (3) When indicated, atrial, ventricular or atrioventricular sequential pacing can be initiated without delay. (4) Large artifact-free right ventricular intracavitary signals can be used for reliable and consistent operation of any device requiring QRS triggering mechanisms. (5) Monitoring of pulmonary arterial or pulmonary capillary wedge pressure and withdrawal of blood samples from the central circulation is possible. This device can be particularly useful in patients with hemodynamic difficulties as well as arrhythmias.

Prompt recognition and early treatment of serious arrhythmias have significantly reduced the in-hospital mortality of patients with acute myocardial infarction[1,2] and improved the postoperative management of patients. The surface electrocardiograms commonly used for rhythm monitoring have the disadvantages of signal distortion by patient movement and base-line drift, which make their use difficult for automated monitoring of arrhythmias. Furthermore, differentiation of complex arrhythmias with the use of surface electrograms may be difficult because of uncertainty in identification of the P wave. Direct recording of intraatrial and intraventricular electrograms, which provide large atrial (P wave) and ventricular (QRS) signals, respectively, facilitates the diagnosis of complex arrhythmias.[3–5]

In severely ill patients with heart disease and in patients after major surgery, arrhythmias commonly accompany circulatory problems. Hemodynamic monitoring in such patients with the use of flow-directed balloon catheters is now widely practiced.[6,7] This study reports the development of and initial clinical experience with a balloon flotation catheter used to monitor both cardiac arrhythmias and hemodynamic status.[8] This catheter can also be used for immediate temporary cardiac pacing in case of emergency.

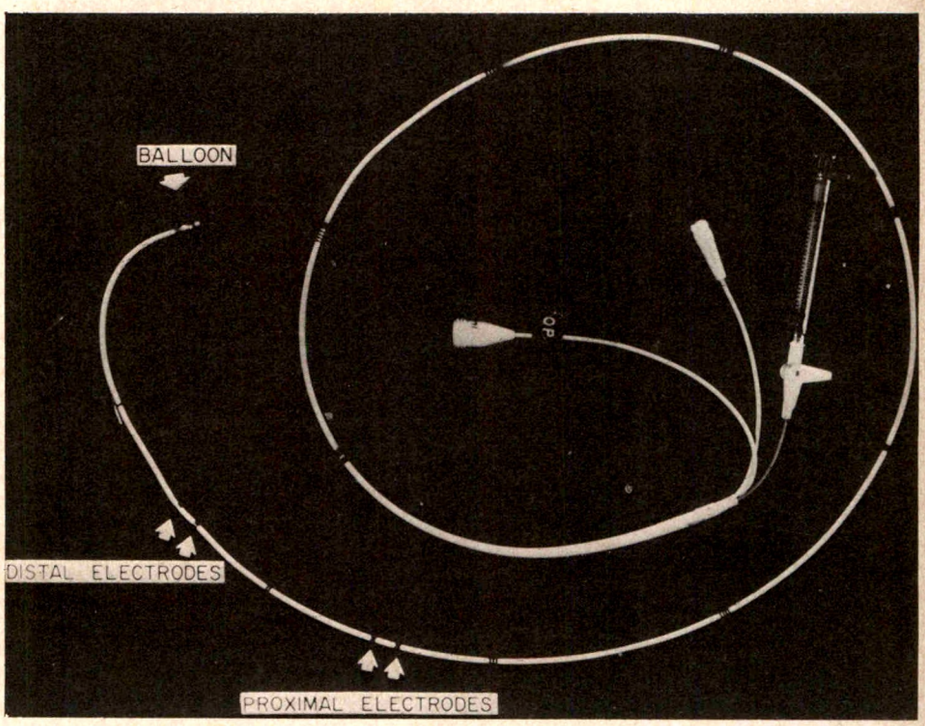

FIGURE 1. Balloon flotation electrode catheter for cardiac monitoring and emergency pacing. The distance from the tip is marked in 10 cm intervals. The position of the proximal (25 and 26 cm) and distal (17 and 18 cm) electrode pairs is indicated by **arrows.** The proximal end of the catheter consists of the lumen for inflation of the balloon, distal lumen and the special adapter for the electrode cables.

Method

Catheter Construction

The basic device (Fig. 1) is essentially similar to the standard flow-directed (Swan-Ganz) catheter[6] but, in addition, incorporates two pairs of electrodes. It is size 7F and extruded from polyvinylchloride with three parallel lumens. One lumen serves to inflate the flow guidance balloon with 1.5 to 2 ml of air. The bursting volume of the balloon is 3 ml. The second lumen opens at the tip and is used for recording of intravascular pressure and withdrawal of blood samples from the central circulation. The third lumen carries the leads from the electrodes, which are properly insulated to prevent current leakage and connected to an adapter proximally. For the average patient the electrodes are located on the shaft of the catheter, 17 and 18 cm and 28 and 29 cm from the tip for the ventricular and atrial electrodes, respectively. When the catheter tip is in the pulmonary artery or its main branches, the proximal (with reference to the catheter tip) electrodes lie in the upper part of the right atrium and the distal electrodes in the right ventricle. The electrical signals are amplified and displayed on an oscilloscope and examples recorded on the Brush recorder.

The catheter shaft is stiffened up to the ventricular electrodes so that an acute angle forms at the site of the distal electrodes between the stiffer proximal and more flexible distal portion. This arrangement carries the electrodes toward the right ventricular endocardium and permits consistent right ventricular endocardial pacing (Fig. 2).

Catheter Insertion

The catheter is inserted at the bedside, usually into a median basilic or deep brachial vein by a cutdown procedure. When the catheter is inserted without fluoroscopic control, intracardiac pressure at the catheter tip and the bipolar electrogram from the proximal pair of electrodes are monitored. The balloon is inflated when the catheter has been advanced 40 cm from the right arm or 50 cm from the left arm. We prefer insertion from the left arm, because passage of the catheter from the right arm is occasionally difficult because of the usual acute angle at the junction of the superior vena cava and the right subclavian vein. When the tip reaches the pulmonary artery, the proximal electrodes record characteristic intraatrial signals and the distal electrodes ventricular signals.

The ideal catheter position is such that the proximal electrodes record a high right atrial electrogram, that is, a large atrial complex (P wave) and a proportionately small ventricular complex (QRS). In this position a characteristic intraventricular electrogram, that is, large QRS complex and very small P wave, is recorded from the distal electrodes and pulmonary arterial pressure is recorded from the tip with the balloon deflated (Fig. 3). When portable fluoroscopic equipment is available in the cardiac care unit, such proper placement of the catheter can be facilitated.

Initial Clinical Trials

The new catheter has been evaluated in 43 patients with a wide variety of cardiac diagnoses, with and without cardiac arrhythmias. Preliminary observations on its value and examples of its application follow.

Ease of insertion: When the catheter was passed at the bedside without fluoroscopy, the passage time to the pulmonary artery was similar to that of the standard (Swan-Ganz) flotation catheters; serious ventricular arrhythmias during passage were uncommon. However, 2 to 11 premature ventricular contractions were observed during the passage of the catheter in 10 of 43 patients.

Stability of intracardiac electrograms: When the catheter was properly positioned, that is, with the

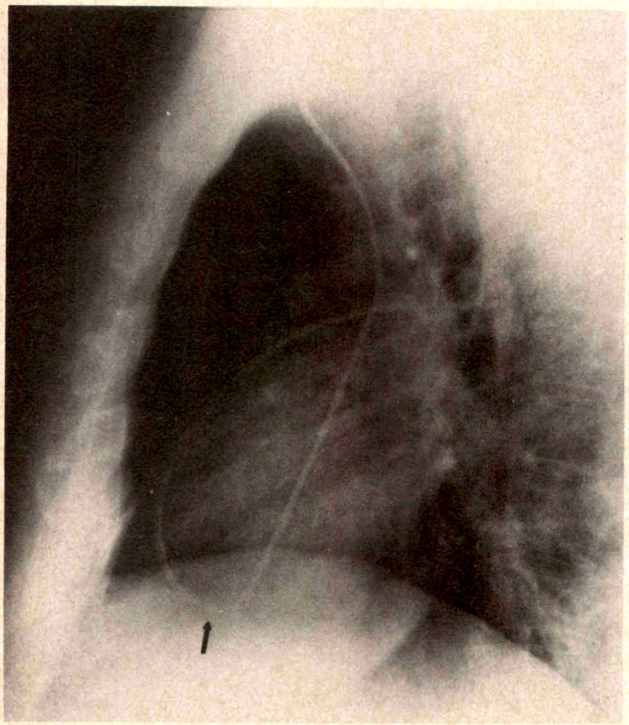

FIGURE 2. Lateral chest X-ray film of a patient with the balloon flotation electrode catheter in position. When the catheter tip is in the pulmonary artery, an acute angle forms in the right ventricular cavity **(arrow).** The distal electrodes are situated at the peak of the angle and thus lie closer to the ventricular endocardium.

proximal electrodes in the high right atrium and distal electrodes in the right ventricle, signals recorded with appropriate filters (atrial, 50 to 300 hertz; ventricular, 15 to 300 hertz) were very stable. There was virtually no base-line drift and respiratory variation was slight. During movement of the patient, when the surface electrogram was distorted by artifacts, both intraatrial and intraventricular electrograms remained free of artifacts (Fig. 4).

Diagnosis of arrhythmias: Simultaneous recording of intraatrial and intraventricular signals facilitates the diagnosis of arrhythmias (Fig. 5). Differentiation between supraventricular tachycardia with aberrant conduction and atrioventricular (A-V) dissociation was not possible from analysis of the surface electrograms. The presence of independent atrial and ventricular signals in the intracavitary electrograms helped in the diagnosis of A-V dissociation.

Emergency pacing: In addition to monitoring intracardiac pressures and cardiac rhythm, this catheter allowed prompt initiation of atrial, ventricular or A-V sequential pacing.

Atrial pacing: With the catheter in the appropriate position, atrial pacing was achieved in the majority of patients (Fig. 6). In 39 of 43 patients, the atrial pacing threshold was less than 6 milliamperes. Temporary atrial pacing for more than 24 hours was performed in two patients. Phrenic nerve stimulation resulting in diaphragmatic contractions occasionally occurred; readjustment of the electrode position and use of minimal current usually resolved this problem. Atrial pacing was inconsistent in the remaining four patients, all of whom had a markedly dilated right atrium. For consistent atrial pacing, proper positioning of the catheter as outlined earlier is essential. Use of fluoroscopy facilitates proper positioning of the proximal electrodes at the right atrial-superior vena caval junction. In patients with cardiomegaly, when the tip of the catheter was in the distant pulmonary arterial branches, the atrial electrodes tended to move into the right atrial cavity and atrial pacing could not be performed. In such circumstances, the catheter needed to be withdrawn to position the atrial electrodes at the atrial-superior vena caval junction to achieve atrial pacing.

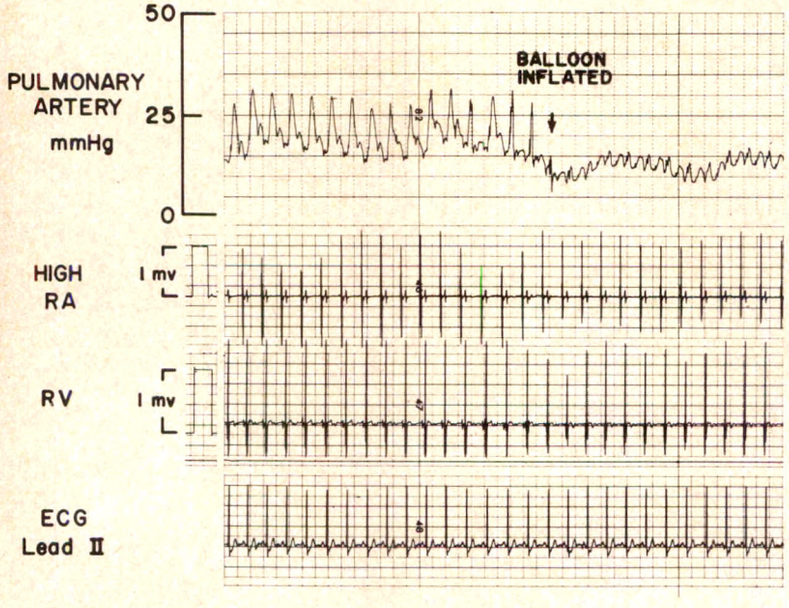

FIGURE 3. Simultaneous recordings of intraatrial and intraventricular electrograms as well as intracardiac pressure with the use of balloon flotation electrode catheter. With the proximal electrodes positioned in the high right atrium, intraatrial electrograms **(upper panel)** demonstrate very large P waves and small QRS complexes. Intraventricular electrograms recorded from the distal electrodes **(middle panel)** show large QRS complexes and very small P waves. Pulmonary arterial pressure (balloon deflated) and pulmonary capillary wedge pressure (balloon inflated) are also recorded **(upper panel).** Lack of base-line drift and noise artifact, despite small catheter movement during inflation of the balloon, is evident in the intracavitary electrograms. ECG = electrocardiogram; RA = right atrium; RV = right ventricle.

· *Ventricular pacing:* Bipolar ventricular pacing with the latest model of the electrode catheters (with greater shaft stiffness than previous models) was reliable and consistent. Thus, satisfactory and uniform ventricular pacing with a threshold of 0.5 to 5 milliamperes could be achieved in 16 of the 17 patients in whom the latest model of the electrode catheter was tested (Fig. 7).

Sequential atrioventricular pacing: In the presence of complete A-V block, A-V pacing could be per-

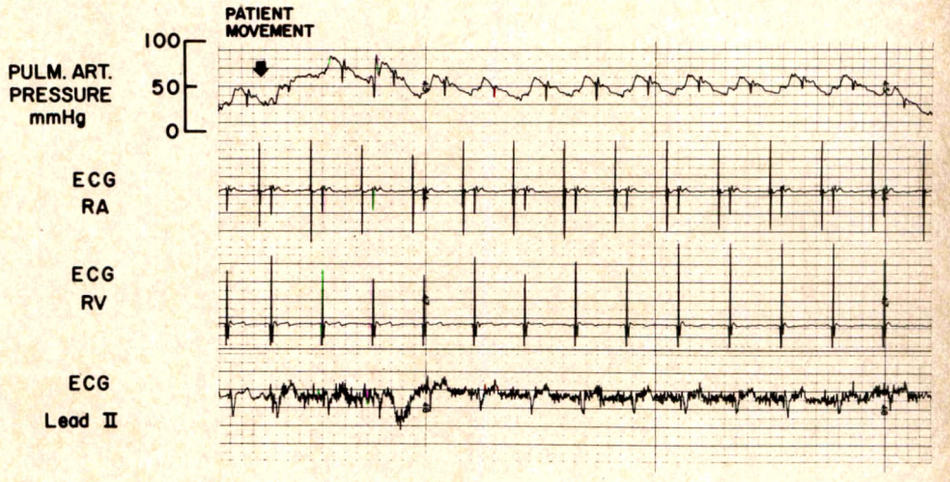

FIGURE 4. Lack of noise artifacts in intracavitary electrograms during movement of the patient. Although recorded surface electrograms are distorted by noise artifact, simultaneously recorded intracavitary electrograms are virtually noise-free. PULM. ART. = pulmonary arterial.

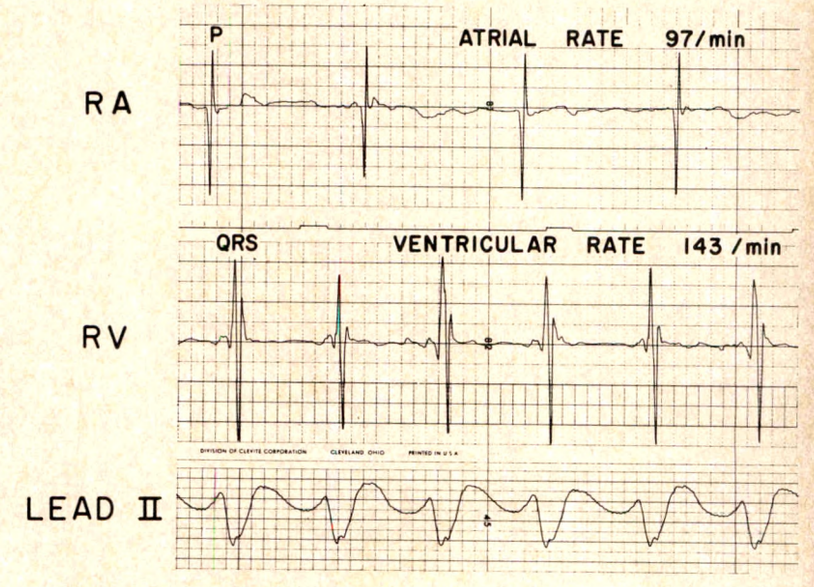

FIGURE 5. Diagnosis of complex arrhythmias from analysis of simultaneously recorded intraatrial and intraventricular signals with the use of balloon flotation electrode catheters. In this instance, differentiation between supraventricular tachycardia with aberrant conduction and ventricular tachycardia with A-V dissociation was not apparent from the surface electrocardiogram. However, the presence of independent atrial and ventricular signals in the intracavitary electrograms establishes the diagnosis of A-V dissociation.

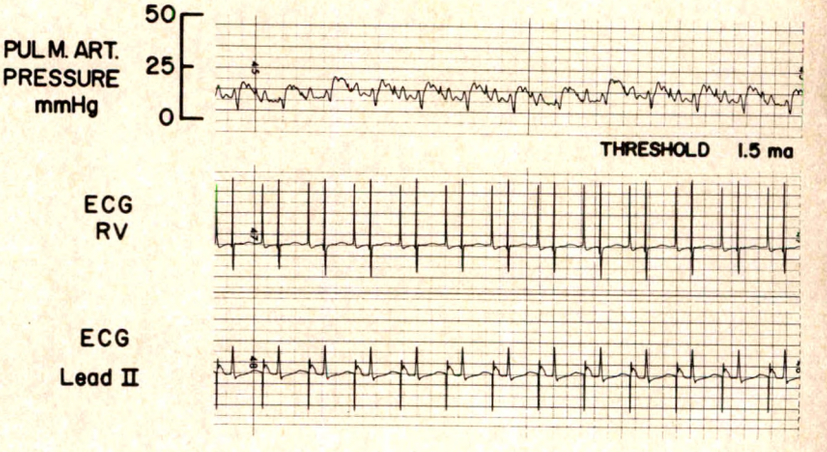

FIGURE 6. Atrial pacing with use of balloon flotation electrode catheters. Consistent atrial pacing could be achieved with a threshold of less than 2 milliamperes.

formed sequentially by using the proximal and distal electrodes for atrial and ventricular stimulation, respectively (Fig. 8). In four patients studied to date, the current needed for sequential pacing did not exceed 6 milliamperes.

Reliable QRS signals for counterpulsation: The distal electrodes can provide very large QRS complexes, virtually free of noise, that can be used for reliable operation of any device requiring a QRS-triggering mechanism. An example is shown in Figure 9. Consistent counterpulsation was achieved when the intraventricular QRS complex was used to trigger the external counterpulsation apparatus, in contrast to frequent misses observed when the surface electrogram was used for triggering.

Hemodynamic monitoring: Like other flow-directed balloon-tipped catheters, this catheter can be used for monitoring intracardiac pressures—pulmonary arterial pressure with the balloon deflated and pulmonary capillary wedge pressure with the balloon inflated. The lumen opening at the tip also permits the withdrawal of blood samples from the central circulation.

Discussion

Intracavitary electrograms from the right atrium and right ventricle have been obtained with ease by

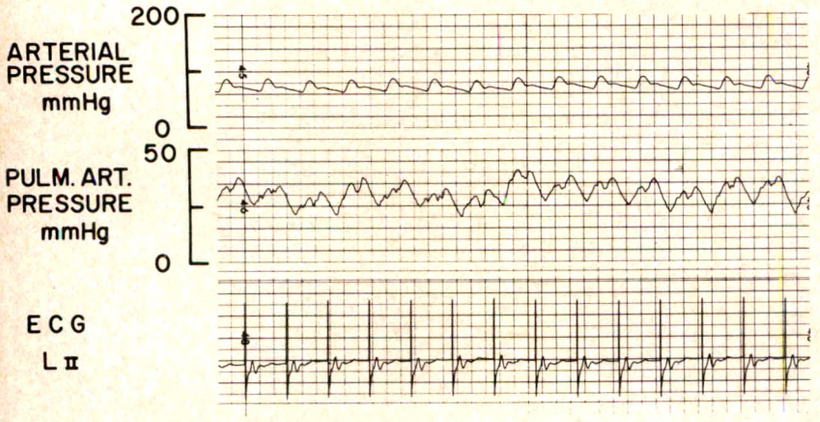

FIGURE 7. Ventricular pacing with use of balloon flotation electrode catheters. Consistent ventricular pacing could be performed with a threshold of 2 milliamperes.

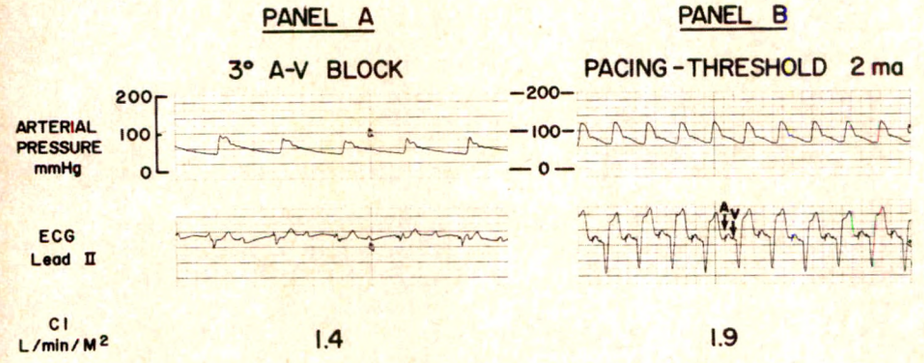

FIGURE 8. Sequential A-V pacing with use of balloon flotation electrode catheters in a patient with acute myocardial infarction complicated by third degree A-V block. Sequential pacing could be achieved with a threshold of 6 milliamperes. Hemodynamics were significantly better during sequential pacing **(Panel B)** than in the presence of complete A-V block **(Panel A).** CI = cardiac index.

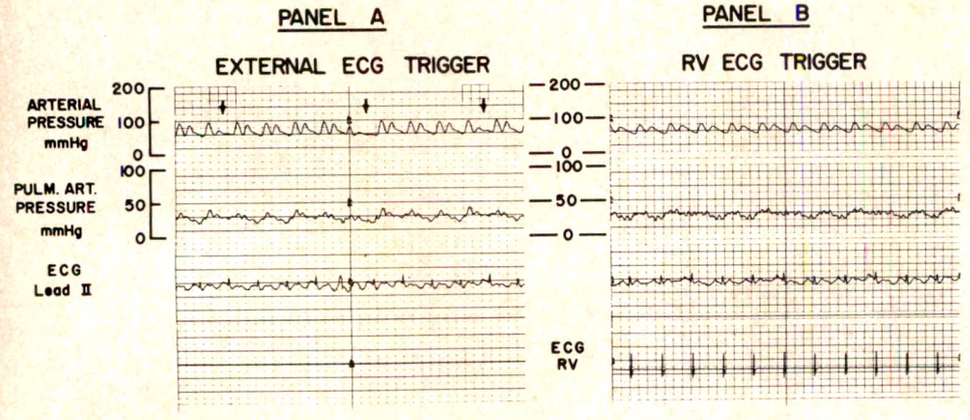

FIGURE 9. Consistent triggering of the external counterpulsation apparatus with the use of large QRS complexes in the right intraventricular (RV) electrogram **(Panel B)** in contrast to frequent misses observed **(arrows)** when the surface electrogram was used for triggering **(Panel A).**

the incorporation of suitable electrodes on the flow-directed (Swan-Ganz) catheter. They offer potential diagnostic advances and provide stabilized signals suitable for computerized monitoring of cardiac rate and rhythm. In our brief clinical experience, no greater difficulty was encountered in insertion than with other Swan-Ganz catheters, and no significant complications were encountered.

Bedside applications: When the catheter was properly positioned, ventricular pacing could be achieved reliably and consistently. In addition, atrial or atrioventricular pacing was usually possible. Several options relative to extended application of bedside catheterization present themselves. First, the technique permits cardiac monitoring without surface leads in cardiac or postoperative patients who require hemodynamic monitoring of ventricular function for which a Swan-Ganz catheter would be inserted. In such patients, reliance on a rate meter to indicate serious arrhythmias would appear feasible.

Because of the increasing number of patients being simultaneously monitored in critical care areas, use of automated on-line computer monitoring of cardiac rhythm is becoming more and more necessary. Bipolar intraatrial and intraventricular electrograms recorded from the proximal and distal pairs of electrodes with appropriate filters provide large atrial (P wave) and ventricular (QRS) signals. In addition, there is no base-line drift and very little respiratory variation, and both atrial and ventricular signals are virtually artifact-free. These characteristics of intracavitary electrograms are particularly suitable for on-line computer monitoring of cardiac rhythm. Admittedly, excessive arm movement may cause displacement of the electrodes and thereby variation in the amplitude of the intracavitary signals. Moderate restraint in the arm movement or subclavian approach of catheter insertion will prevent gross catheter movements.

In patients with complex cardiac arrhythmias, atrial electrograms are not commonly obtained. Use of the present electrode catheter is rapid and safe. The additional availability of simultaneous right ventricular electrograms should considerably strengthen the diagnostic possibilities of such studies. Furthermore, the long-term stability (6 to 24 hours) of such electrodes may allow for therapeutic evaluation of antiarrhythmic agents to be carried out in selected instances, with rational selection of therapy based on more objective data than has been the case. Such data may be recorded and analyzed by portable tape equipment (Avionics).

Both intraatrial and intraventricular electrograms recorded with the use of this catheter are bipolar electrograms; therefore, proper orientation of P and QRS vectors cannot be identified. However, the capability of simultaneously recording clear atrial and ventricular signals may substantially aid in the diagnosis of potentially malignant arrhythmias and conduction disturbances such as ventricular and supraventricular premature beats, tachycardia, atrioventricular dissociation and atrioventricular block.

Prophylactic placement of pacemaker catheters is sometimes indicated in patients with atrioventricular or intraventricular conduction abnormalities. This flotation catheter provides standby pacing ability in addition to hemodynamic monitoring and the benefit of sequential ventricular pacing after spontaneous or induced atrial activation.

Finally, the availability of atrial pacing may permit optimization of the heart rate in a routine manner to achieve the most favorable hemodynamic response. For this purpose, atrial and ventricular electrodes will also be incorporated in certain models of the thermodilution catheter.

Problems: Among the major problems associated with application of balloon-tipped electrode catheters is the need for several catheters with differences in distance between the electrodes and the catheter tip and between electrodes to accommodate heart chambers and great vessels of various sizes. Also, isolated amplifiers of high reliability suitable for these applications are costly at present. Nevertheless, our preliminary experience indicates that important interpretive and practical benefits can be achieved by application of this device.

Retrograde Catheterization of the Left Atrium in Idiopathic Hypertrophic Subaortic Stenosis

BERT WONG, MD*
RENE A. LANGOU, MD
LAWRENCE S. COHEN, MD, FACC
STEVEN WOLFSON, MD, FACC

New Haven, Connecticut

Retrograde catheterization of the left atrium utilizing the Shirey technique was successfully performed in four patients with idiopathic hypertrophic subaortic stenosis. By traversing the inflow tract of the left ventricle on pullback from the left atrium to the aorta, this method served to separate definitively true hypertrophic subaortic stenosis from cavity obliteration. It was accomplished with relative ease and no complications. In patients with suspected idiopathic hypertrophic subaortic stenosis who are to have retrograde left heart catheterization, this approach to the left atrium is recommended as an alternative to the transseptal technique.

In recent years many noninvasive methods have been developed that greatly assist in the recognition and diagnosis of idiopathic hypertrophic subaortic stenosis. At cardiac catheterization the definitive diagnosis of this condition depends on the hemodynamic demonstration of a dynamic subvalvular obstruction to left ventricular outflow and the angiographic demonstration of narrowing of the left ventricular outflow tract during systole by abnormal anterior motion of the anterior mitral valve leaflet and asymmetric septal hypertrophy.[1,2] Accurate assessment of the subvalvular obstruction is essential for diagnosis and for meaningful evaluation of subsequent therapy. However, intraventricular pressure differences simulating obstruction have been shown to occur with cavity obliteration, producing entrapment and compression of the catheter by cardiac muscle.[3,4]

It is possible to distinguish an intraventricular pressure gradient representing true outflow obstruction from one indicating catheter entrapment by demonstrating that the catheter lies in the inflow tract of the left ventricle at the time that a gradient is recorded. This area, just below the mitral valve, never completely empties in systole and is proximal to the obstructing muscular septum.[2,5] Catheter placement at this site has been accomplished by utilizing the transseptal technique to place a catheter in the left ventricle by way of the left atrium. Simultaneous left ventricular and brachial arterial recordings are obtained to measure the outflow tract gradient as the catheter is drawn back through the left ventricular inflow tract and across the mitral valve. An alternative method of entering the left atrium—retrograde catheterization of the left atrium from the left ventricle, as described by Shirey and Sones[6]—has received little attention. To our knowledge this retrograde method has not been specifically applied for the purpose of validating the intraventricular gradient in patients with suspected idiopathic hypertrophic subaortic stenosis.

We have studied four consecutive patients with hypertrophic subaortic stenosis by retrograde catheterization of the left atrium. Left ventricular outflow tract obstruction was evaluated in each case by recording pressures while withdrawing the catheter from the left atrium to the aorta. Subvalvular left ventricular outflow tract obstruction was documented in each case.

TABLE I

Clinical Data

Case no.	Age (yr) & Sex	Symptoms	Murmur with Valsalva Maneuver	LVET with AN (% Predicted)	ECG	Chest X-ray Film
1	39M	Chest pain, dyspnea	Increased	...	Left axis deviation	Normal
2	34M	Chest pain	No change	Increased (148%)	WPW type A	LVH
3	32M	None	Increased	Increased (128%)	Q waves in leads II, III, aVF	Normal
4	19M	Chest pain	Increased	Increased (125%)	Axis = −120°	LVH

AN = amyl nitrite inhalation; ECG = electrocardiogram; LVET = left ventricular ejection time; LVH = left ventricular hypertrophy; WPW = Wolff-Parkinson-White syndrome.

TABLE II

Cardiac Catheterization Data

Case no.	State	Pressures (mm Hg)					Left Ventricular Angiogram
		LA Mean	LV Inflow	LV Outflow	Ao	CO	
1	Rest	8	145/6	120/6	120/70	5.9	ASH, SAM
2	Rest	10	220/20	120/20	120/85	4.0	ASH, SAM
3	Amyl nitrite	5	190/15	110/15	110/80	4.6	ASH, SAM
4	Amyl nitrite	20	150/20	70/20	70/45	5.0	ASH, SAM

Ao = aortic pressure (systolic/diastolic); ASH = asymmetric septal hypertrophy; CO = systemic cardiac output (liters/min); LA = left atrial; LV = left ventricular (systolic peak/end-diastolic); SAM = systolic anterior motion of the anterior leaflet of the mitral valve.

Material and Methods

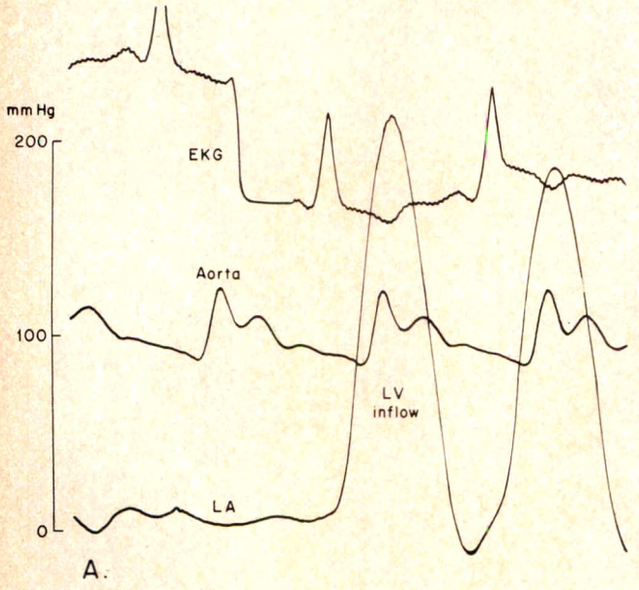
Four consecutive patients with idiopathic hypertrophic subaortic stenosis underwent diagnostic cardiac catheterization. The clinical, hemodynamic and angiographic features of these patients are presented in Tables I and II. All patients had documented physical, hemodynamic and angiographic findings of idiopathic hypertrophic subaortic stenosis.

Phonocardiograms and systolic time interval measurements were made according to the methods of Weissler et al.,[7] using a four channel direct-writing ink jet recorder (Elema Schonander, Mingograf 34). A high impedance microphone (EMT25C) was used for heart sounds and an EMT510C pressure transducer was utilized for recording the carotid arterial tracing. All recordings were obtained simultaneously with electrocardiographic lead II at a paper speed of 100 mm/sec.

Cardiac catheterization was performed with the patient in the postabsorptive state after sedation with intramuscularly administered diazepam or meperidine, or both. Under local anesthesia, the brachial artery and vein were isolated in the right antecubital fossa. With use of the Seldinger technique, a no. 6 Cook multipurpose catheter was introduced into the left brachial artery and advanced into the aorta for pressure monitoring. Left heart catheterization was performed through a brachial arteriotomy with a no. 8 Shirey catheter. Under fluoroscopic observation, the left atrium was entered retrograde with the Shirey catheter with use of the following technique: With continuous pressure monitoring, a large loop was formed in the aorta and prolapsed into the left ventricle; the loop was then rotated to point the tip posteriorly until it crossed the mitral valve and entered the left atrium. A pullback pressure recording was then obtained together with simultaneous aortic pressure tracings (Fig. 1). If no resting gradient was demonstrated, pullback pressure recordings across the mitral valve were obtained after administration of amyl nitrite (Fig. 2). Cardiac output was determined by the Fick method. Left ventricular cineangiography was then performed in the 30° right and 60° left anterior oblique projections.

Results

Clinical features: All four patients had a subvalvular left ventricular outflow gradient documented at the time of cardiac catheterization, and all four had asymmetric septal hypertrophy and abnormal systolic anterior motion of the anterior leaflet of the mitral valve demonstrated by left ventricular angiography (Fig. 3). Three of the patients had chest pain with exertion and one was asymptomatic. The physical examination of all four patients revealed a systolic ejection murmur at the left sternal border. The electrocardiogram was abnormal in each patient. Chest



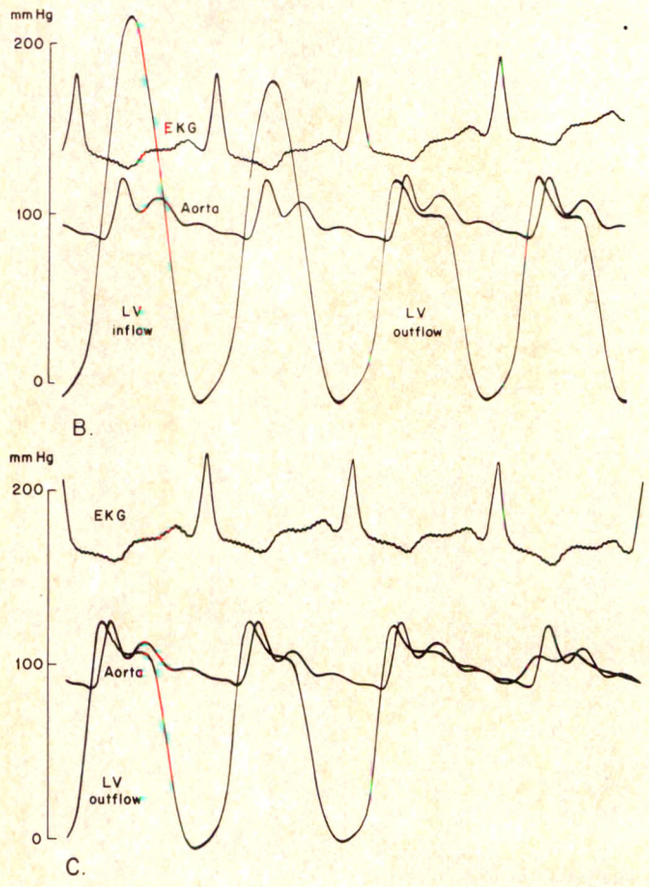


FIGURE 1. Case 2. Continuous retrograde pullback from the left atrium (LA) to the left ventricular (LV) inflow tract **(A)**, the left ventricular inflow tract to the left ventricular outflow tract **(B)** and the left ventricular outflow tract to the aorta **(C)**, with simultaneous recordings of aortic pressure. EKG = electrocardiogram.

roentgenograms revealed left ventricular hypertrophy in two patients and normal findings in two patients.

Intraventricular pressure gradients: Two patients had a resting gradient of 25 and 100 mm Hg, respectively. The third and fourth patients had no gradient at rest but had a gradient of 80 mm Hg after amyl nitrite inhalation (Table II). In each case purposeful catheterization of the left atrium was accomplished without complication. Catheter-induced extrasystoles were frequently encountered but were easily abolished by adjustment of catheter position. There were no episodes of ventricular tachycardia or ventricular fibrillation. The procedure required 15 to 30 minutes from the time the catheter was introduced into the artery until the left atrium was entered. Withdrawal of the Shirey catheter from the left atrium to the left ventricle, with simultaneous recording of aortic pressures, revealed a gradient between the ventricle and the aorta on the first beat recorded from the left ventricle. Pullback to the aorta disclosed the gradient to be subvalvular in all instances.

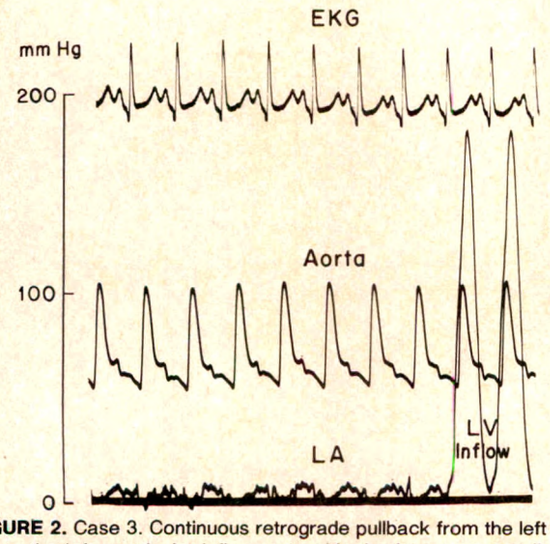

FIGURE 2. Case 3. Continuous retrograde pullback from the left atrium to the left ventricular inflow tract with simultaneous recording of aortic pressure. Tracings recorded during amyl nitrite inhalation.

In one instance (Case 4), the pullback was inadvertently abrupt and the catheter loop was observed to "flip" with a rotary motion from the inflow to the outflow tract of the left ventricle. No gradient was recorded with respect to the aorta on the first intraventricular pressure tracings (Fig. 4, top). On a second withdrawal from the left atrium (Fig. 4, bottom), controlled withdrawal was achieved, and an immediate gradient was documented.

Discussion

Since its description by Ross[8,9] in 1958 the transseptal technique of left heart catheterization has gained wide acceptance. However, it is not a benign

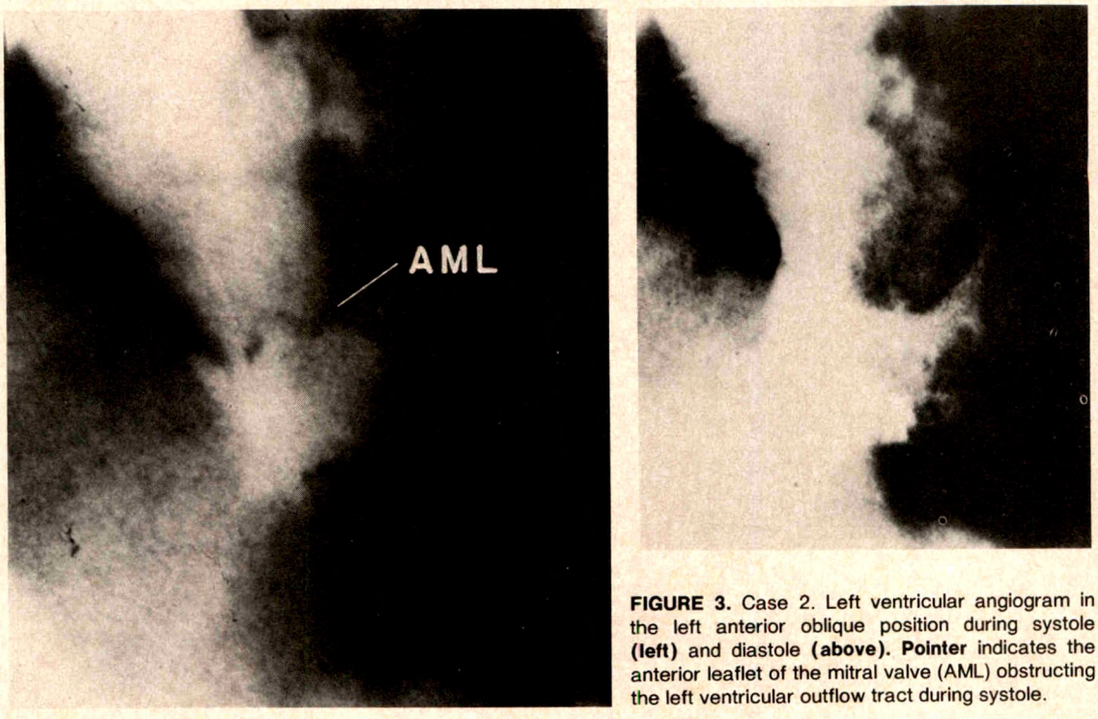

FIGURE 3. Case 2. Left ventricular angiogram in the left anterior oblique position during systole **(left)** and diastole **(above). Pointer** indicates the anterior leaflet of the mitral valve (AML) obstructing the left ventricular outflow tract during systole.

procedure, being associated with a small but significant incidence of complications including inadvertent puncture of the aorta, ventricle and pericardium, pericardial tamponade, retroperitoneal hemorrhage and pulmonary embolism. In 5 to 25 percent of patients the technique is unsuccessful.[10,11] Occasionally physical conditions such as kyphoscoliosis or thrombophlebitis preclude the use of the transseptal approach and an alternative method is required. In recent years, especially since the development of coronary arteriography, retrograde arterial catheterization of the left side of the heart has become almost routine and has decreased the indications for transseptal catheterization of the left heart chambers. In many centers transseptal catheterization of the left heart chambers is now limited to situations in which the pulmonary wedge pressure cannot be obtained (or is not a valid reflection of left atrial pressure), the aortic valve cannot be crossed retrograde, or idiopathic hypertrophic subaortic stenosis is present.

Patients with idiopathic hypertrophic subaortic stenosis must be distinguished from patients with spurious pressure gradients related to cavity obliteration and catheter entrapment. This is of particular importance if surgery is contemplated since patients with cavity obliteration are usually not candidates for surgical intervention. Demonstration of an intraventricular pressure gradient with a high pressure zone on the immediate ventricular side of the mitral valve supports the diagnosis of true muscular obstruction. A catheter in this position cannot be entrapped in left ventricular muscle. One method of guaranteeing proper catheter position is to approach the left ventricle through the left atrium. During a pullback tracing from the left ventricular apex to the left atrium

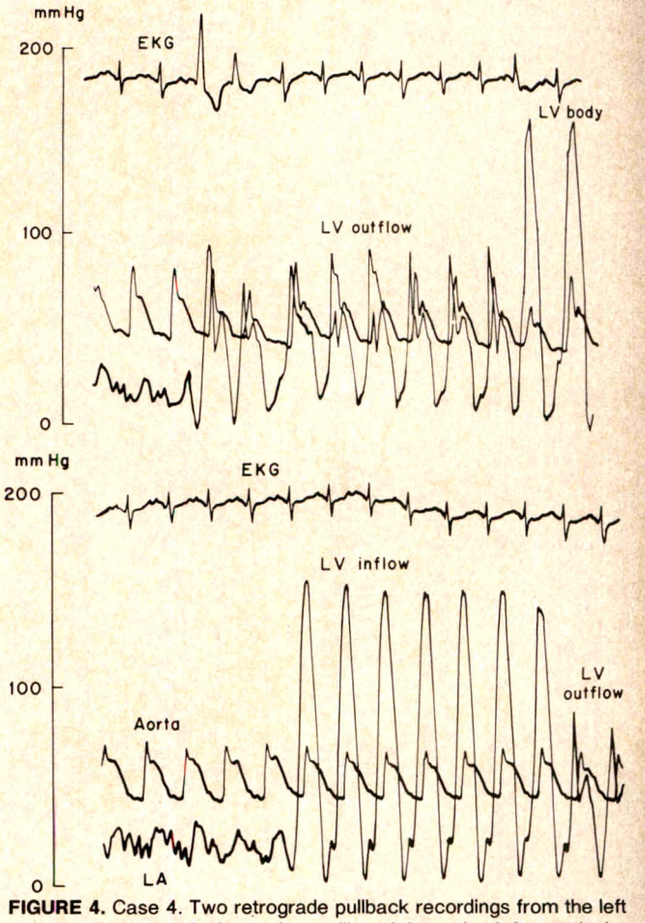

FIGURE 4. Case 4. Two retrograde pullback recordings from the left atrium. In **top panel,** the catheter flipped from the left ventricular (LV) inflow tract to the outflow tract and was then advanced to the body of the left ventricle. In **bottom panel,** a controlled pullback into the inflow tract was observed fluoroscopically.

the catheter traverses the left ventricular inflow tract to distinguish true obstruction from catheter entrapment. Conversely, a catheter introduced in retrograde fashion into the left atrium traverses the same zone when withdrawn from the left atrium to the aorta.

In 1966, Shirey and Sones[6] first described their experience with retrograde left heart catheterization utilizing the Shirey catheter. In their series of 315 patients, the left atrium was successfully entered in 90 percent of cases. The success rate was 85 percent in patients with mitral stenosis and 97 percent in patients with mitral regurgitation. The complications encountered were five episodes of ventricular fibrillation and one episode of ventricular tachycardia, all successfully treated. There were two episodes of hemopericardium related to catheter puncture of the left ventricular myocardium.

The retrograde approach for catheterization of the left atrium in patients with idiopathic hypertrophic subaortic stenosis has been previously mentioned.[2,12] Both Ross et al.[2] and Gault and Simon[12] used the transseptal approach as the method of choice, but in both series there was one patient whose left atrium was entered retrograde. Ross et al. commented that this occurrence was not surprising since the anterior leaflet of the mitral valve was contiguous with the aorta and could be traversed in diastole. Moreover, because significant mitral regurgitation is present in 50 percent of patients with idiopathic hypertrophic subaortic stenosis, one would not expect the retrograde approach to be difficult in these patients. The resting gradient in our four patients with idiopathic hypertrophic subaortic stenosis ranged from none to severe. Three of the four patients had mild mitral regurgitation. Retrograde catheterization of the left atrium was performed with relative ease and with no complications. Catheter-induced extrasystoles often occurred, but there were no episodes of ventricular tachycardia or fibrillation. Even though our laboratory does not use this procedure routinely, the time required to perform it is comparable to that required for transseptal catheterization, and the risk of serious complications is less.

A false negative result can occur, but can be anticipated if the pullback is observed under fluoroscopy. If the catheter loop moves abruptly, with a rotary motion, it can move rapidly from the left ventricular inflow to the outflow tract, entering the infundibulum, and demonstrating no gradient. A slow, controlled withdrawal, without sudden changes in position, is unlikely to yield misleading results.

Thus, if retrograde arterial catheterization of the left side of the heart is proposed for patients with suspected idiopathic hypertrophic subaortic stenosis, we would advocate use of retrograde catheterization of the left atrium. The technique would eliminate the need for transseptal catheterization, with its attendant risk of complications and requirement of a separate entry site.

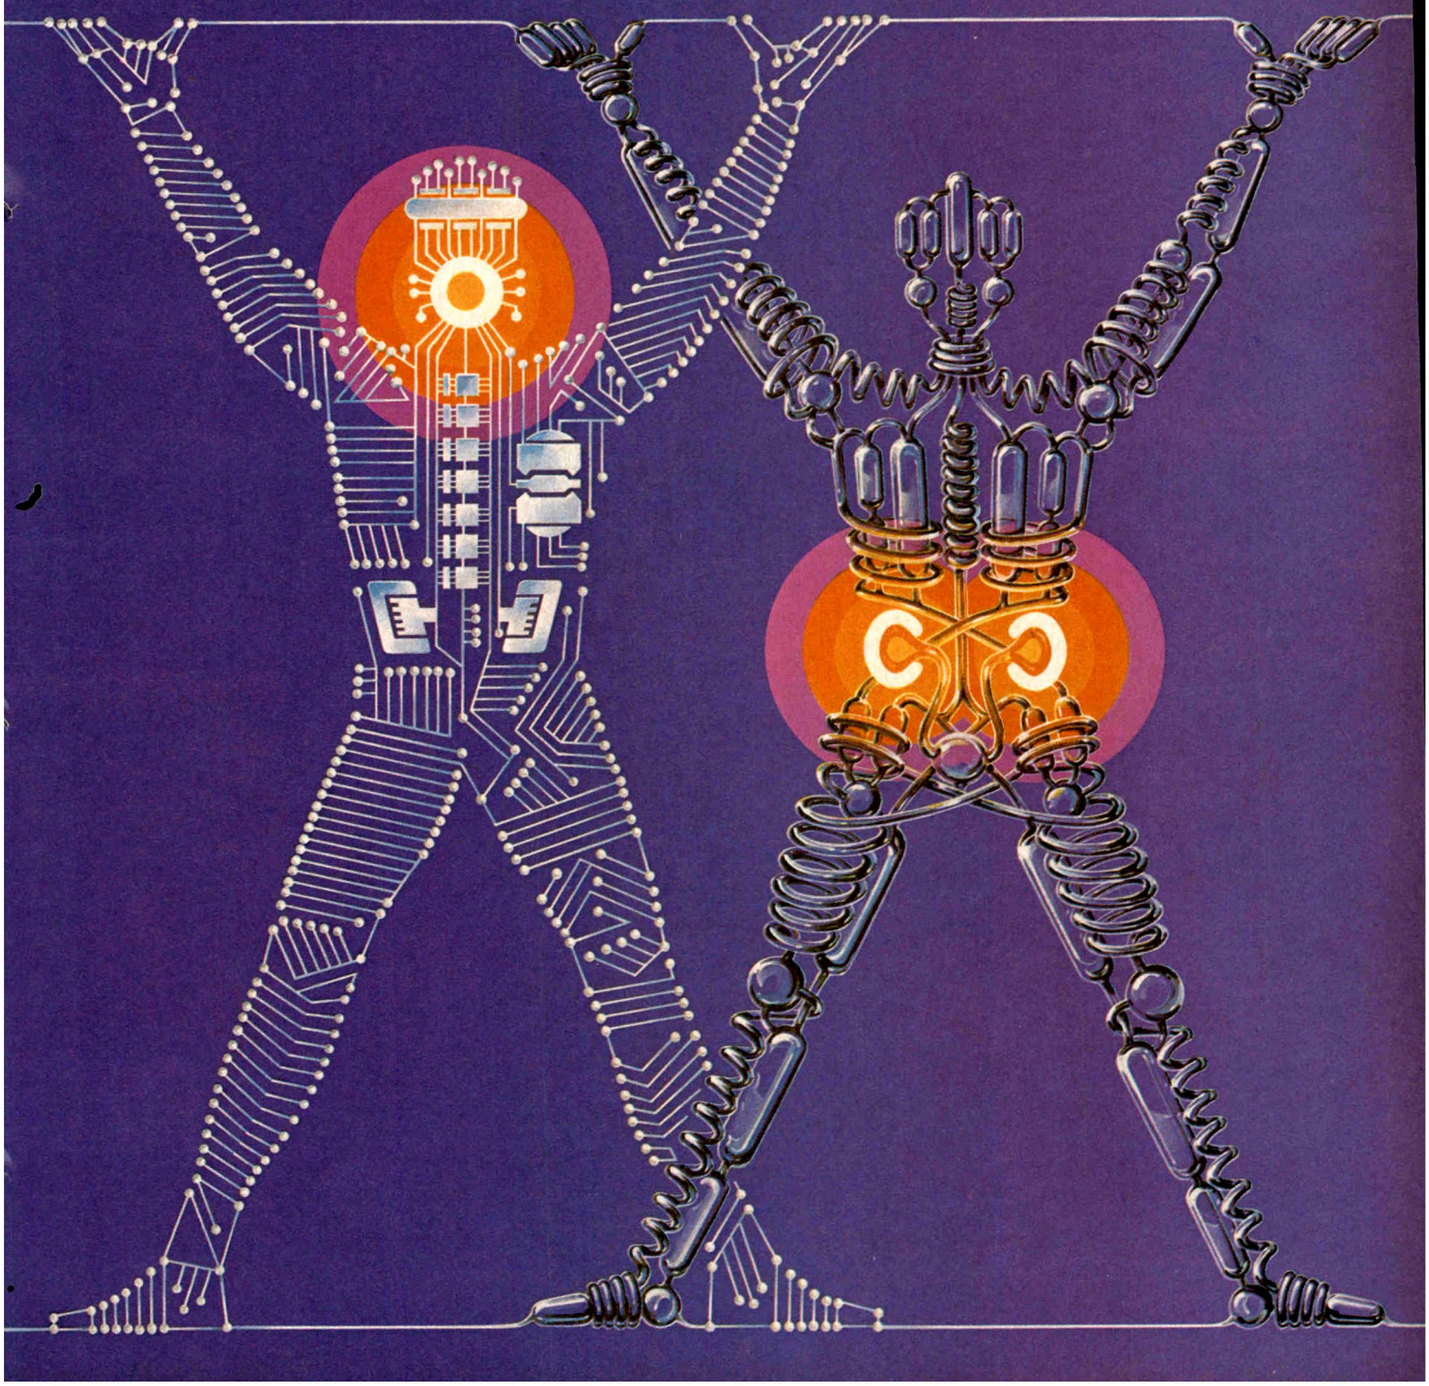
nonreserpine

Announcing Combipres®

Each tablet contains: Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

The only major new combination antihypertensive in a decade

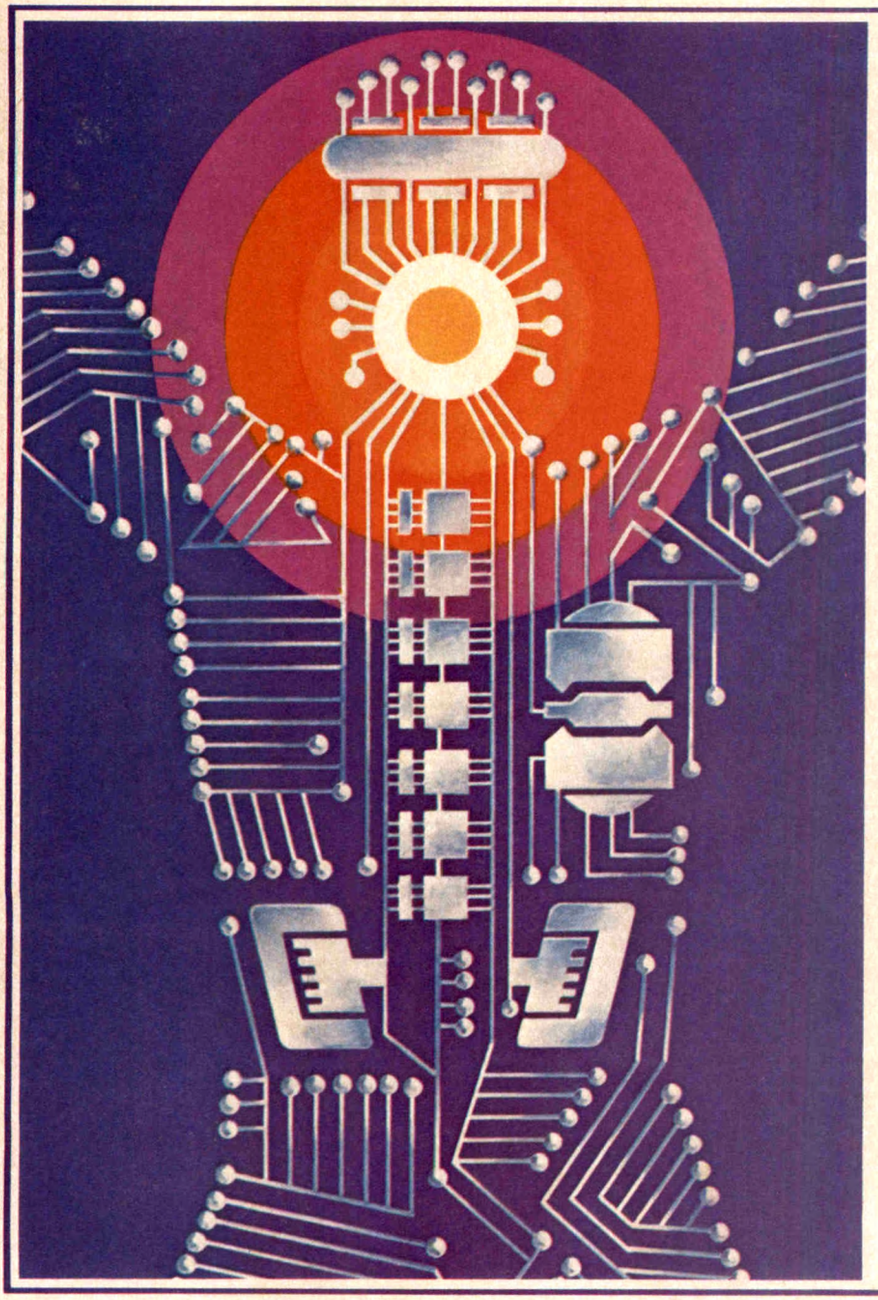
Please see last page of advertisement for a brief summary of the prescribing information including precautions, warnings, and adverse reactions.



new Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride,
0.1 or 0.2 mg and chlorthalidone, 15 mg

.1 and .2



Catapres®
(clonidine hydrochloride)
contributes:

Action at the vasomotor centers, as shown in animal studies—not a rauwolfia derivative or a sympathetic blocker or a "false transmitter"

Maximal blood pressure lowering without the weeks of delay common with the rauwolfia class of antihypertensives

Significant blood pressure reduction without alteration of normal hemodynamic responses to exercise

Mild and infrequent orthostatic hypotension

Little or no change in renal blood flow and glomerular filtration rate

Reduced plasma renin activity and excretion of aldosterone and catecholamines (see Actions section)

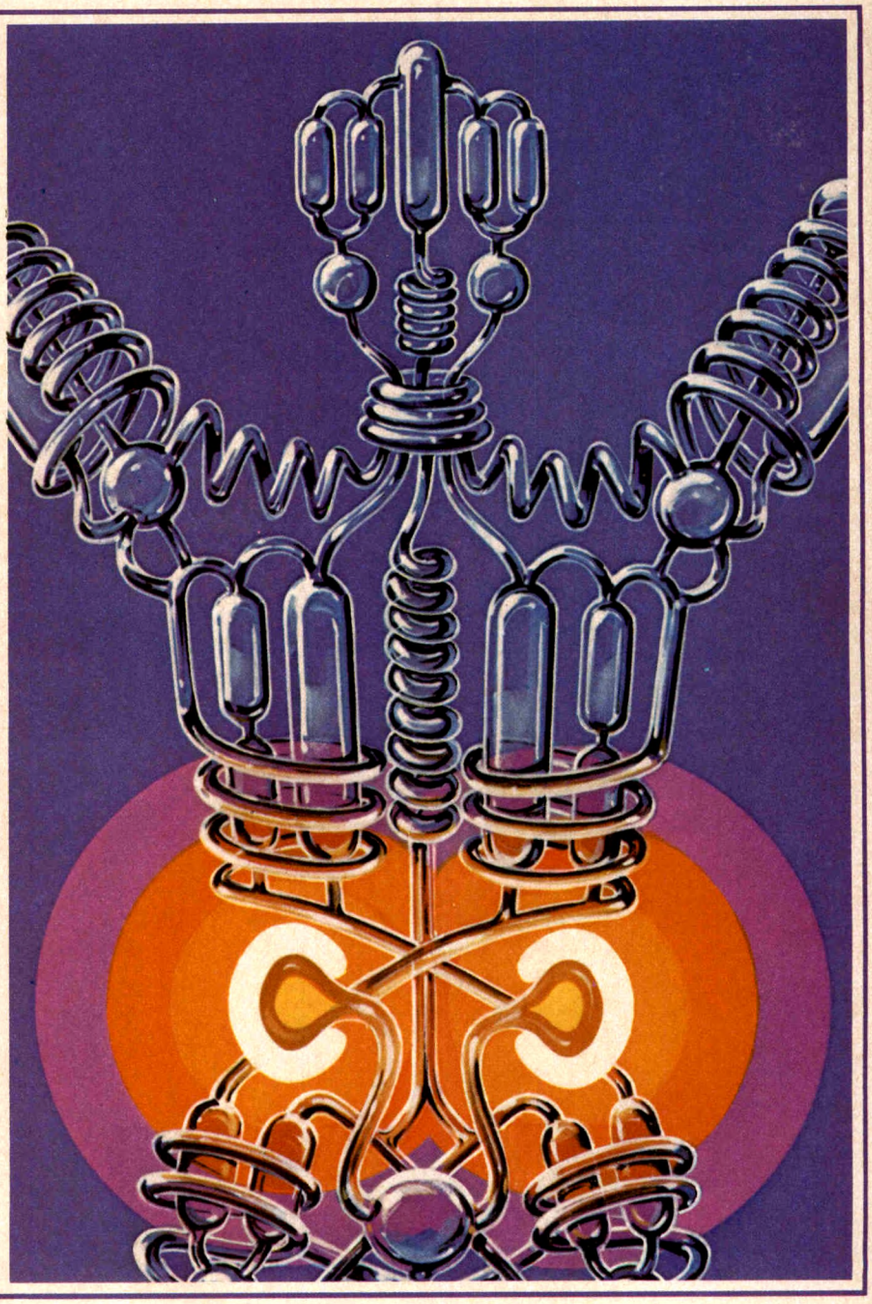
Combines Catapres (clonidine hydrochloride) with a diuretic—the only major new combination antihypertensive in a decade

Chlorthalidone contributes:

Pharmacologic action similar to the thiazides

Smooth, extended diuretic/antihypertensive effect

Additive or potentiating effect on adjunctive antihypertensive agents



The most common adverse reactions with Combipres are dry mouth, drowsiness, and sedation. As with thiazide-containing combination antihypertensives, hypokalemia, hyperuricemia, and decreased glucose tolerance may occur. Combipres is contraindicated in patients with known sensitivity to chlorthalidone and in those with severe renal or hepatic disease.

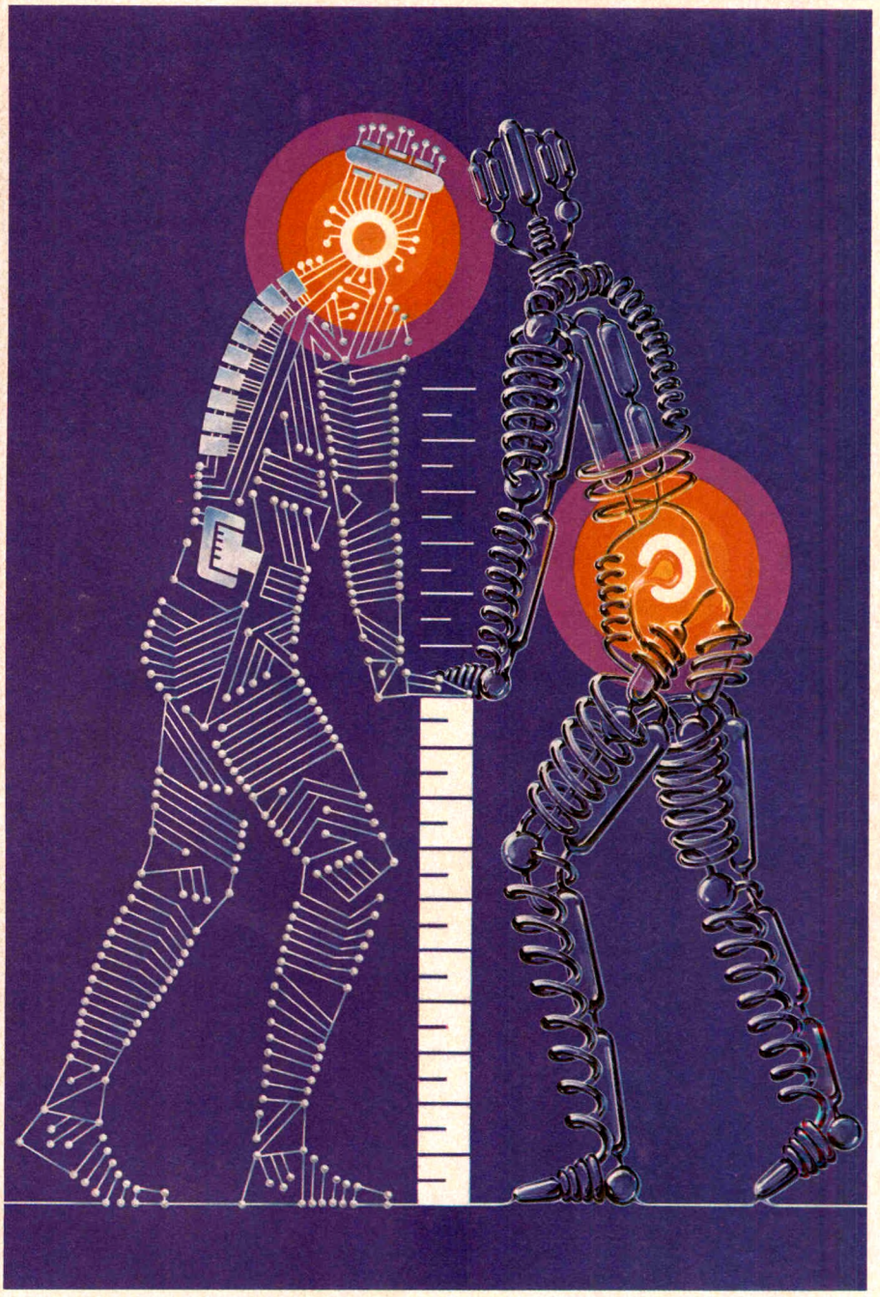
Please see last page of advertisement for a brief summary of the prescribing information including precautions, warnings, and adverse reactions.

See box Warning on next page concerning the appropriate use of Combipres.

new Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride,
0.1 or 0.2 mg and chlorthalidone, 15 mg

.1 and .2



Works harder

Usually exerts a more pronounced antihypertensive effect than either component alone in equivalent doses*

Works broadly

Wide therapeutic range—mild to severe hypertension

Works conveniently

Simplifies therapy for the hypertensive patient who needs more than one drug*

Works for less

Costs less than two separate prescriptions*

Works and works and works

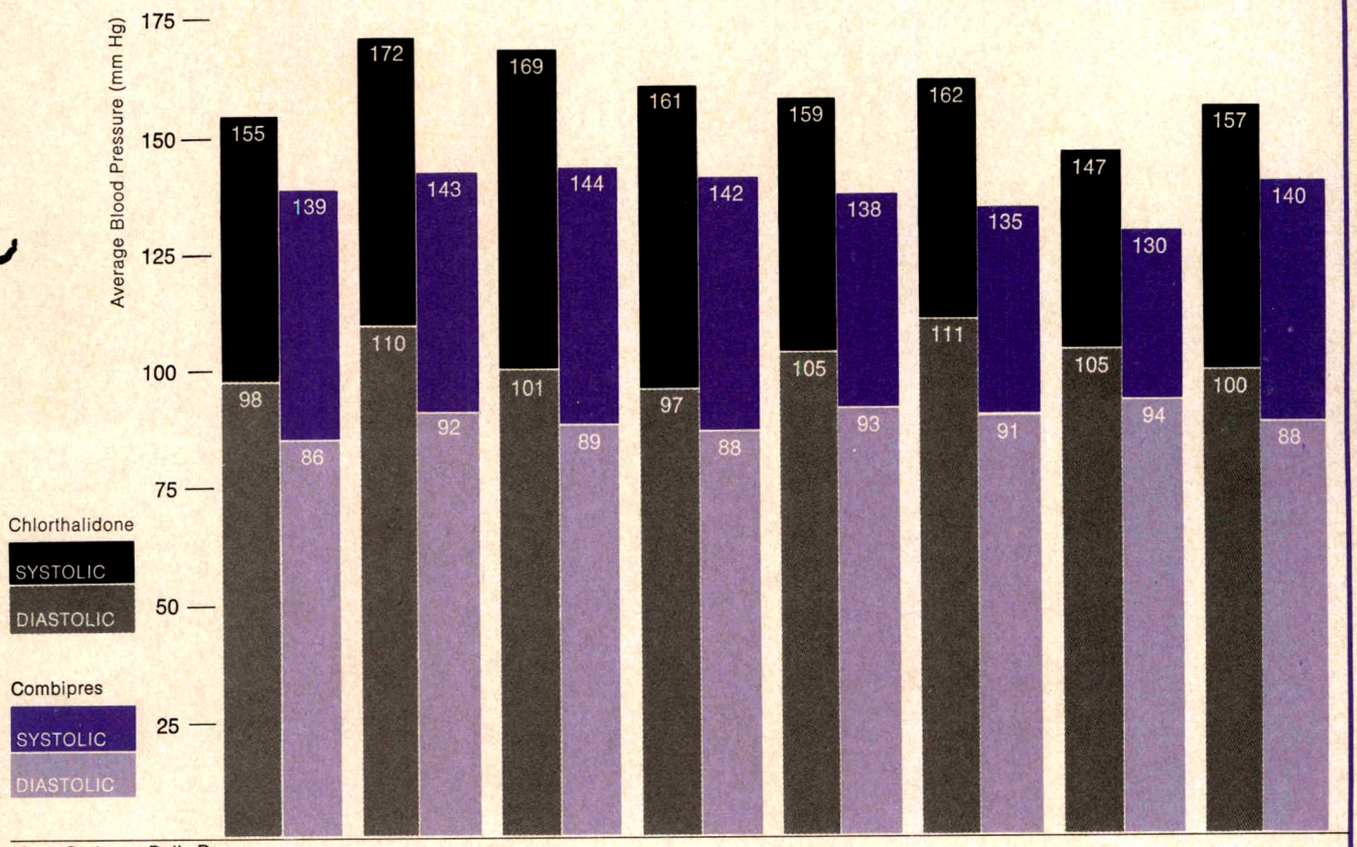
Convenience and economy encourage patients to stay on medication, help assure continued blood pressure control over the long course of therapy*

*__WARNING__ Combipres is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

The only major new combination antihypertensive in a decade

Works in the majority of hypertensive patients

Chlorthalidone vs Combipres
A Comparison of Standing Blood Pressure Response in 8 Studies



Mean Optimum Daily Dose Chlorthalidone (mg)	50	50	47.7	50	50	50	71	50
Combipres (mg)	0.3	0.48	0.47	0.4	0.43	0.68	0.52	0.4

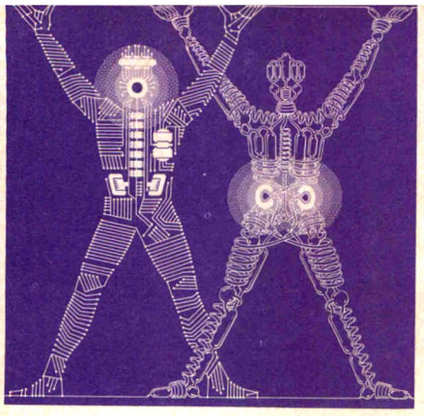
Study	1	2	3	4	5	6	7	8

Please see last page of advertisement for a brief summary of the prescribing information including precautions, warnings, and adverse reactions.



reserpine

new Combipres®

Each tablet contains: Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

Guidelines for Titrating Catapres and Chlorthalidone Dosages:

Initial doses: Catapres—one 0.1 mg tablet twice daily. Chlorthalidone—50 mg daily.

Dosage increments: While daily chlorthalidone doses remain at 50 mg, further increments of Catapres of 0.1 mg or 0.2 mg per day can be made at intervals of 2 to 14 days depending on severity of hypertension. The usual daily dose of Catapres ranges between 0.2 and 0.8 mg. Studies indicate that 2.4 mg is the maximum effective daily dose, but doses as high as this have rarely been used.

Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

WARNING: This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Actions: Catapres (clonidine hydrochloride): The mechanism of action appears to be central alpha-adrenergic stimulation as demonstrated in animal studies. This results in inhibition of bulbar sympathetic cardioaccelerator and sympathetic outflow from the brain. Other studies in humans have provided evidence of a reduction in plasma renin activity and the excretion of aldosterone and catecholamines. The exact relationship between these pharmacologic actions of Catapres (clonidine hydrochloride) in humans and its antihypertensive effect has not been fully elucidated at this time.

Chlorthalidone: The diuretic action of chlorthalidone is thought to be due to inhibition of sodium and chloride reabsorption in the proximal tubule.

Indication: The drug is indicated in the treatment of hypertension (see box warning).

Contraindications: Patients with known hypersensitivity to chlorthalidone and patients with severe renal or hepatic diseases.

Warnings: Tolerance may develop in some instances necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxicity findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefit outweighs the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Combipres in children.

Precautions: When discontinuing Combipres, reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of Combipres therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect of the clonidine hydrochloride component. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other antihypertensive agent, Combipres should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Combipres should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmological findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Patients predisposed toward or affected by diabetes should be tested periodically while receiving Combipres, because of the hyperglycemic effect of chlorthalidone.

Because of the possibility of progression of renal failure, periodic determination of the BUN is indicated. If, in the physician's opinion, a rising BUN is significant, the drug should be stopped.

The chlorthalidone component of Combipres may lead to sodium and/or potassium depletion. Muscular weakness, muscle cramps, anorexia, nausea, vomiting, constipation, lethargy or mental confusion may occur. Severe dietary salt restriction is not recommended in patients receiving Combipres.

Periodic determinations of the serum potassium level will aid the physician in the detection of hypokalemia. Extra care should be given to detection of hypokalemia in patients receiving adrenal corticosteroids, ACTH or digitalis. Hypochloremic alkalosis often precedes other evidence of severe potassium deficiency. Frequently, therefore, more sensitive indicators than the potassium serum level are the serum bicarbonate and chloride concentrations. Also indicative of potassium depletion can be electrocardiographic alterations such as changes in conduction time, reduction in amplitude of the T wave; ST segment depression; prominent U wave. These abnormalities may appear with potassium depletion before the serum level of potassium decreases. To lessen the possibility of potassium deficiency, the diet, in addition to meat and vegetables, should include potassium-rich foods such as citrus fruits and bananas. If significant potassium depletion should occur during therapy, oral potassium supplements in the form of potassium chloride (3 to 4.5 gm/day), fruit juice and bananas should be given.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy.

Clonidine hydrochloride: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one case of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash; impotence, urinary retention; increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Chlorthalidone: Symptoms such as nausea, gastric irritation, anorexia, constipation and cramping, weakness, dizziness, transient myopia and restlessness are occasionally observed. Headache and impotence or dysuria may occur rarely. Orthostatic hypotension has been reported and may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics. Skin rashes, urticaria and purpura have been reported in a few instances.

A decreased glucose tolerance evidenced by hyperglycemia and glycosuria may develop inconsistently. This condition, usually reversible on discontinuation of therapy, responds to control with antidiabetic treatment. Diabetics and those predisposed should be checked regularly.

As with other diuretic agents hypokalemia may occur (see Precautions). Hyperuricemia may be observed on occasion and acute attacks of gout have been precipitated. In cases where prolonged and significant elevation of blood uric acid concentration is considered potentially deleterious, concomitant use of a uricosuric agent is effective in reversing hyperuricemia without loss of diuretic and/or antihypertensive activity.

Idiosyncratic drug reactions such as aplastic anemia, thrombocytopenia, leukopenia, agranulocytosis, and necrotizing angiitis have occurred, but are rare.

The remote possibility of pancreatitis should be considered when epigastric pain or unexplained gastrointestinal symptoms develop after prolonged administration.

Other adverse reactions which have been reported with this general class of compounds include: jaundice, xanthopsia, paresthesia and photosensitization.

Overdosage: *Catapres (clonidine hydrochloride):* Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals abolishes all effects of Catapres overdosage.

Chlorthalidone: Symptoms of overdosage include nausea, weakness, dizziness, and disturbances of electrolyte balance. There is no specific antidote, but gastric lavage is recommended, followed by supportive treatment. Where necessary, this may include intravenous dextrose and saline with potassium administered with caution.

How Supplied: Combipres® 0.1 (Each tablet contains clonidine hydrochloride, 0.1 mg + chlorthalidone, 15 mg). It is available as pink, oval, single-scored compressed tablets in bottles of 100.

Combipres® 0.2 (Each tablet contains clonidine hydrochloride, 0.2 mg + chlorthalidone, 15 mg). It is available as blue, oval, single-scored compressed tablets in bottles of 100.

For complete details, please see full prescribing information.

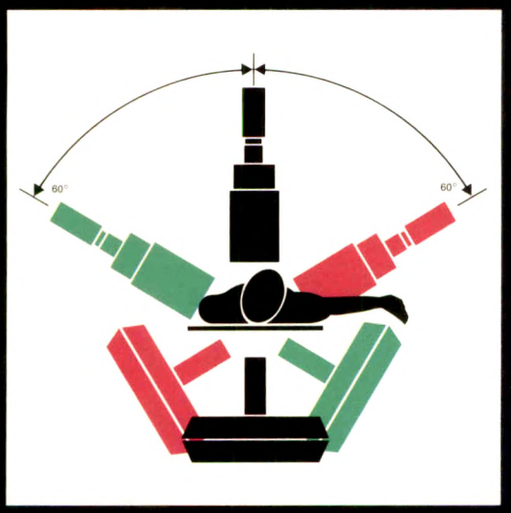
Four why's to improve one way...with Philips

1

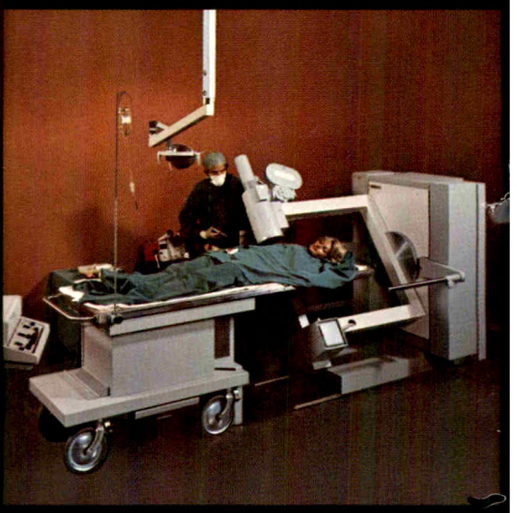
The patient remains stationary during catheterization.



Why? Because the Cardio Diagnost's U-arm rotates the X-ray beam around the patient. And the entire U-arm can be raised or lowered effortlessly. An easier, more efficient examination...a stationary, comfortable, more cooperative patient.

2

You can scan freely in any patient plane...with one hand.



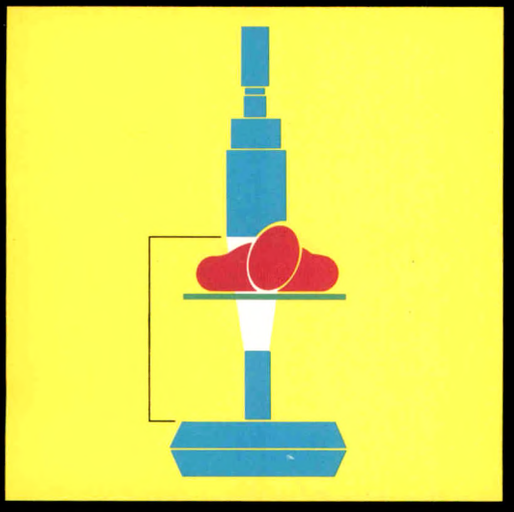
Why? Superb engineering. With one hand and virtually no effort, you can elevate, lower or rotate the U-arm to scan freely in any patient plane. The scanning motion can be locked at right angles to the central ray and scanning can be kept close to the chest wall. Your other hand is free for catheter control.

PHILIPS®

cardiac angiography
Cardio Diagnost

3

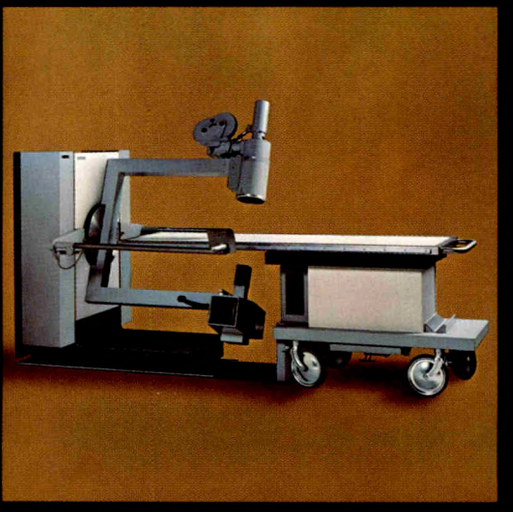
The finest image quality available...in fluoroscopy and 35mm cine.



Why? Philips 6″ Image Intensifier provides the finest contrast and resolution available. The I.I. is close to the chest wall; the distance from tube to intensifier is fixed; beam collimation is precise.

4

A built-in patient transfer system.



Why? Because the Cardio's examination table is actually a mobile cart. The patient can be prepped, examined and wheeled to a post-op room on the same table. Multiple carts make this feature extremely valuable wherever cardiac angiography is a routine procedure.

Need more why's? Ask any one of our many satisfied users. Or write us. We'll provide all you need...or show you the one way in a major institution near you.

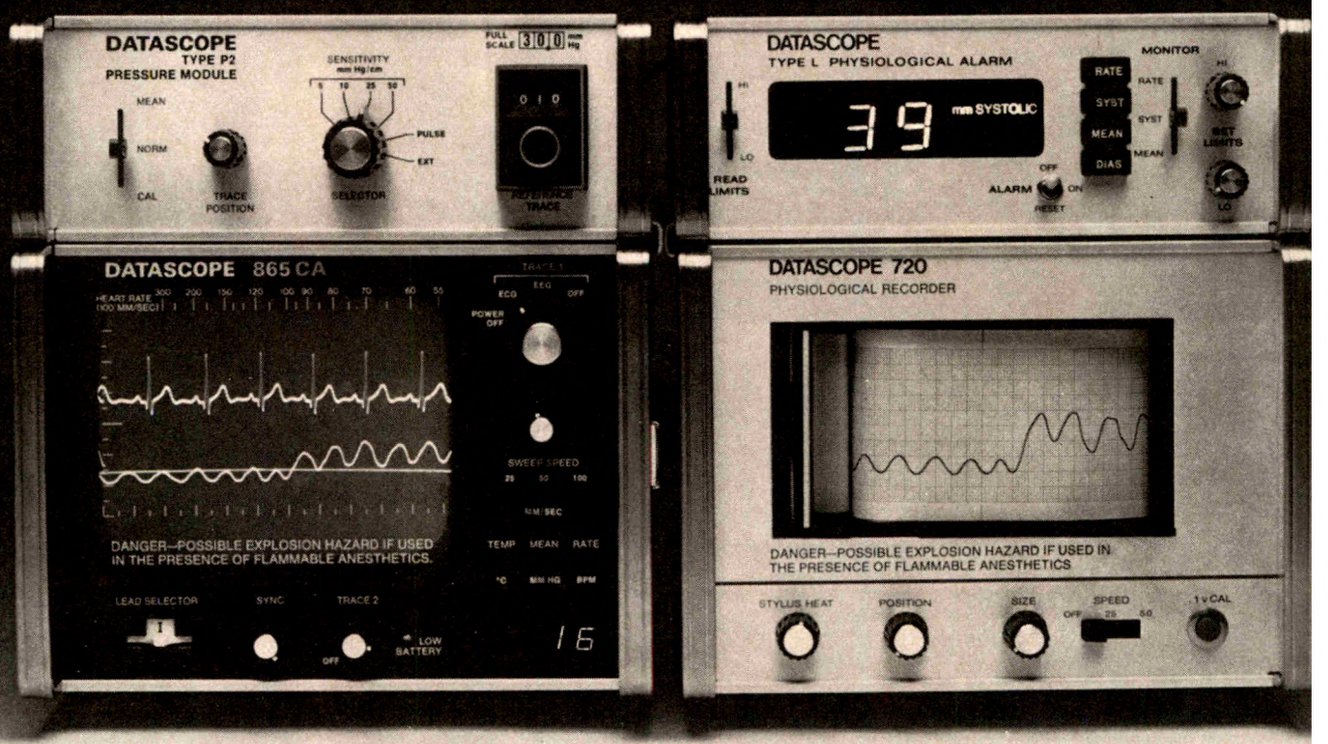
NEWS FROM AMERICAN HEART ASSOCIATION

WEDGE PRESSURE MONITORING. UNCOMPLICATED.



The Swan-Ganz® Catheter simplified monitoring. It took you out of the cath lab and into ICU/CCU.

The Datascope Wedge Pressure Group can simplify your job at the bedside even more.

First, we've simplified the job of passing the catheter. Ours is the only monitor made that has an electronic cursor, a unique movable reference trace. It makes reading the pressure changes much easier, much faster, much more accurate.

And once the catheter has been passed, we've simplified the job of monitoring. In fact, we've taken it to the point where the nursing staff can handle it without any assistance.

If you've gotten used to big, bulky monitoring equipment, our wedge pressure group will come as a pleasant surprise. It's extremely light, and compact. It easily fits at bedside.

And it's portable. You can move it where you need it, when you need it.

So you don't have to have a unit for every bed.

Which not only makes life simpler for the people who use it, but also for the people who buy it.

For more information on the Datascope Wedge Pressure Group, write: Datascope Corp., 580 Winters Ave., Paramus, N.J. 07652.

Peritrate® SA Sustained Action
(pentaerythritol tetranitrate) 80mg

CAUTION: Federal law prohibits dispensing without prescription.

Description: Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.

(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop.

(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later. Tablets should not be chewed.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 (N 0047-0004-51) and 1000 (N 0047-0004-60). Also in unit dose—package of 10 x 10 strips (N 0047-0004-11).

Additional Dosage Forms: Peritrate 20 mg—light green, scored tablets in bottles of 100 (N 0047-0001-51) and 1000 (N 0047-0001-60). Also in unit dose—package of 10 x 10 strips (N 0047-0001-11). Peritrate 10 mg—light green, unscored tablets in bottles of 100 (N 0047-0007-51) and 1000 (N 0047-0007-60).

Full information is available on request.

Defense against attack.

For over 22 years, Peritrate® has been considered by many physicians as one of the top defensive measures for patients with angina pectoris. In many patients Peritrate used prophylactically helps decrease the frequency and severity of angina attacks.* With minimal side effects.

Peritrate can also help reduce nitroglycerin requirements and, therefore, nitroglycerin side effects. Is it any wonder so many physicians continue to prefer Peritrate prophylaxis for their angina patients?

LONG-ACTING PROTECTION AGAINST ANGINA PAIN*

Peritrate® SA
Sustained Action

Warner/Chilcott
Div. Warner-Lambert Company
Morris Plains, N.J. 07950
PE-GP-51

The Great Wall of China, an immense 1,400-mile-long man made barrier 20 to 30 feet high and 15 to 20 feet thick, helped defend China from the attack of Mongol hordes for more than 2,000 years.

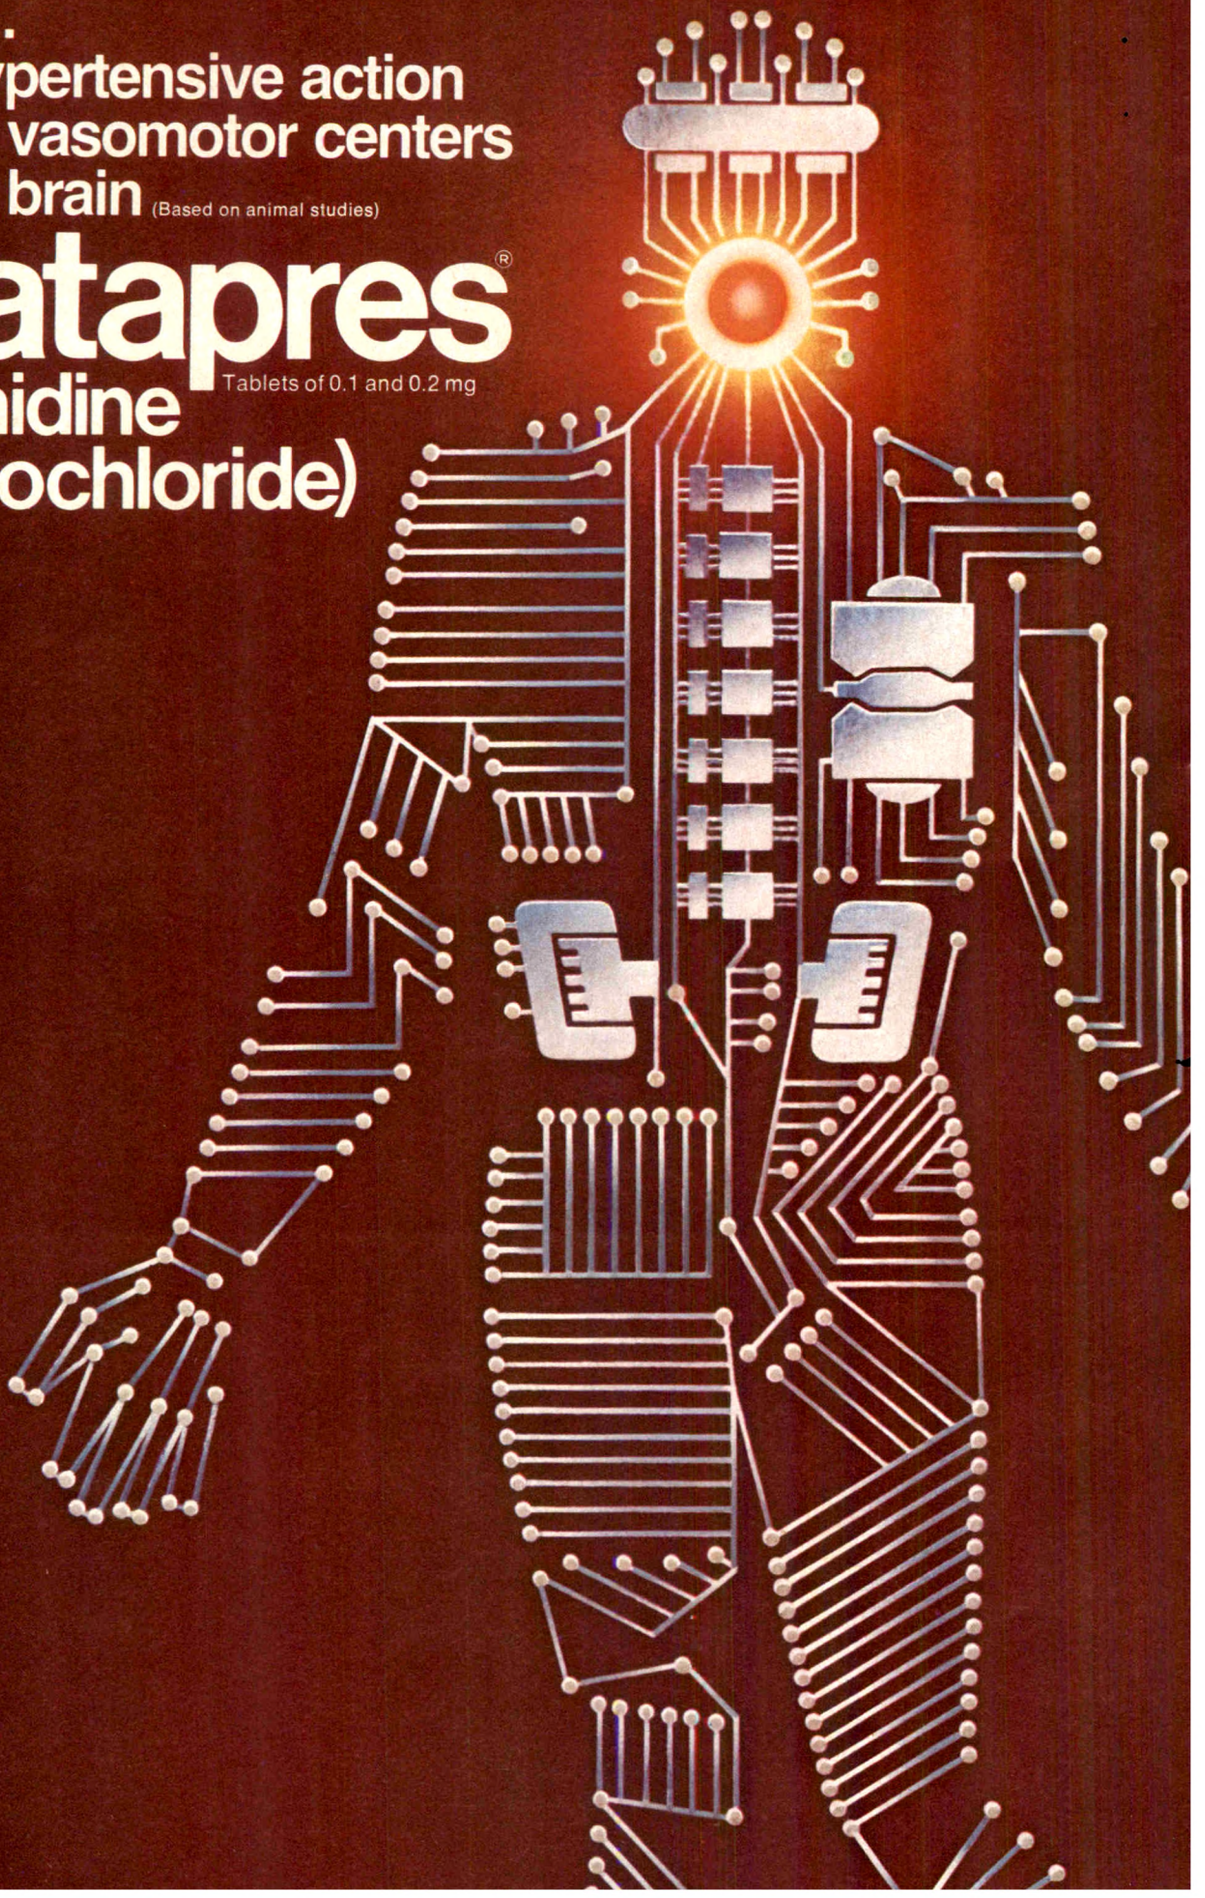
*The drug has been evaluated as possibly effective for this indication.
See brief summary.

Now...
antihypertensive action
at the vasomotor centers
in the brain (Based on animal studies)

Catapres®

Tablets of 0.1 and 0.2 mg

(clonidine
hydrochloride)

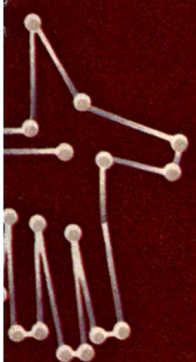


Central action

Catapres appears to lower blood pressure through central alpha-adrenergic stimulation, as shown in animal studies. This results in diminution—but not blocking—of sympathetic outflow from cardioaccelerator and vasoconstrictor centers in the medulla.

Not a "depleter", "blocker", "inhibitor" or "false transmitter"

Not a rauwolfia



BOEHRINGER INGELHEIM

Boehringer Ingelheim

Boehringer Ingelheim Ltd.
Elmsford, New York 10523

Effective in hypertension, mild to severe

Mild and infrequent orthostatic hypotension

Normal hemodynamic responses to exercise are unaffected

Renal blood flow and glomerular filtration rate essentially unchanged

Mild to moderate potency

The most common side effects are dry mouth, drowsiness and sedation. These generally tend to diminish with continued therapy. Other potential adverse reactions are listed in the Brief Summary.

Catapres® (clonidine hydrochloride)
Tablets of 0.1 mg and 0.2 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy. The following reactions have been associated with the drug, some of them rarely. (In some instances an exact causal relationship has not been established). These include: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one report of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride.

Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash, impotence, urinary retention, increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres (clonidine hydrochloride) by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals usually abolishes all effects of Catapres (clonidine hydrochloride) overdosage.

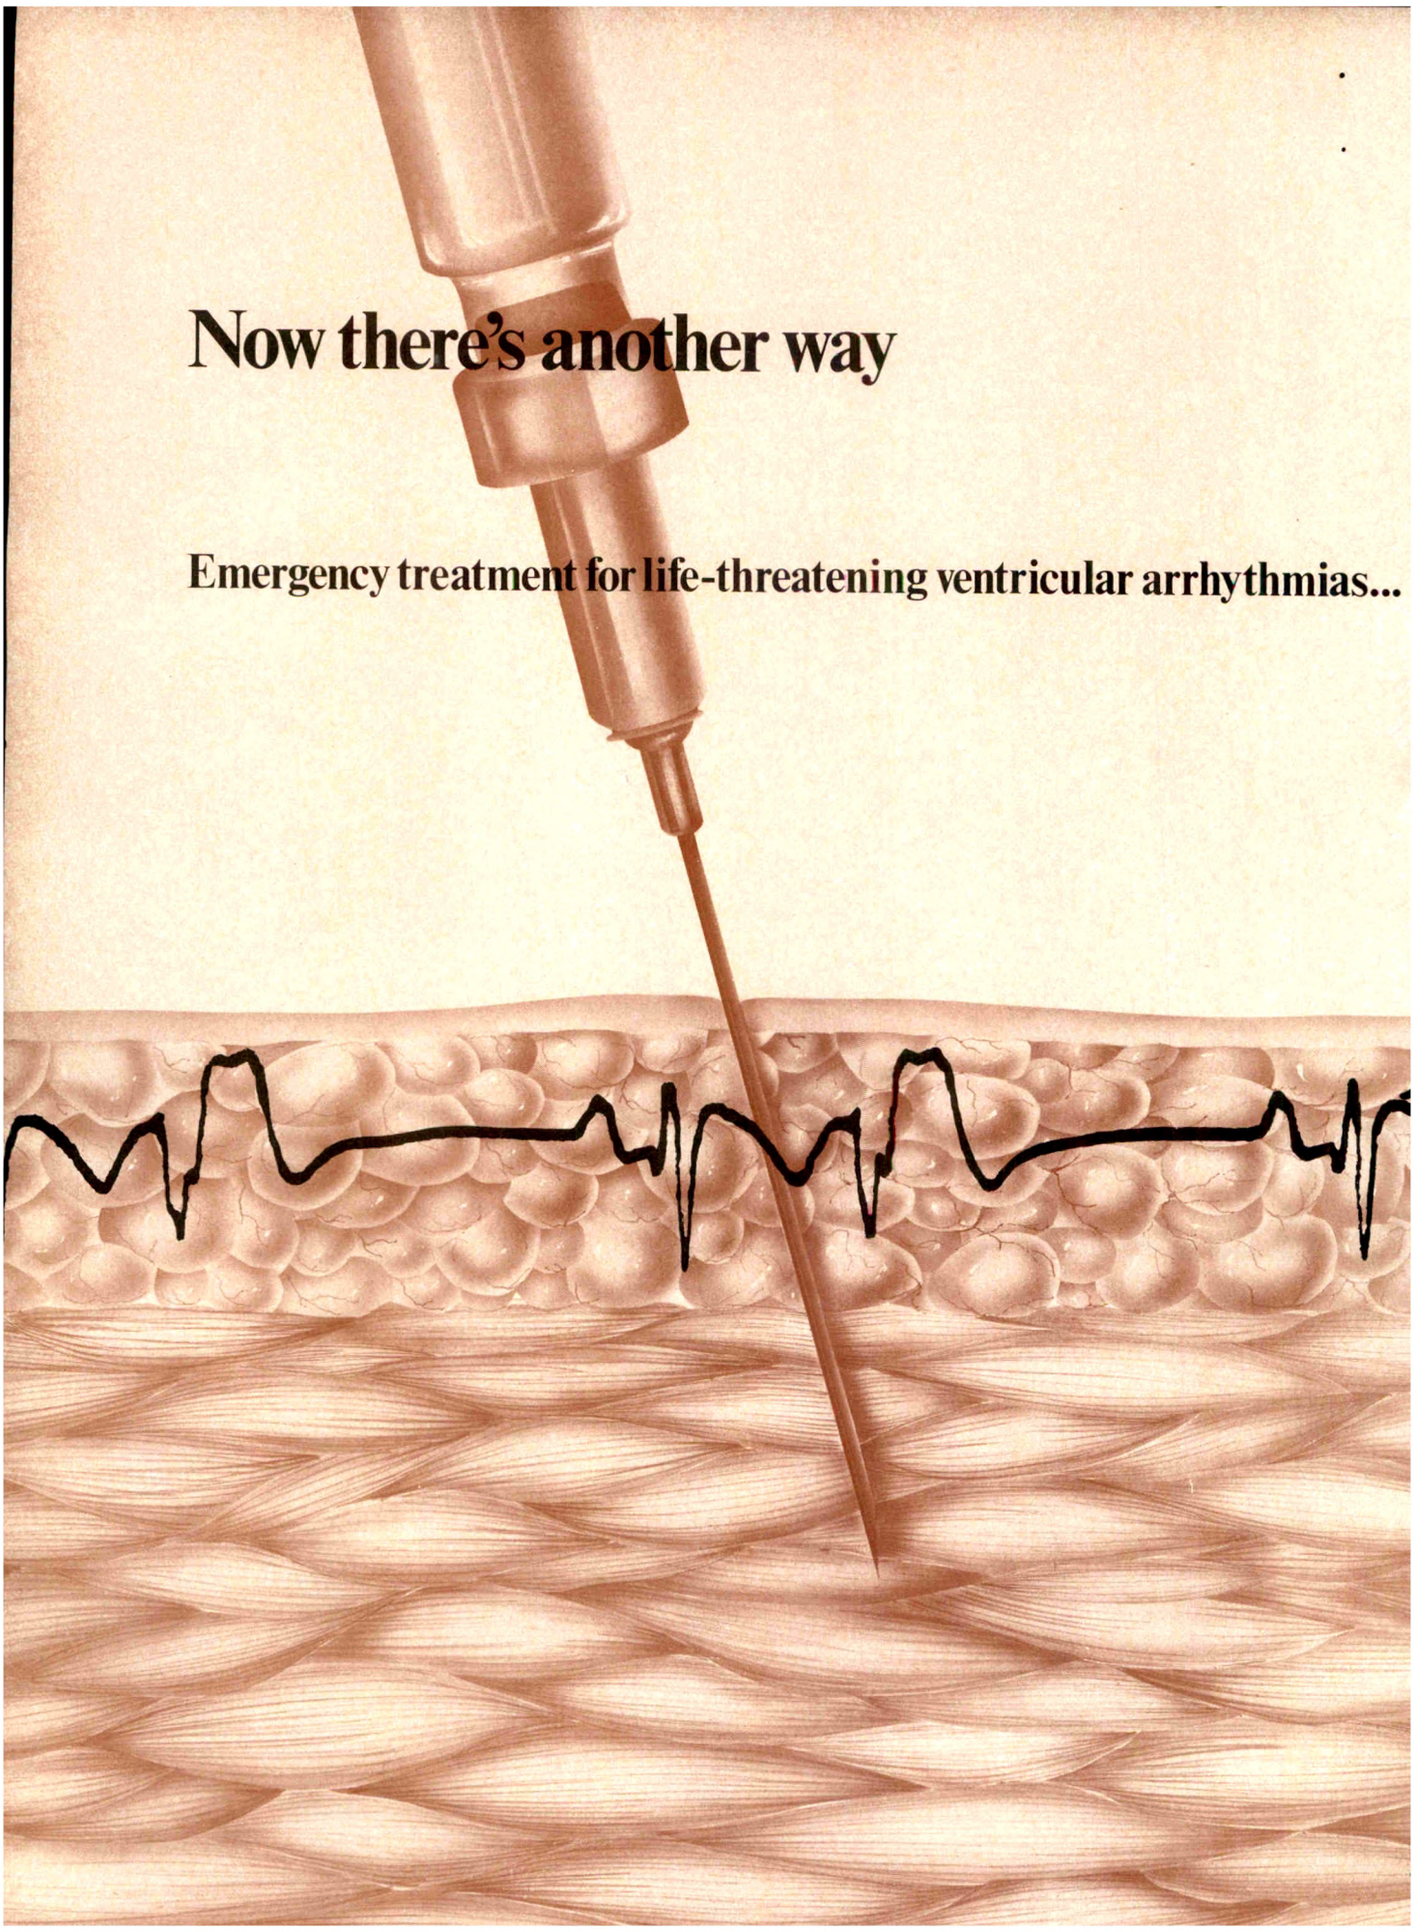
How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0.1 mg (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100.

For complete details, please see full prescribing information.

Under license from
Boehringer Ingelheim GmbH

Now there's another way

Emergency treatment for life-threatening ventricular arrhythmias...



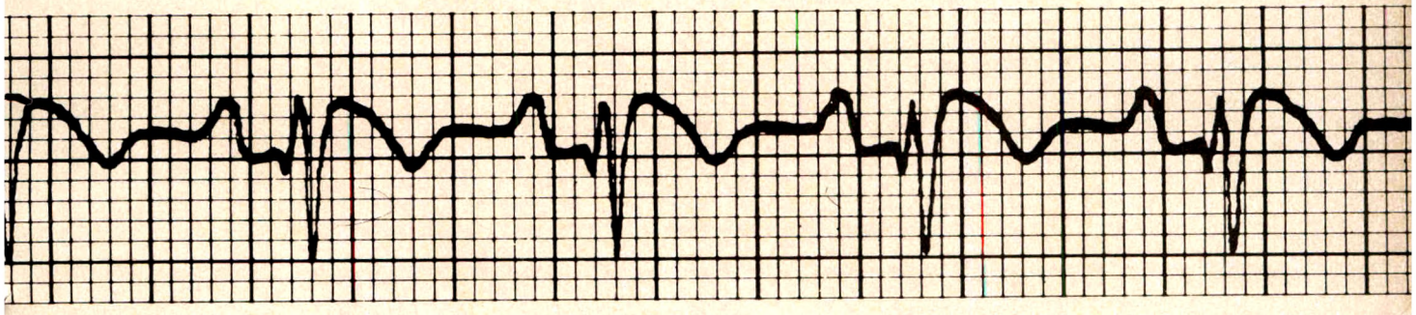
When an appropriate dose of Xylocaine is administered by the intramuscular (deltoid) route, effective antiarrhythmic blood levels are usually attained within 5-15 minutes and may persist for 60-90 minutes. Xylocaine Intramuscular is specifically indicated in the acute management of life-threatening ventricular arrhythmias when justified:

- by a physician when ECG equipment is not available to verify diagnosis, but potential benefits may outweigh possible risks
- by a physician when IV facilities are not available
- by paramedical personnel in a mobile coronary care unit directed by a physician viewing a transmitted ECG

New Xylocaine® (lidocaine) HCl

Intramuscular injection for cardiac arrhythmias

Usual dosage: For the average 150 lb man, 3 ml (300 mg) injected in deltoid muscle. See complete instructions in package insert.



Before prescribing or administering, please consult complete product information, a summary of which follows:

Contraindications: Patients with known hypersensitivity to local anesthetics of the amide type, and patients with Adams-Stokes syndrome or severe degrees of sinoatrial, atrioventricular or intraventricular block.

Warnings: ASPIRATE FREQUENTLY TO AVOID INADVERTENT INTRAVASCULAR ADMINISTRATION.

ECG monitoring is recommended. However, in emergency situations when a physician suspects ventricular arrhythmia and ECG equipment is not available, a single dose may be administered when the physician determines potential benefits outweigh possible risks. If possible, have emergency resuscitative drugs and equipment immediately available to manage potential adverse reactions involving cardiovascular, respiratory, or central nervous systems.

Intramuscular use of Xylocaine® may result in increased creatine phosphokinase levels and compromise the use of this enzyme determination, without isoenzyme separation, in diagnosing acute myocardial infarction.

Pediatric use is not recommended.

Precautions: Observe usual precautions in the presence of impaired renal or hepatic function, hypovolemia and shock, and all forms of heart block.

Adverse Reactions: Although serious adverse reactions to Intramuscular Xylocaine have been rare, the following previously have been reported following lidocaine administration:

1. Central Nervous System—lightheadedness; drowsiness; dizziness; apprehension; euphoria; tinnitus; blurred or double vision; vomiting; sensations of heat, cold, or numbness; twitching; convulsions; unconsciousness; respiratory depression and arrest.
2. Cardiovascular System—hypotension; cardiovascular collapse; bradycardia which may lead to cardiac arrest.

Cross-sensitivity with procainamide or quinidine has not been reported.

Soreness at injection site, occasionally.

Supplied in 5 ml ampules, in cartons of 10. Each ml contains 100 mg of Xylocaine HCl and sodium hydroxide to adjust pH. A 3 ml injection provides the recommended dose.

FOR INTRAMUSCULAR USE ONLY.

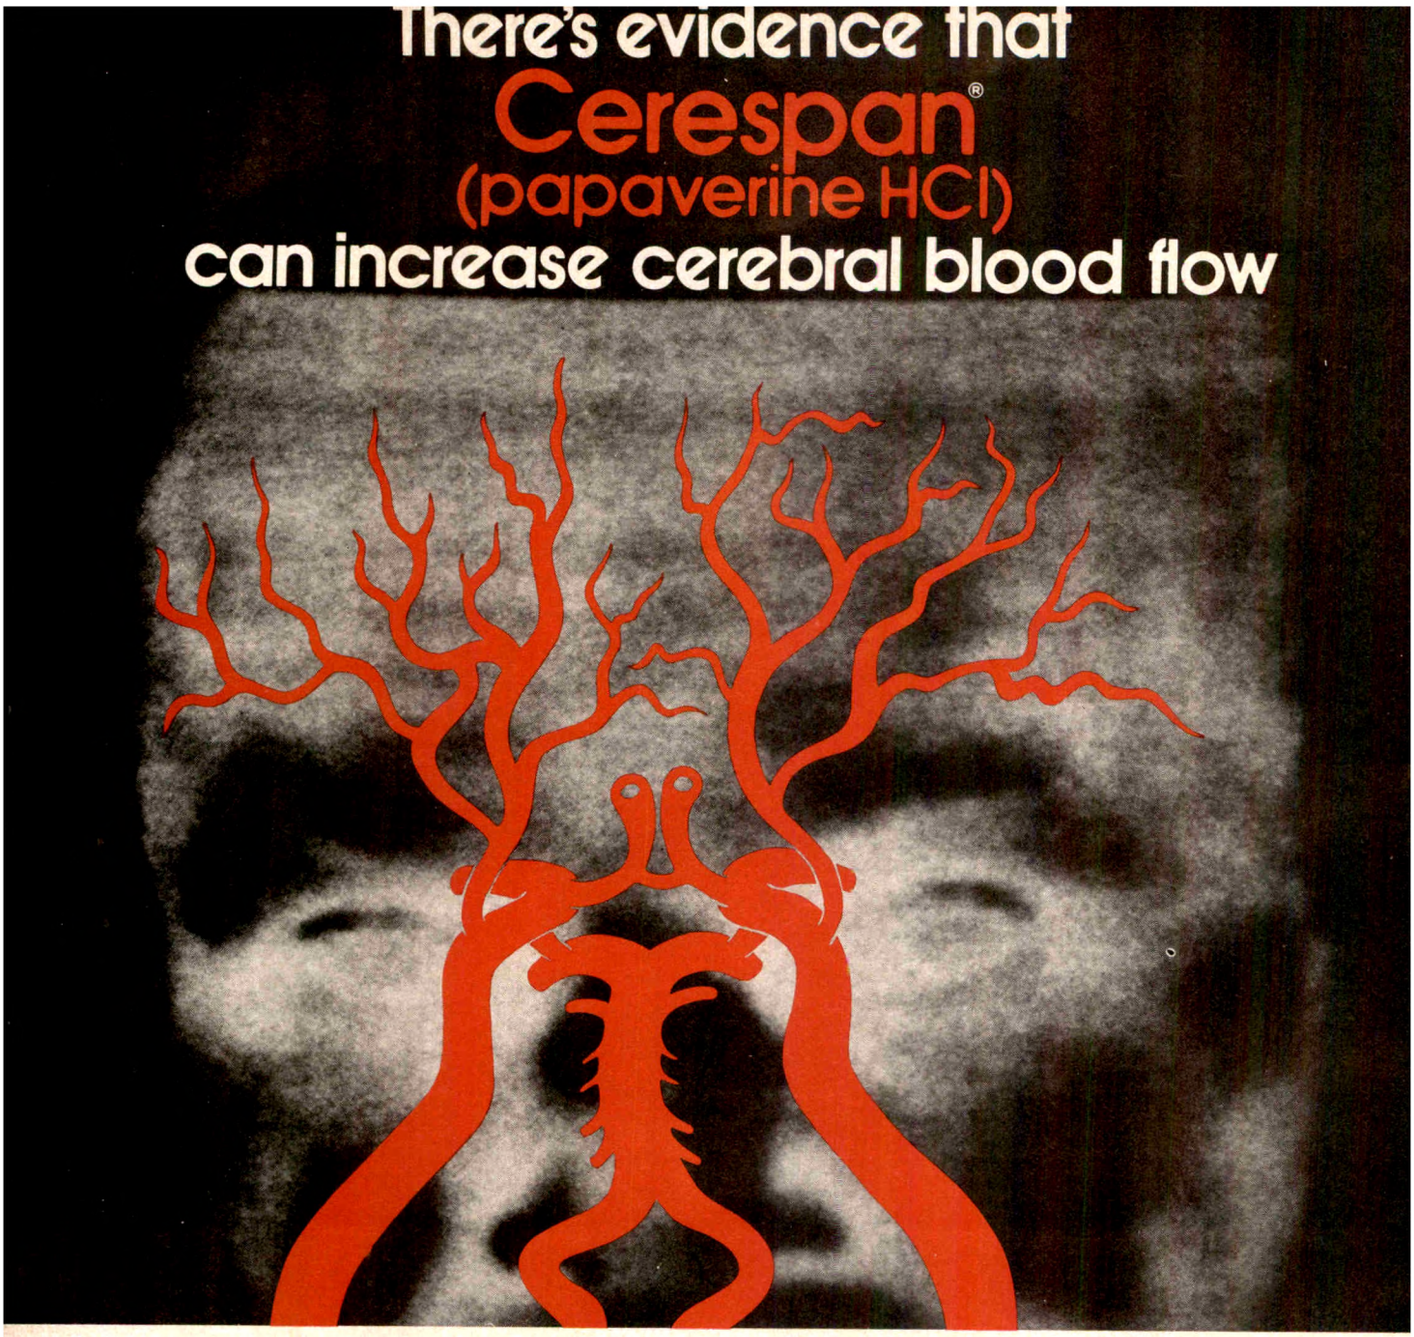
There's evidence that Cerespan® (papaverine HCl) can increase cerebral blood flow



"... improvements in the thermograms were attributed to an increase in cerebral blood flow due to the direct vasodilating effect of Cerespan (papaverine hydrochloride)."*

To help increase blood flow to the brain ... to help lessen the impact of transient ischemic attacks

Simple q. 12 h. dosage encourages adherence to the therapeutic regimen

*Karpman, H. L. and Sheppard, J. J.: Effect of Papaverine Hydrochloride on Cerebral Blood Flow as Measured by Changes in Thermograms in Patients with Cerebrovascular Disease. Data on file, Department of Medical Research, USV Pharmaceutical Corp.

Cerespan® 150 mg. in micro-dialysis cells (papaverine HCl) q. 12 h.

BRIEF SUMMARY: Each Cerespan capsule contains papaverine HCl 150 mg. in micro-dialysis cells.
Indications and Dosage: For relief of cerebral and peripheral ischemia associated with arterial spasm, 1 capsule q. 12 h.
Precautions: Use with caution in glaucoma. Discontinue drug if hepatic hypersensitivity with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests occur.
Adverse reactions: Anorexia, nausea, abdominal distress, constipation or diarrhea, skin rash, malaise, drowsiness, vertigo, sweating and headache.
Supplied: Bottles of 100 and 1000; drums of 5000; single-dose blister pack, boxes of 500.

Right Ventricular Volume in Congenital Heart Disease

ELIZABETH A. FISHER, MD
IRA W. DuBROW, MD
ALOIS R. HASTREITER, MD, FACC

Chicago, Illinois

Methods for angiographic determination of right ventricular volume were compared in right ventricular cast studies and in vivo using a semiautomated Simpson's rule, elliptical and rectangular cross sections and a simple geometric model, a prism with a triangular base. In cast studies excellent correlation coefficients were obtained for all three methods (r = 0.97 to 0.98). In vivo, excellent linear correlation was obtained when the methods were compared (r = 0.98 to 0.99, P <0.001).

Normal mean right ventricular volumes (70 patients) in milliliters per square meter ±1 standard deviation were: end-diastolic volume 64 ± 15, end-systolic volume 25 ± 8 and stroke index 39 ± 11; ejection fraction was 0.61 ± 0.08. Normal mean left ventricular end-diastolic and end-systolic volumes (77 patients) were lower (59 and 19, respectively), and ejection fraction was higher (0.68). Stroke index was the same. Other results showed decreased mean end-diastolic and end-systolic volumes and stroke index, increased ejection fraction (P <0.001, <0.025, <0.025 and <0.005, respectively) in 34 patients with pulmonary stenosis, and increased mean end-diastolic and end-systolic volumes and stroke index (P <0.001, <0.050, <0.001, respectively) in 11 patients with an atrial left to right shunt. In both groups postoperatively, as well as in patients with a ventricular septal defect, tetralogy of Fallot or myocardial disease, mean volumes and ejection fraction were normal.

We conclude that a geometric model can be used to determine right ventricular volume with accuracy. In children, the right ventricle can adapt reversibly to chronic increases in afterload and preload; it is not necessarily overloaded by a ventricular septal defect or tetralogy of Fallot, and it is relatively unaffected by severe myocardial disease.

Simpson's rule has been shown to be an accurate method for angiographic determination of right ventricular volume.[1,2] This method has had limited clinical use and right ventricular volume data are scanty because of the time-consuming and tedious measurements and calculations required when the technique is performed manually. The purpose of this paper is threefold: (1) to describe a semiautomated system for right ventricular volume determination by Simpson's rule; (2) to compare this system with a simple geometric model used as a basis for simplified manual right ventricular volume determination; and (3) to present right ventricular volume data in a large group of infants and children, with both normal and abnormal right ventricles.

Methods

Ventricular Volume Determinations

Right ventricular casts: Radiopaque plastic casts of dog, monkey, baboon and lamb hearts were made, utilizing Batson's no. 17 Anatomical Corrosion Compound (Polysciences, Inc., Rydal, Pa.). Forty-eight casts with right

From the Division of Pediatric Cardiology, University of Illinois Hospital and Abraham Lincoln School of Medicine, Chicago, Ill. This study was supported in part by The University of Illinois Foundation Goodenberger Medical Research Grant 2-44-33-66-3-14. Manuscript accepted November 26, 1974.

ventricles ranging in volume from 0.36 to 95.48 cc were prepared. The hearts were pressure-fixed[3] and injected with the partially polymerized liquid mixed with barium sulfate paste to make it radiopaque. After the casts hardened the heart tissue was dissected free, the residual tissue was digested with concentrated potassium hydroxide solution, and the respective chamber casts were cut apart. True volumes were determined by water displacement. Radiographic volumes were determined from biplane frontal and lateral radiographs of the casts placed in anatomic position. The films were projected and the cast outlines traced by hand on paper. Plastic grids with 1 by 1 cm lead lines were radiographed at the center of each cast in both projections for purposes of correction for X-ray magnification.

Simpson's rule: Volumes were calculated by Simpson's rule, assuming the cross-sectional areas to be either elliptical or rectangular. Manually, the drawings of the frontal and lateral projections were divided into 10 equally spaced sections by 11 horizontal lines. The volume of each section was $\pi \cdot X/2 \cdot Y/2 \cdot h$ for the elliptical cross section (where X is the frontal diameter and Y is the lateral diameter of the ellipse and h is the height of the section). For the rectangular cross section, the volume of each section was $X \cdot Y \cdot h$ (where X is the frontal length and Y the lateral length of the rectangle and h is the height of the section). The sections were then summed to give the volume of the solid, as

$$\frac{\pi h}{3}\left[\frac{1}{4}(X_0Y_0 + X_{10}Y_{10}) + \right.$$

end segments

$$(X_1Y_1 + X_3Y_3 + \ldots + X_9Y_9) +$$

odd-numbered segments

$$\left.\frac{1}{2}(X_2Y_2 + X_4Y_4 + \ldots + X_8Y_8)\right]$$

even-numbered segments

for the elliptical cross-section and

$$\frac{4h}{3}\left[\frac{1}{4}(X_0Y_0 + X_{10}Y_{10}) + \right.$$

end segments

$$(X_1Y_1 + X_3Y_3 + \ldots + X_9Y_9) +$$

odd-numbered segments

$$\left.\frac{1}{2}(X_2Y_2 + X_4Y_4 + \ldots + X_8Y_8)\right]$$

even-numbered segments

for the rectangular cross section.

By the *semiautomated* method, the drawings were traced with an electronic planimeter (Numonics Corporation, electronic graphics calculator) linked to a programming calculator (Wang 700C series) and plotting output writer (Wang 702 series). Using the X, Y coordinates the calculator was programmed to automatically divide the drawings by horizontal lines spaced at 5 mm intervals and to calculate the volumes by the formulas given above.

Prism method: By inspection of the casts it was considered that a prism with a triangular base was the *simple* geometric solid that most closely corresponded to the shape of the right ventricular casts. The frontal and lateral projections were assumed to be rectangular and to form the sides of a triangle in the horizontal plane.

The model and derivation of the formula for its volume are shown in Figure 1A. Simplified, the formula is $A_f \cdot A_1/2L$, where A_f is the area of the frontal projection, A_1 is the area of the lateral projection and L is the average of the frontal and lateral lengths. Frontal length was measured as the length of a perpendicular drawn between two parallel lines that intersected the top and bottom of the frontal projection. Lateral length was measured from the top of the pulmonary valve to the apex of the lateral projection (Fig. 1B). Areas were determined by planimetry.

For each method, calculated volumes were plotted against true volumes and a linear regression analysis was made.

In vivo volume determinations: Right and left ventricular volumes were determined from biplane cineangiocardiograms performed as a part of routine diagnostic cardiac catheterization studies. All patients were studied in the postabsorptive state. Only patients older than age 6 months were sedated with use of meperidine (Demerol®), promethazine (Phenergan®) and methazine (Sparine®) in intramuscular doses of 0.5 to 1 mg/kg, 0.25 to 0.5 mg/kg and 0.25 to 0.5 mg/kg, respectively. For patients older than age 2 years, additional sedation with droperidol-fentanyl (Innovar®), 0.025 cc/kg up to 1 cc intravenously, was given if required. Biplane cineangiocardiograms were filmed at 64 or 80 frames/sec after the high speed injection of 1 to 2 cc/kg of contrast medium (Conray 400®) into the inferior vena cava or right atrium. Cycles with premature contractions were not used. The earliest cardiac cycle with sufficient contrast to allow accurate tracing of chamber outlines was utilized, and in most cases right and left heart volumes could be determined from the same injection. Correction was made for X-ray magnification by a grid system as described earlier.

Comparison of right and left ventricular volumes: Left ventricular volumes were determined by the standard Dodge biplane method,[4] assuming the left ventricle to be an ellipse of revolution. The volume was calculated as $4\pi/3 \cdot L_1/2 \cdot L_2/2 \cdot L_3/2$, where L_1 = the longer of two lines drawn from the center of the aortic valve to the apex in the frontal and in the lateral projections, L_2 = the short axis of the frontal projection and L_3 = the short axis of the lateral projection. L_1 was measured directly; L_2 and L_3 were calculated by the formulas: $L_2 = 4A_f/\pi L_1$ and $L_3 = 4A_1/\pi L_1$, where A_f and A_1 are the areas of the frontal and lateral projections of the ventricle, respectively. Volumes were corrected by a regression equation determined from left ventricular cast studies: $V' - 0.85V$, where V' = corrected volume and V = calculated volume.

As a test of the methods, angiographic stroke volumes of the right and left ventricles were compared in 91 infants and children with no shunts or valvular insufficiency. Right and left ventricular volumes and ejection fractions were also compared in two groups of patients believed to have normal right or left heart chambers (70 and 77 patients, respectively).

Comparison of methods: Angiographic right ventricular volumes were determined by Simpson's rule (semiautomated method), elliptical and rectangular cross sections and the prism method in 218 infants and children and the results compared after correction with the appropriate regression equations obtained from the cast studies.

Case Material

Normal right ventricular volumes: Right ventricular volume was determined in 70 infants and children believed to have a normal right heart chamber. All patients in this group had a peak systolic pressure of less than 35 mm Hg and an end-diastolic pressure of less than 5 mm Hg in the

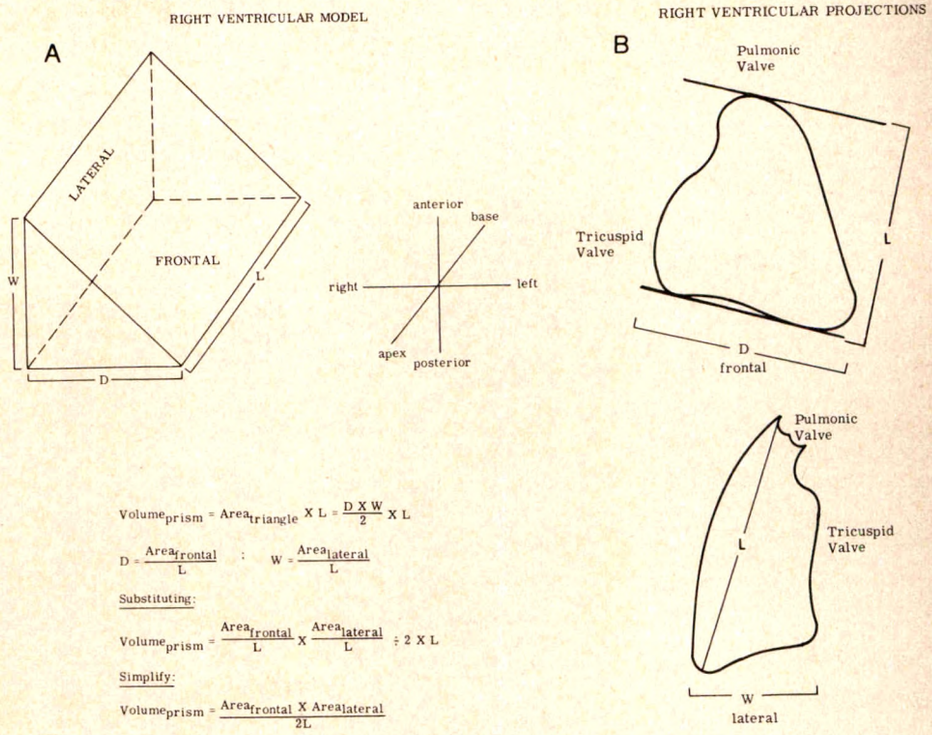

FIGURE 1. Right ventricular model **(A)** and projections **(B).** Corresponding measurements are indicated. D = average width in frontal plane; L = average length; W = average width in lateral plane.

right ventricle. The group contained 31 patients with normal hemodynamic status studied because of arrhythmias, pulmonary disease, mediastinal masses, abnormal electrocardiograms or atypical murmurs. Nine patients had a small patent ductus arteriosus and five had undergone surgical closure of a patent ductus. Four patients had mild pulmonary stenosis (peak systolic gradient less than 15 mm Hg), 10 had mild to moderate aortic stenosis and 2 had undergone surgery for aortic stenosis. Five patients had mild to moderate mitral insufficiency, one mitral stenosis, one mild aortic insufficiency and two systemic hypertension. Their ages ranged from 0.5 to 21.75 years and body surface areas from 0.35 to 1.83 m^2.

Abnormal right ventricular volumes: Five groups of patients with an abnormal right ventricle were studied and the results compared with normal findings.

Group 1 consisted of 44 patients with pulmonary stenosis. Ten of these had undergone surgery at least 1 year previously and had a residual peak systolic gradient from the pulmonary artery to the right ventricle of less than 20 mm Hg and a right ventricular peak systolic pressure less than 40 percent of systemic peak systolic pressure. Only one patient had radiographic cardiac enlargement postoperatively, and he had significant pulmonary insufficiency. The ages of the patients studied postoperatively ranged from 1.75 to 16.5 years and body surface areas from 0.51 to 1.73 m^2. Of the 34 patients studied preoperatively, 20 had a pressure gradient of less than 50 mm Hg; the remainder (14 patients) had a gradient of 50 mm Hg or more. In 8 patients of this group peak right ventricular pressure was less than 40 percent of systemic, in 11 it was 40 to 60 percent, in 7 it was 60 to 100 percent and in 8 it was 100 percent of systemic pressure or greater. The ages of the patients studied preoperatively ranged from 0.75 to 23.0 years and body surface areas from 0.36 to 1.72 m^2.

Group 2 contained 21 patients with a left to right shunt at the atrial level. Eleven of these were studied preoperatively, nine with a secundum atrial septal defect, one with a primum atrial septal defect and one with total anomalous pulmonary venous drainage. Their ages ranged from 0.83 to 16.67 years and body surface areas from 0.31 to 1.60 m^2. Ten patients of this group were studied postoperatively, two who had undergone correction of total anomalous pulmonary venous drainage, one with repair of a secundum atrial septal defect and seven with repair of a primum atrial septal defect. They were studied 0.17 to 5.0 years postoperatively, with seven studied 1 to 2 years postoperatively. Their ages ranged from 0.17 to 16.33 years and body surface areas from 0.34 to 1.70 m^2. None had significant radiographic cardiac enlargement or residual lesions postoperatively.

Group 3 contained 49 patients with a ventricular septal defect. Sixteen had a moderate to large subaortic defect with a pulmonary to systemic blood flow ratio greater than 1.5:1. Fifteen had a small shunt with a pulmonary to systemic flow ratio less than 1.5:1; two in this group had had a previous pulmonary arterial banding. The ages of these 31 patients ranged from 0.04 to 23.42 years and body surface areas from 0.20 to 1.87 m^2. The remaining 18 patients in this group had undergone operation at least 1 year previously. Their ages ranged from 0.45 to 16.33 years and body surface areas from 0.45 to 1.60 m^2. Only one had a large residual defect.

Group 4 contained 22 patients with tetralogy of Fallot, 11 studied preoperatively and 11 studied at least 1 year after operation. In the patients studied postoperatively, ages ranged from 4.67 to 17.42 years and body surface areas from 0.75 to 1.89 m^2. Two had significant pulmonary insufficiency, one manifesting radiographic cardiac enlargement. One postoperative patient had a residual ventricular septal defect with small left to right shunt, and one had significant residual pulmonary stenosis. In the patients studied preoperatively ages ranged from 0.17 to 5.33 years and body surface areas from 0.26 to 0.77 m^2. Although one patient had significant pulmonary insufficiency, his heart size was radiographically normal.

TABLE I

Regression Analysis of Right Ventricular Cast Studies

Method	r value	SEE	Regression Equation
Simpson's ellipse, manual	0.97	5.79	$V' = 0.77V - 2.92$
Simpson's rectangle, manual	0.97	5.79	$V' = 0.60V - 2.99$
Simpson's ellipse, auto	0.97	3.77	$V' = 0.71V - 1.15$
Simpson's rectangle, auto	0.97	3.76	$V' = 0.56V - 1.15$
Prism	0.98	2.94	$V' = 1.16V - 1.04$

auto = semiautomated method; SEE = standard error of the estimate; V = calculated volume; V′ = corrected volume.

Group 5 contained 12 patients believed to have myocardial disease. Ten had endocardial fibroelastosis, three with an associated tiny ventricular septal defect. Two had a primary cardiomyopathy (one due to Pompe's disease and one of unknown origin). All had an abnormal electrocardiogram. Nine manifested left ventricular enlargement, one right ventricular enlargement, one combined ventricular enlargement and one Wolff-Parkinson-White syndrome, type B. Eight had radiographic cardiac enlargement, and six had hepatomegaly at the time of study. Eight had a history of congestive heart failure, but only three had failure at the time of study. Eight patients were receiving digoxin. At cardiac catheterization all standard hemodynamic measurements were normal in seven patients; four had elevated left ventricular end-diastolic pressure, one had elevated right ventricular end-diastolic pressure and one had elevated right and left ventricular end-diastolic pressures. Cardiac output, measured by the Fick method in only four patients, was normal. These patients' ages ranged from 0.08 to 14.98 years and body surface areas from 0.2 to 1.54 m^2.

Results

Right ventricular casts: Regression analysis comparing true and calculated cast volumes (Table I) yielded high correlation coefficients for all methods. Standard errors were low for all methods and lowest (2.94) for the prism method. The Y intercepts for all methods were about 1 cc, making them applicable to calculation of small volumes. For the respective cross-sectional models (ellipse or rectangle), the regression equations for Simpson's rule were quite similar using either the manual or semiautomated method.

In vivo volume determinations—comparison of right and left ventricular volumes: There was a very high correlation between left and right ventricular stroke volumes in patients with no shunts or valvular insufficiency ($r = 0.94$, $P < 0.001$). Normal mean left ventricular end-diastolic and end-systolic volumes were slightly lower, and ejection fraction was slightly higher than corresponding right ventricular values (Table II).

Comparison of methods: The volumes calculated by Simpson's rule, when corrected with the appropriate regression equation from the cast studies, were nearly identical for either elliptical or rectangular cross section ($r = 0.99$, $P < 0.001$). Comparison of these values with those calculated by the prism method also gave excellent correlation for the normal group (Fig. 2A) as well as all abnormal groups (Fig. 2B) ($r = 0.98$, $P < 0.001$ for both). Despite the very high correlation between the prism method and Simpson's rule, in some of the abnormal groups the volumes (compared using the Student t test for paired data) were significantly different (Table III).

In the remainder of this section, all volumes discussed are for Simpson's rule, elliptical cross section. Corresponding values for the prism method are given in Table III.

Normal right ventricular volumes: In the 70 patients believed to have a normal right ventricle, mean end-diastolic volume/m^2 body surface area was 64 ± 15 (1 standard deviation) ml. Only seven of the patients were less than 1 year of age and their mean end-diastolic volume/m^2 was 60 ± 15 ml, not significantly lower than that for the total group or the group over 1 year of age (64 ± 16). There was a high linear correlation of end-diastolic volume with age ($r = 0.87$, $P < 0.001$) and with body surface area ($r = 0.92$, $P < 0.001$). When normal volumes were ex-

Gentzler et al.[2]	RV	Adult	81	39	42	0.51
Kennedy et al.[7]	LV	Adult	70	24	45	0.67

EDV/m^2 = end-diastolic volume per square meter of body surface area; EF = ejection fraction; ESV/m^2 = end-systolic volume per square meter of body surface area; LV = left ventricle; RV = right ventricle; SI = stroke index.

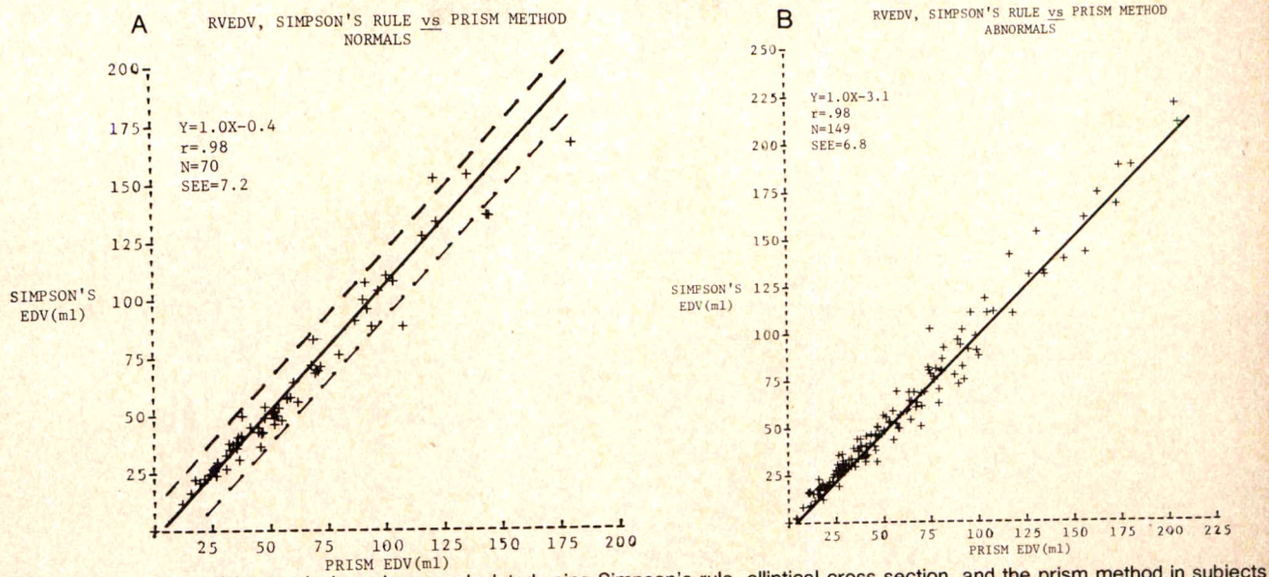

FIGURE 2. Comparison of right ventricular volumes calculated using Simpson's rule, elliptical cross section, and the prism method in subjects with normal **(A)** and abnormal **(B)** conditions. EDV = end-diastolic volume; N = number of cases; RVEDV = right ventricular end-diastolic volume; SEE = standard error of the estimate; X = volume calculated by prism method; Y = volume calculated by Simpson's rule.

pressed per square meter of body surface area, there remained a small but significant correlation with age (r = 0.40, P <0.01). Normal values for end-systolic volume/m^2, stroke index and ejection fraction are given in Table III.

Abnormal right ventricular volumes: The data are summarized in Table III and shown graphically in Figures 3 to 7. *In Group 1* (pulmonary stenosis) values for mean end-diastolic volume/m^2, end-systolic volume/m^2 and stroke index were below normal (P <0.001, <0.025 and <0.025, respectively). Mean ejection fraction was higher than normal (P <0.005). Six patients had an end-diastolic volume/m^2 more than 2 standard deviations below the normal mean value. In these patients right ventricular pressure was 35 percent of systemic pressure in one, 57 percent of systemic pressure in one and from 84 to 113 percent of systemic pressure in four. When the subjects were considered as groups with a right ventricular pressure of less than 40 percent, 40 to 60 percent, 60 to 100 percent and 100 percent or more of systemic pressure, respectively, mean volumes were not statistically different for the groups (end-diastolic volume/m^2 51 ± 11, 52 ± 14, 41 ± 14 and 56 ± 18, respectively). The third group (right ventricular pressure 60 to 100 percent of systemic pressure) contained four of the six patients with an end-diastolic volume more than 2 standard deviations below the normal mean value. When end-diastolic volume in milliliters was plotted against body surface area (Fig. 3) four points fell outside the 90 percent confidence limits for normal subjects. These corresponded to two patients with a right ventricular pressure 60 to 100 percent of systemic pressure, one patient with a right ventricular pressure 40 to 60 percent of systemic pressure and one with a right ventricular pressure less than 40 percent of systemic pressure. Postoperatively, mean volumes and ejection fraction were normal. The one patient with an end-diastolic volume more than 2 standard deviations above the normal mean value had pulmonary insufficiency and radiographic cardiac enlargement.

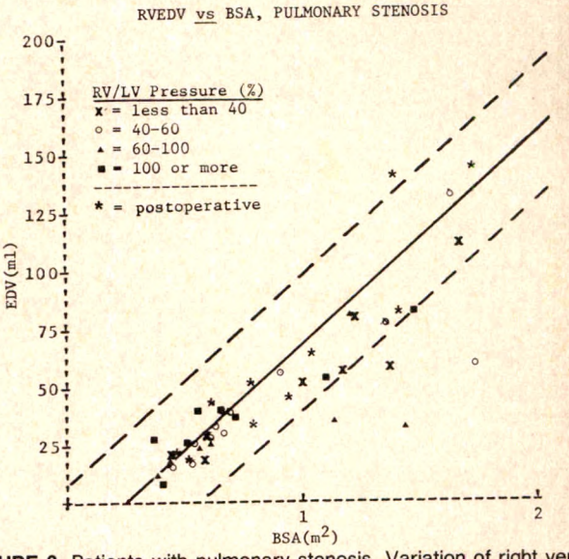

FIGURE 3. Patients with pulmonary stenosis. Variation of right ventricular end-diastolic volume (RVEDV) with body surface area (BSA). Normal mean and 90 percent confidence limits are indicated by the **solid** and **dashed lines,** respectively. LV = left ventricular; RV = right ventricular.

In Group 2 (atrial left to right shunt) mean volumes were considerably above normal (end-diastolic volume/m^2, P <0.001; end-systolic volume/m^2, P <0.050; stroke index, P <0.001), but ejection fraction was normal. Postoperatively, volumes were at normal levels.

ASD = atrial left to right shunt; D = difference between volumes by Simpson's rule and by prism method; Myo = myocardial disease; N = normal; NS = not significant; P = prism; *P* = significance of difference from normal; PS = pulmonary stenosis; S = Simpson's rule; SD = Standard deviation; ToF = Tetralogy of Fallot; VSD = ventricula septal defect.

. *Group 3* (ventricular septal defect) had normal mean volumes with no difference found between patients with a large or small shunt or those studied before or after operation. The two patients with pulmonary arterial banding had low normal volumes.

In Group 4 (tetralogy of Fallot) the mean volumes both pre- and postoperatively were normal. One patient studied preoperatively had an end-diastolic volume more than 2 standard deviations above the normal mean value (124 ml/m^2). He did not have radiographic cardiac enlargement, but his right ventricular end-diastolic pressure was elevated for age (8.6 mm Hg). A second patient studied preoperatively had high normal end-diastolic volume (94 ml/m^2). He had moderate pulmonary insufficiency, but his end-diastolic pressure and radiographic heart size were normal. The one patient studied postoperatively with an end-diastolic volume/m^2 slightly above 2 standard deviations from the normal mean value (95 ml) had significant pulmonary insufficiency. Ejection fraction was decreased in this patient (0.36) and in one other patient studied postoperatively (0.41). In neither one was heart size increased radiographically. Two other patients studied postoperatively had an end-diastolic

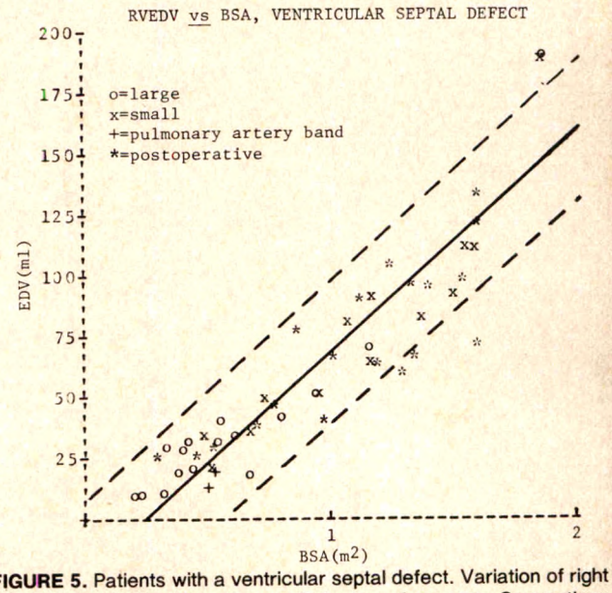

FIGURE 5. Patients with a ventricular septal defect. Variation of right ventricular end-diastolic volume with body surface area. Conventions as in Figure 3.

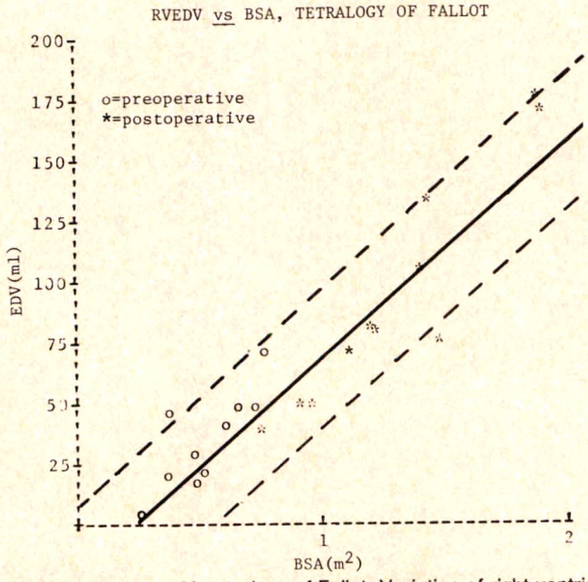

FIGURE 6. Patients with tetralogy of Fallot. Variation of right ventricular end-diastolic volume with body surface area. Conventions as in Figure 3.

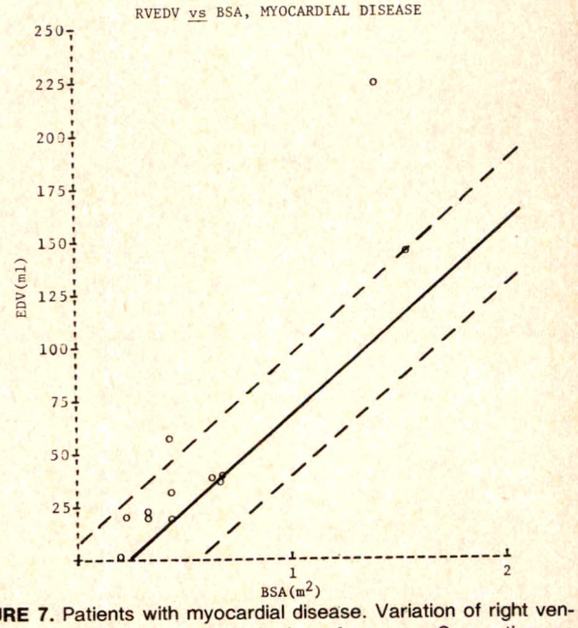

FIGURE 7. Patients with myocardial disease. Variation of right ventricular end-diastolic volume with body surface area. Conventions as in Figure 3.

volume at the upper limits of normal (94 and 91 ml/m^2, respectively). Both had moderate pulmonary insufficiency, and one had cardiac enlargement by X-ray examination.

In Group 5 (myocardial disease) mean end-diastolic volume/m^2, mean end-systolic volume/m^2 and mean ejection fraction were normal. Only two patients in this group had an end-diastolic volume more than 2 standard deviations above the normal mean value (135 and 161 ml/m^2, respectively). Right ventricular stroke volume was increased in the former patient (65 ml/m^2). That patient had a normal ejection fraction (0.52), but ejection fraction was decreased (0.34) in the other. Corresponding left ventricular values for these patients were: end-diastolic volume/m^2 203 and 219 ml, stroke index 76 and 57 ml, ejection fraction 0.37 and 0.36 and end-diastolic pressure 26 and 10 mm Hg. Cardiac output (Fick method) was 4.9 liters/min per m^2 in the second patient, and 2.9 liters/min per m^2 (with use of an assumed oxygen consumption) in the first patient. The second patient had elevated right ventricular end-diastolic pressure (10 mm Hg). Both had clinical evidence of right-sided heart failure with hepatomegaly. The first patient had massive mitral insufficiency believed to be secondary to cardiac dilatation.

Discussion

The use of an electronic planimeter linked to a programming calculator and output writer greatly facilitates the application of Simpson's rule to right ventricular volume determination. It is comparable in accuracy to the manual method, but the equipment is expensive and is not available in most laboratories. Therefore, Simpson's rule remains limited in its clinical usefulness. The prism method requires no such equipment, the measurements are easily made manually and the calculations are quite simple.

Objections to the use of a geometric model have been raised on the basis that it is less accurate than Simpson's rule. However, in a previous report[2] comparing Simpson's rule with a geometric model in right ventricular case studies, little difference was shown in *r* values between the methods. No in vivo volume data were presented. Arcilla et al.[8] and Thilenius and Arcilla[6] used a geometric model but did not compare results with Simpson's rule. Graham et al.[1] compared Simpson's rule with two geometric models, finding little difference in the cast studies; they did not present a comparison of in vivo volumes by the various methods. Our investigation indicates that a simple geometric model, a prism with a triangular base, can be compared in accuracy with Simpson's rule both in cast studies and in in vivo volume calculations.

Normal Ventricular Volumes

In comparing our right and left heart volumes we found the right ventricle to be slightly larger and to have a lower ejection fraction than the left. Other studies, one in infants and children[6] and another in adults,[2,9] have found the same relation between the right and left ventricles, but Graham et al.[1,8] did not demonstrate any such differences in their studies (Table II). Although further data are needed to clarify this issue, it appears that the right ventricle is slightly larger than the left.

Our normal data are comparable with those of previous reports,[1,6] but we failed to demonstrate significantly lower volumes in infants. However, our youngest "normal" patient was 6 months old and only 7 of the 70 patients were less than 1 year of age, whereas in Graham's study 6 patients were 5 months of age or younger and 7 of 16 in the normal group were less than 1 year of age.

After normalization of volumes for body surface area, there remained a significant positive correlation with age. This observation is in agreement with other investigators' findings of smaller volumes in young infants. Also, in this regard, Gentzler et al.[2] reported in adults with normal right heart chambers higher values than those reported by others[1,6] in children.

Abnormal Right Ventricular Volumes

Pulmonary stenosis: In contrast to Graham et al.,[1] we found a small but definite decrease in mean right ventricular volume and stroke index, plus increased ejection fraction, in patients with pulmonary stenosis. Similar changes have been reported in left ventricular volume and ejection fraction in pediatric patients with aortic stenosis.[5] The right ventricle, as well as the left, is capable of ejecting an increased fraction of its volume of blood when exposed to a chronic increase in afterload. Whether this is due to increased contractility or to muscular hypertrophy remains to be investigated. The finding of normal mean volumes and ejection fraction in postoperative patients in this group lends support to the presence of a reversible adaptation to increased afterload in these patients. The individual patient in the postoperative group with increased volume had increased preload; thus, his condition was analogous to that of patients in Group 2 (atrial left to right shunt).

Gentzler et al.[2] described only two adult patients with pulmonary stenosis, both of whom had low values for end-diastolic volume (more than 2 standard deviations below the normal mean value in one). Both had a normal ejection fraction. Whether or not long-term pressure load of the right ventricle leads to compromise of function remains to be studied.

Atrial septal defect: Demonstration of a large increase in right ventricular volume in atrial left to right shunt is in agreement with findings by Graham et al.[1] in atrial septal defect and total anomalous pulmonary venous drainage and by Gentzler et al.[2] in patients with tricuspid insufficiency and atrial septal defect. Decreased ejection fraction in the patients in the latter study may have been due to long-term volume overload (increased preload) or to coronary artery disease or myocardial disease of other causes. In the absence of other such factors the right ventricle adapts to increased preload by increased end-diastolic and end-systolic volumes as well as increased

stroke index, probably through the Starling mechanism. The finding of normal or nearly normal volumes postoperatively is evidence for a reversible adaptation to increased preload in children.

Ventricular septal defect: No data are available on in vivo right ventricular volume in ventricular septal defect in children. Gentzler et al.[2] reported findings in two adult patients with a ventricular septal defect, one of whom also had right ventricular hypertension. Right ventricular volume was increased in the latter patient and normal in the other. In our group of 34 patients ventricular septal defect did not in most cases result in volume overload of the right ventricle. It may be that the site of the defect (in our study group all moderate to large defects were subaortic) results in shunting directly from the left ventricle to the pulmonary artery without overloading the right ventricle. Patients with a large muscular ventricular septal defect might then be expected to have an enlarged right ventricle.

Tetralogy of Fallot: Patients with tetralogy of Fallot generally have normal heart size by X-ray examination, and this correlates well with our finding of normal mean right ventricular volume in this group. The lesion is a complex one and may, in the evolution of the disease, present predominantly a volume or a pressure load to the right ventricle. In general, the latter predominates and the right ventricle responds by hypertrophy but not enlargement. In the group of patients studied, right ventricular volume tended to be high normal or increased in the presence of pulmonary insufficiency, a situation resulting in increased preload.

Myocardial disease: Our finding of normal mean right ventricular volume in patients with myocardial disease is in accord with similar findings by Gentzler et al.[2] in 7 of 13 patients with myocardial compromise. It is also in agreement with clinical and pathologic evidence that myocardial disease affects primarily the left side of the heart. Since cardiac output was measured in only four of these patients it cannot be stated whether or not decreased cardiac output and then decreased preload to the right ventricle resulted in normal right ventricular volume. However, the finding of normal or increased right ventricular stroke volume is evidence against this premise.

In summary, we have shown that a simple geometric model can be used to determine angiographic right ventricular volume with accuracy and that the results correlate well with those obtained utilizing Simpson's rule. The normal right ventricle is slightly larger than the left and has a lower ejection fraction. In chronic pressure load or increased afterload, the right ventricle tends to be smaller than normal and ejection fraction is increased. In chronic volume load or increased preload it is larger than normal but has a normal ejection fraction. In ventricular septal defect, tetralogy of Fallot and myocardial disease, the right ventricle is generally normal in size.

Acknowledgment

We gratefully acknowledge the assistance of Dr. F. A. O. Eckner in preparation of the casts. We also thank Mr. Frank Domanszky, Ms. Audra Jarasius, Ms. Marilyn Williams and Mr. William Johnson for expert technical assistance.

Advances in Clinical Vectorcardiography

ALBERTO BENCHIMOL, MD, FACC
KENNETH B. DESSER, MD, FACC

Phoenix, Arizona

With use of the Frank lead system, still loop and timed vectorcardiograms were recorded in more than 5,000 patients subjected to complete right and left heart catheterization and selective coronary cineangiography. Data so obtained demonstrated clinical superiority of the vectorcardiogram over the standard 12 lead scalar electrocardiogram. Specific advantages of the vectorcardiogram include (1) recognition of undetected atrial and ventricular hypertrophy, (2) greater sensitivity in identification of myocardial infarction, and (3) superior capability for diagnosis of multiple infarctions in the presence of fascicular and bundle branch blocks. The timed biplane vectorcardiogram is as useful as any number of simultaneously recorded electrocardiographic leads for the analysis of complex arrhythmias and beat to beat changes in intraventricular conduction. Since the validity and usefulness of this technique have been established, it should become part of the routine noninvasive evaluation of patients with cardiovascular disorders.

Recent discussion at national scientific meetings and examination of current publications in cardiology indicate a resurgence of activity in the field of clinical vectorcardiography. The advent of aortocoronary bypass surgery has provided a major stimulus for such investigation, and papers have appeared describing the influence of cardiac revascularization on the vectorcardiogram.[1–3] Closely linked to these operative interventions has been the widespread application of cardiac catheterization and selective coronary arteriography. Prior to 1960 the diagnostic value of vectorcardiography could be validated only by postmortem examination. Fortunately, it is now possible to evaluate merits of the technique by correlation with angiographic and hemodynamic findings in living subjects. During the past 10 years we have had the opportunity of examining this correlation in more than 5,000 subjects with a variety of cardiac abnormalities.

The purpose of this paper is to review recent advances in clinical vectorcardiography. Furthermore, specific advantages of the vectorcardiogram over the standard scalar electrocardiogram will be discussed.

Vectorcardiographic Lead Systems

The multiplicity of lead systems has been a source of consternation to both neophytes and experienced vectorcardiographers. Ideally, the clinician or beginner might peruse basic papers relating to each method and thereby decide on the lead system of his choice. Unfortunately, he would encounter a maze of theoretical equations based on cube, triangle, parallelogram or tetrahedron torso projections.[4] Physicists notwithstanding, this confrontation could discourage even the most aggressive initiate, who might withdraw from vectorcardiography altogether. During the past 5 years, the literature on this subject, as well as discussion at postgraduate courses in basic and advanced vectorcardiography, has indicated that more than 85 percent of those interested in the technique utilize the Frank lead system. No investigator has demonstrated the *clinical* superiority of any other lead system and, with the

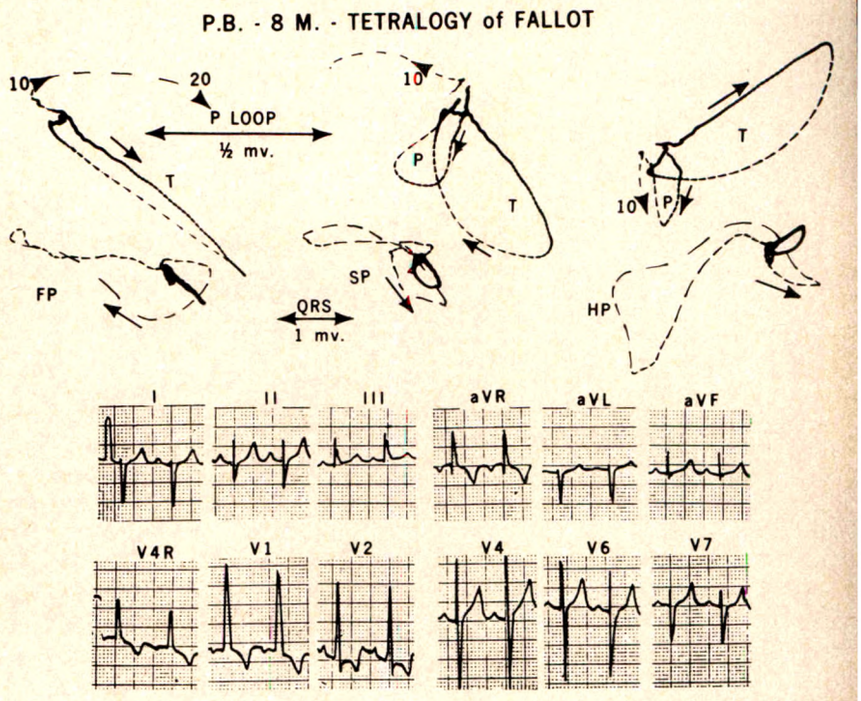

FIGURE 1. Vectorcardiogram and electrocardiogram from an 8 year old boy with tetralogy of Fallot. Note the inverted P wave in scalar lead V_1. Left sagittal plane (SP) and horizontal plane (HP) P loops are directed entirely anteriorly, diagnostic of right atrial enlargement. Large rightward directed QRS vector forces indicate right ventricular hypertrophy. FP = frontal plane.

thought of uniformity in mind, it is suggested that the Frank technique be adopted for use in all clinical vectorcardiographic laboratories. Interestingly, "majority rule" applies to electrocardiography, where the basic 12 lead tracing is generally accepted worldwide despite practical advantages of high lateral and posterior unipolar recordings. The laudable goal of uniformity[4] dictates that the most widely utilized system be applied for clinical vectorcardiograms, regardless of theoretical reservations concerning instability of the trielectrode technique for recording the horizontal plane forces.[5]

The frontal, left sagittal and horizontal plane Frank vectorcardiograms[6] described here were recorded with subjects in the supine position. The fourth intercostal space was used for placement of the chest electrodes.[7] All vectorcardiograms were recorded on a DR-8 Electronics for Medicine oscilloscopic photographic recorder using a vectorcardiographic channel. Still and timed vectorcardiograms[8,9] ("running loops") were magnified to provide better analysis of the P loop together with the initial and terminal components of the QRS loop. The loops were interrupted at 2 msec intervals.

Atrial Hypertrophy

Analysis of the vectorcardiographic P loop is clearly superior to the 12 lead electrocardiogram for the diagnosis of right, left and biatrial hypertrophy. Selvester and Haywood[10] found the timed vectorcardiogram more than three times as sensitive as the conventional electrocardiogram in detecting atrial abnormalities defined by conventional criteria. It is not widely appreciated that a large negative P wave deflection in lead V_1 is, under certain conditions, a sign of *right* and not of left atrial hypertrophy. In such cases the vectorcardiographic P loop may be directed entirely anteriorly and thus be diagnostic of right atrial hypertrophy. Examination of the P loop configuration demonstrates that the vast majority of the P loop area is projected on the negative side of the V_1 perpendicular, thus accounting for inverted P waves in this lead (Fig. 1). The absence of an inverted P wave in lead V_1 in association with low amplitude P waves of increased duration in the standard and augmented leads may render the electrocardiographic differential diagnosis of left atrial hypertrophy and intraatrial conduction defect quite difficult. In such cases the vectorcardiogram provides a definitive means of diagnosis. P loops of prolonged duration with major posteriorly oriented vector voltage indicate left atrial enlargement under these conditions (Fig. 2).

Ventricular Hypertrophy

Right ventricular hypertrophy: Numerous carefully performed studies have demonstrated superiority of the vectorcardiogram for the diagnosis of right ventricular hypertrophy. Hamer[11] concluded that the vectorcardiogram was more successful than the electrocardiogram in recognition of right ventricular hypertrophy in patients with mitral valve disease. Major diagnostic rightward directed QRS vector forces are frequently observed in the vectorcardiograms of subjects with mitral stenosis, pulmonary hypertension and borderline findings on scalar electrocardiograms (Fig. 3). With use of quantitative measurements, it has been ascertained that the vectorcardiogram is a reliable method for predicting right ventricular pressures in groups of patients with atrial septal defect,[12] pulmonary stenosis,[13] pulmonary heart disease and mitral stenosis.[14] Liebman et al.[15] noted that the Frank vectorcardiogram provided an excellent means of predicting normal versus abnormal pulmonary function tests in subjects with cystic fibrosis. Furthermore, it was demonstrated that the standard electrocardiogram was not as accurate as the Frank vectorcardiogram in this clinical setting.

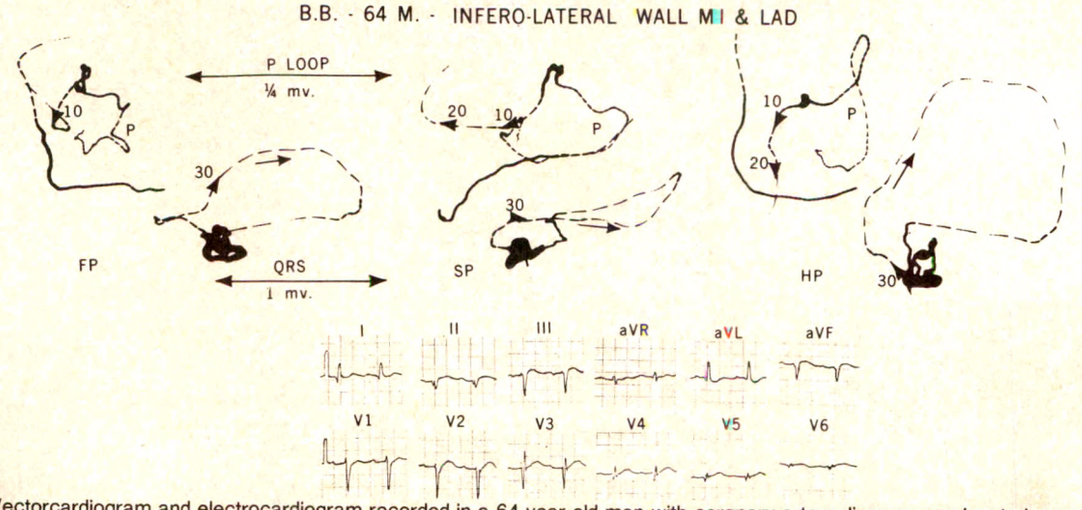

FIGURE 2. Vectorcardiogram and electrocardiogram recorded in a 64 year old man with coronary artery disease, an elevated mean pulmonary arterial "wedge" pressure and left atrial enlargement. The electrocardiogram shows low amplitude P waves of 0.12 second duration. The P wave in scalar lead V_1 is predominantly upright. P loop vectorcardiograms demonstrate large leftward and posteriorly directed forces with a 0.20 mv maximal P loop deflection vector in the horizontal plane. These findings are diagnostic of left atrial hypertrophy. There is associated electrovectorcardiographic evidence of an inferolateral wall myocardial infarction (MI) and abnormal frontal plane left axis deviation (LAD).

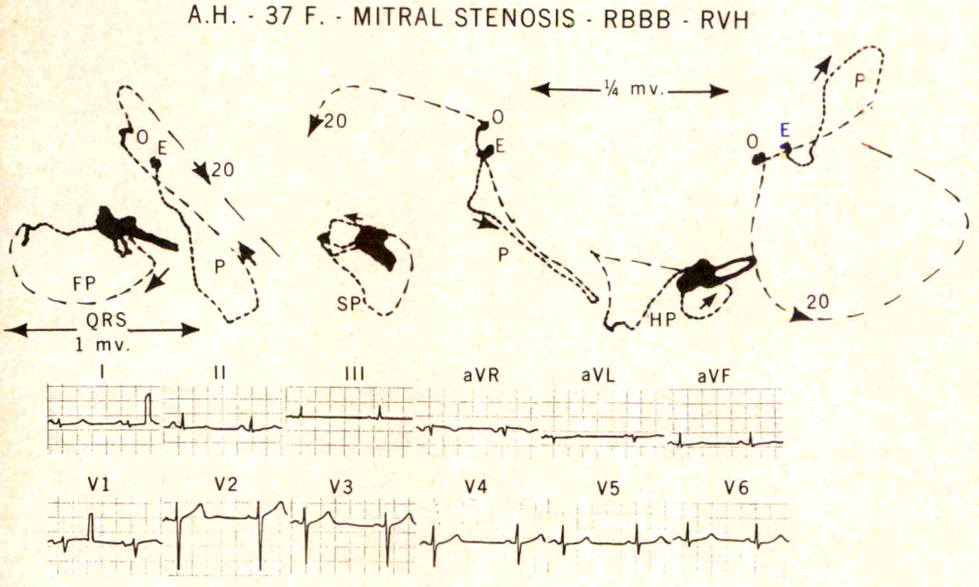

FIGURE 3. Vectorcardiogram and electrocardiogram from a 37 year old woman with mitral stenosis and pulmonary hypertension. The vectorcardiogram shows large posteriorly and leftward directed P loop voltage with major frontal plane and horizontal plane rightward oriented QRS forces. The QRS duration is 118 msec. A terminal delay in inscription of the QRS vectors suggests right bundle branch block (RBBB). These findings are diagnostic of left atrial and right ventricular enlargement (RVH), which were noted at cardiac catheterization. The scalar electrocardiogram demonstrates minor P wave notching and S waves in leads I, aVL, aVF and V_4 to V_6. Such electrocardiographic findings are nondiagnostic and frequently noted in normal women under the age of 40 years.

Some of the most striking discrepancies between vectorcardiographic and electrocardiographic interpretation are seen during the involutionary stages of right ventricular hypertrophy. The Frank vectorcardiogram has been shown to be a more sensitive technique for assessing such changes[16] (Fig. 4). Electrocardiograms in patients with diagnostic type "B" patterns of right ventricular hypertrophy in horizontal plane vectorcardiograms frequently show normal findings and are notoriously inaccurate in predicting right heart pressures.

Hamby et al.[17] found the analysis of Frank vectorcardiograms useful in distinguishing T loop abnormalities arising as a consequence of right ventricular hypertrophy from those related to ischemic heart disease. The absence of uncomplicated dextrocardia in an otherwise healthy adult patient with vectorcardiographic features of severe right ventricular hypertrophy should bring to mind the diagnosis of congenital complete defect of the left pericardium[18] (Fig. 5). Rotational and right heart mass displacement effects may produce these unusual vectorcardiographic findings, which are still incompletely understood.

Left ventricular hypertrophy: The diagnosis of left ventricular hypertrophy is facilitated by vectorcardiography, especially when there is coexisting myocardial infarction. Attenuation of leftward-directed forces by myocardial infarction may render the electrocardiographic diagnosis of left ventricular hypertrophy difficult. Under these conditions, the presence of posteriorly directed QRS forces of greater than 2.2 mv in the horizontal plane vectorcardiogram

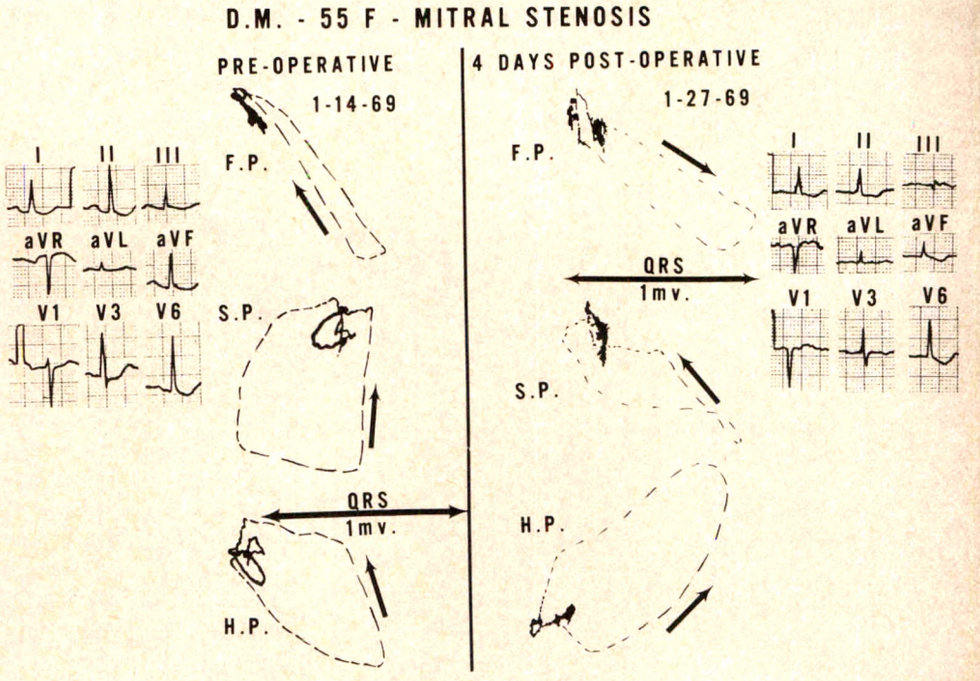

FIGURE 4. Preoperative and postoperative vectorcardiograms and electrocardiograms from a 55 year old woman with mitral stenosis. The preoperative vectorcardiogram shows counterclockwise rotation of the horizontal plane QRS loop with major anteriorly directed forces (type "B" right ventricular hypertrophy). The preoperative pulmonary arterial pressure was 50 mm Hg. Four days after mitral valve replacement the horizontal plane QRS loop is normally directed to the left and posteriorly. There are no significant differences between the preoperative and postoperative electrocardiograms. Furthermore, neither electrocardiogram suggests right ventricular hypertrophy. (Reproduced with permission.[58])

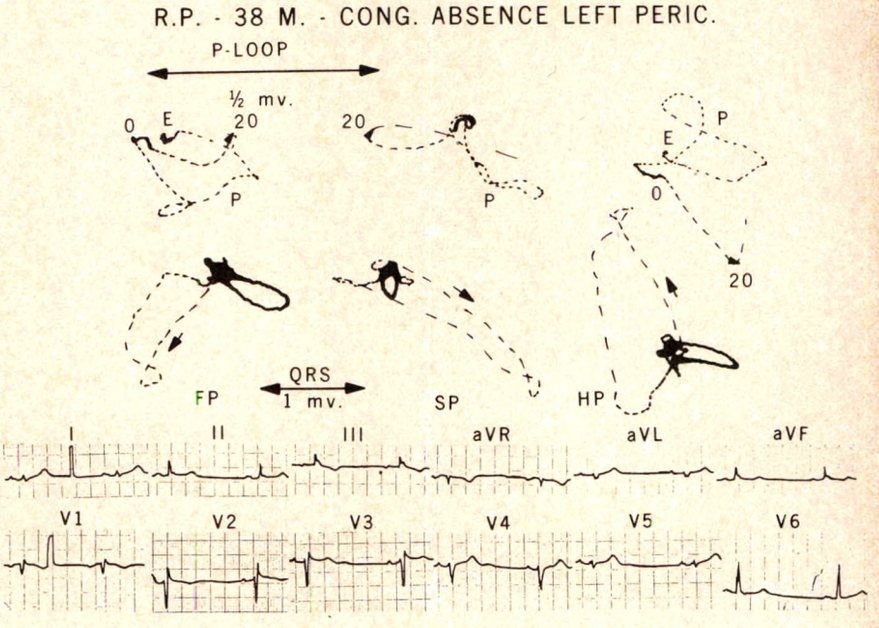

FIGURE 5. Vectorcardiogram and electrocardiogram recorded in a 38 year old man with congenital (CONG.) complete absence of the left pericardium (PERIC.) and no catheterization evidence of coronary, valvular or myocardial disease. The vectorcardiogram shows marked displacement of the QRS vectors to the right, with predominant counterclockwise rotation of the horizontal plane QRS loop. These findings simulate type "C" right ventricular hypertrophy.

is virtually diagnostic of underlying left ventricular hypertrophy. Roberts and Fowler[19] published data indicating utility of the Frank vectorcardiogram for serially estimating left ventricular pressure in established cases of transposition of the great arteries.

Electrovectorcardiographic tracings diagnostic of left ventricular hypertrophy and "strain" have been described in well conditioned athletes[20] with no catheterization evidence of heart disease. Whether such changes revert to the "normal" limits of measurement with more sedentary activity is currently unknown.

Biventricular hypertrophy: Varriale et al.[21] reported distinctive qualitative and quantitative features in the horizontal plane Frank QRS loop in two thirds of patients with clinical, hemodynamic and surgical evidence of biventricular hypertrophy. These changes consisted of abnormal posterior vector displacement and counterclockwise inscription along with an S loop of significant duration and magnitude. The frontal plane QRS loop provides additional evidence for right ventricular hypertrophy when the maximal QRS vector is directed toward the right and rotates in a clockwise fashion.

Coronary Artery Disease and Myocardial Infarction

McConahay et al.[22] performed an extremely well designed study on comparative quantitative analysis of the electrocardiogram and Frank vectorcardiogram in subjects with coronary artery disease. Correlations with the coronary arteriogram and left ventriculogram demonstrated that analysis of the quantitative vectorcardiogram was superior to the usual electrocardiographic analysis in the accurate detection of myocardial infarction. Detailed descriptions of the electrocardiographic and vectorcardiographic criteria required for diagnosis were presented, distinguishing this paper from many others on the subject. Maron et al.[23] found the vectorcardiogram to be a useful clinical tool for the diagnosis of significant coronary artery disease and large myocardial infarcts. Interestingly, there was no close correlation between the presence of smaller vector loop "bites" (0.08 to 0.13 mv, 4 to 6 msec) and angiographic data. In our experience the vectorcardiogram has proved to be a very accurate technique for diagnosing myocardial infarction.

Anterior infarction: In the absence of complete left bundle branch block, a posteriorly oriented 20 msec QRS vector is predictive of anterior wall myocardial fibrosis in more than 95 percent of cases (Fig. 6). The term fibrosis is specifically used to denote that coronary artery disease is but a single cause of fibrotic and poorly contracting myocardial segments. Valvular heart disease along with primary and secondary cardiomyopathies can also result in posteriorly[24] or superiorly oriented initial QRS vector forces. In such cases there is usually a substantial myocardial component contributing to the patient's disability. Care must be taken to obtain high resolution and magnification of initial QRS vector loop forces so that spurious diagnoses of myocardial fibrosis are not made (Fig. 7). On occasion, the direct light beam writing instrument has revealed preservation of initial anterior QRS forces that were obscured by P-T vectors on a camera-oscilloscopic device.

Inferior or lateral infarction: During hyperacute stages of myocardial infarction, the vectorcardiogram frequently reveals characteristic alterations

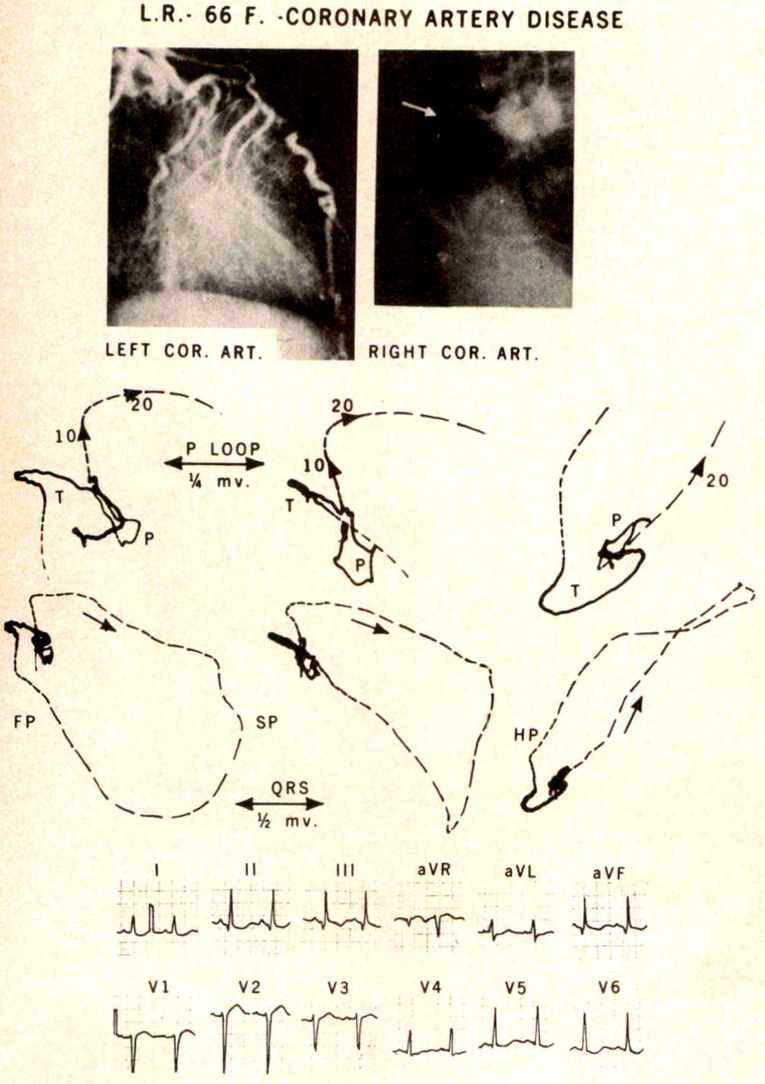

FIGURE 6. Selective coronary arteriograms, vectorcardiogram and electrocardiogram in a 66 year old woman with coronary artery disease. The coronary arteriograms demonstrate multiple obstructive lesions ranging from 80 to 95 percent stenosis in the right, left anterior descending and left circumflex vessels. The vectorcardiogram shows superiorly and posteriorly directed 25 msec QRS vectors diagnostic of, respectively, inferior and anteroseptal wall myocardial infarction. The scalar electrocardiogram demonstrates Q waves in leads II, III and aVF diagnostic of old inferior wall infarction. There is no electrocardiographic evidence of anteroseptal wall myocardial infarction. COR. ART. = coronary artery.

indicating major myocardial destruction at a time when the electrocardiogram shows tall and peaked T waves[25] alone. This advantage of the vectorcardiogram is particularly evident in the case of acute inferior[26] or lateral wall infarction (Fig. 8). When definite initial QRS vector (20 to 30 msec) criteria for inferior wall infarction are not met, there may be characteristic mid to late changes in the frontal plane QRS loop that suggest the correct diagnosis.[27] These alterations consist of large "bites" or unexpected directional deviations of the terminal QRS forces (Fig. 9).

Posterior infarction: The vectorcardiogram is overwhelmingly more sensitive than the electrocardiogram in establishing the diagnosis of posterior wall left ventricular infarction.[28,29] Gray et al.[30] examined the coronary angiograms of 31 patients with vectorcardiographic features of posterior wall myocardial infarction. Of 31 patients with diagnostic loops, 25 had associated coronary disease. Only 6 of the 31 patients had electrocardiographic evidence of posterior wall myocardial infarction. When the scalar electrocardiogram shows unequivocal evidence of an inferior wall infarction, the presence of a dominant R wave in lead V_1 or possibly V_2 strongly suggests coexisting posterior wall damage. On the other hand, there are no well established criteria for infarction based on an isolated R/S ratio greater than 1 in lead V_2 of an otherwise normal-appearing electrocardiogram (Fig. 10). Right ventricular hypertrophy represents a major problem in the electrovectorcardiographic differential diagnosis of posterior wall myocardial infarction. Mathur and Levine[31] found the magnitude of terminal rightward voltage less than 1.0 mv in 88 percent of 85 patients with posterior wall myocardial infarc-

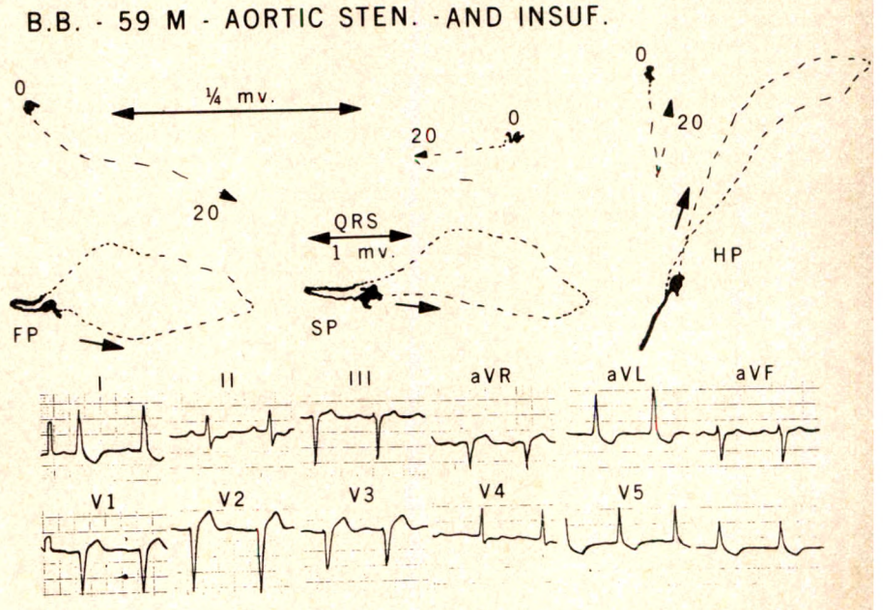

FIGURE 7. Vectorcardiogram and electrocardiogram in a 59 year old man with normal coronary arteries and combined aortic stenosis (STEN.) and insufficiency (INSUF.). At the standard magnification, initial 20 msec QRS vectors are obscured at the E-0 points in the sagittal and horizontal planes. A greater magnification of the early QRS loop indicates preservation of anterior 20 msec QRS vector forces. There is associated left ventricular hypertrophy. The electrocardiogram reveals poor progression of R waves in leads V_1 through V_3 together with evidence of left ventricular hypertrophy and "strain."

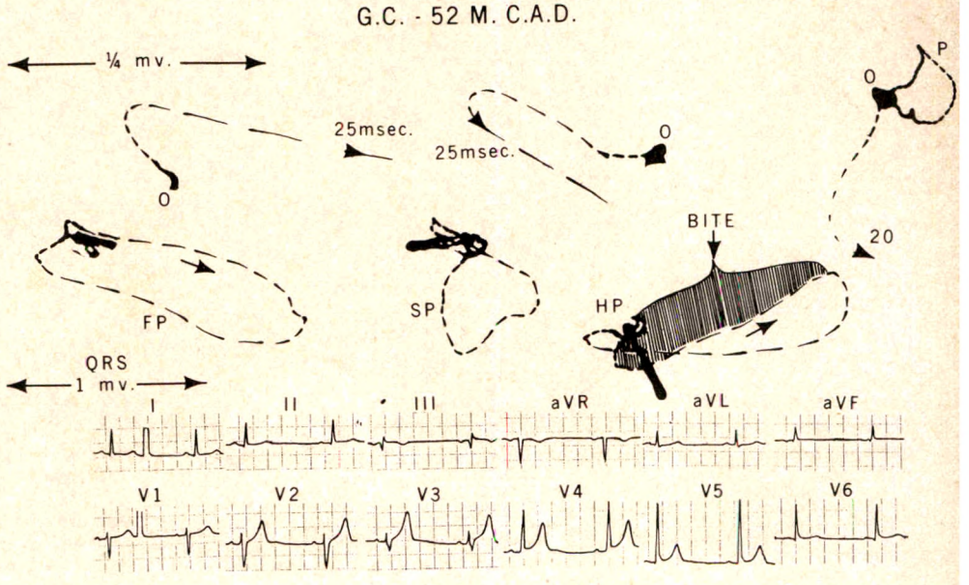

FIGURE 8. Vectorcardiogram and electrocardiogram recorded during the hyperacute stages of anterior wall myocardial infarction in a 52 year old man with coronary artery disease (C.A.D.). The frontal plane and sagittal plane initial 25 msec QRS vectors are directed superiorly and thus diagnostic of inferior wall infarction. Note the extensive "bite" in the horizontal plane QRS loop, indicating loss of left ventricular mass. The electrocardiogram shows S-T segment elevation and peaking of T waves in precordial leads V_2 through V_5.

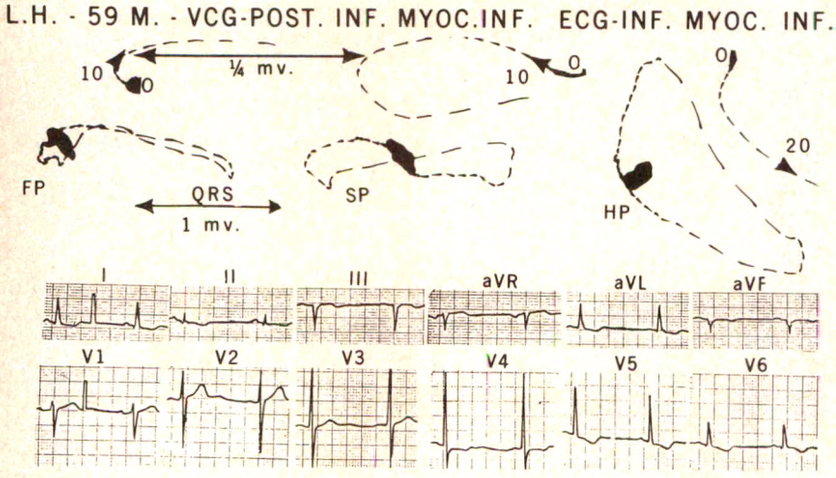

FIGURE 9. Vectorcardiogram (VCG) and electrocardiogram (ECG) from a 59 year old man with diffuse triple vessel coronary artery disease and complete occlusion of the right coronary artery. The initial 24 msec vectors in the frontal plane QRS loop are directed superiorly. The terminal QRS vector forces unexpectedly course in a superior direction, resulting in an inferior QRS loop "bite." The initial 48 msec QRS vectors are oriented anteriorly in the horizontal plane and are thus diagnostic of posterior wall myocardial infarction (MYOC. INF.). There are large QS complexes in scalar leads III and aVF with no electrocardiographic evidence of posterior wall infarction. INF. = inferior; POST. INF. = posteroinferior.

tion. In addition, horizontal plane right axis deviation was unusual in such cases. Concordant direction of the QRS-T loop maximal deflection vectors in the horizontal plane has also been considered to be suggestive of posterior wall infarction.[28] Taken together, all of these findings can still be misleading in the individual case. Type B right ventricular hypertrophy, usually associated with mild to moderate pulmonary hypertension, can result in vectorcardiographic features identical with those seen in posterior wall infarction.[28]

Analysis of T vector: Quantitative and morphologic analysis of the T vector loop has added a new dimension to the detection of underlying coronary artery disease.[32] Gray and Bell[33] compared the resting and postexercise electrocardiograms and vectorcardiograms in 100 patients who underwent selective coronary angiography. Utilizing a Frank frontal or horizontal plane T loop length/width ratio of 2.6 or less or an increase in the S-T segment opening of 0.1 mv or more as ischemic responses, they found that the vectorcardiogram correlated with the presence of severe coronary artery disease in 81 percent of cases. A 1 mm flat electrocardiographic S-T segment depression was found in only 35 of 59 patients (59 percent). In general, clockwise rotation of the T loop in the horizontal plane is indicative of heart disease[34] and may help elucidate the significance of inverted T waves in the right precordial electrocardiographic leads ("juvenile pattern") of patients with questionable or borderline physical findings and history.

Differentiation from hypertrophic cardiomyopathy: Idiopathic hypertrophic subaortic stenosis results in vectorcardiographic changes that are notoriously difficult to distinguish from these of myocardial infarction[35,36] (Fig. 11). Rothfeld and Zucker[37] suggested that the large rightward septal forces associated with hypertrophic subaortic stenosis could be differentiated from those of true myocardial infarction. They observed significant irregular and delayed inscription of the initial QRS vectors when true myocardial infarction was operative. Unfortunately, lateral wall myocardial infarction can also produce uniform inscription of the initial QRS vector forces.

Conduction Abnormalities

Left anterior hemiblock: Distinctive vectorcardiographic patterns compatible with theoretical and experimental models of unifascicular block have emerged within the last decade. Left anterior fascicular block results in preferential initial depolarization of the inferior myocardium. Frontal plane 10 to 20 msec QRS vectors are therefore directed inferiorly and to the right or left.[38–41] The balance of the frontal plane QRS loop courses in a superior direction with counterclockwise rotation and delayed inscription of the terminal 40 msec QRS vectors. Abnormal leftward directed frontal plane maximal QRS deflection vectors arise as a consequence of delayed depolarization of the superior aspect of the left ventricle. During 1971 and 1972, a series of publications appeared that shed new light on certain confusing electrocardiographic patterns of abnormal left axis deviation. Three groups of investigators,[42–45] working independently, set forth vectorcardiographic criteria for the diagnosis of coexisting left anterior hemiblock and inferior wall myocardial infarction. The features most useful for recognition of this entity are clockwise and superior inscription of the initial 20 to 30 msec QRS vectors secondary to inferior wall infarction followed by counterclockwise and delayed inscription of the terminal 40 msec QRS vectors in a superiorly displaced frontal plane loop. Kulbertus et al.[42] validated these criteria by artificially creating left anterior hemiblock aberrancy in subjects with established inferior wall infarction. Combined inferior wall infarction and left anterior hemiblock may be manifested in the electrocardiogram by rS or QS complexes in leads II, III and aVF. The rS pattern does not permit recognition of inferior infarction and a QS complex may be seen in the presence of a completely clockwise frontal plane QRS loop of uncomplicated diaphragmatic infarction. Under these conditions the vectorcardiogram provides a superior method of diagnosis (Fig. 12).

Left posterior hemiblock: This conduction defect produces preferential early depolarization of the superior aspect of the left ventricle, thereby producing

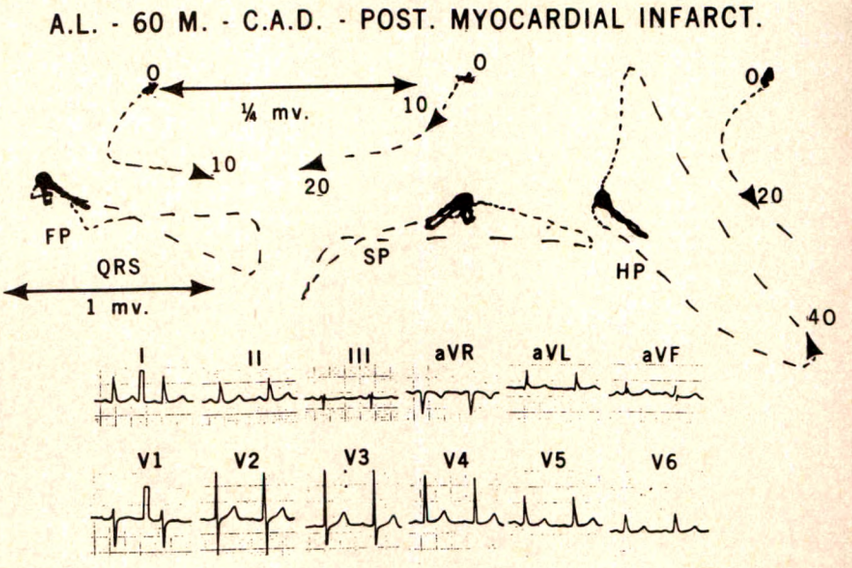

FIGURE 10. Vectorcardiogram and electrocardiogram in a 60 year old man with documented right coronary artery disease (C.A.D.) The horizontal plane vectorcardiogram shows anteriorly displaced initial 46 msec QRS vectors. More than 50 percent of the horizontal plane QRS loop area is anterior to the X axis, a finding diagnostic of posterior (POST.) wall myocardial infarction. There is a tall R wave in scalar lead V_2, but the electrocardiogram is within the normal limits of conventional criteria.

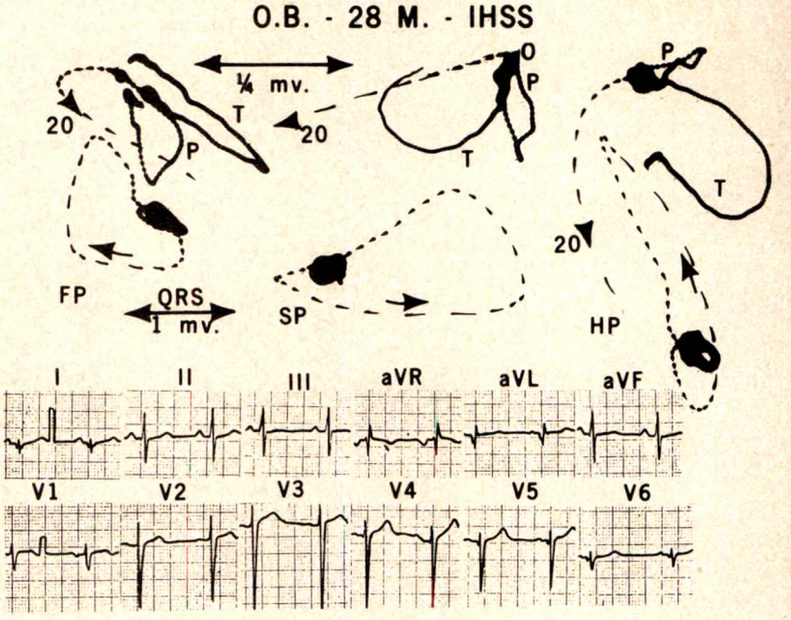

FIGURE 11. Vectorcardiogram and electrocardiogram in a 28 year old man with idiopathic hypertrophic subaortic stenosis (IHSS) and normal coronary arteries. There are electrovectorcardiographic features of lateral wall myocardial infarction and left ventricular hypertrophy. In addition, the vectorcardiogram shows major posteriorly and leftward directed P loop forces, compatible with left atrial hypertrophy. The frontal plane QRS axis in the electrocardiogram is indeterminate whereas the maximal QRS deflection vector in the frontal plane vectorcardiogram is oriented to the right and superiorly.

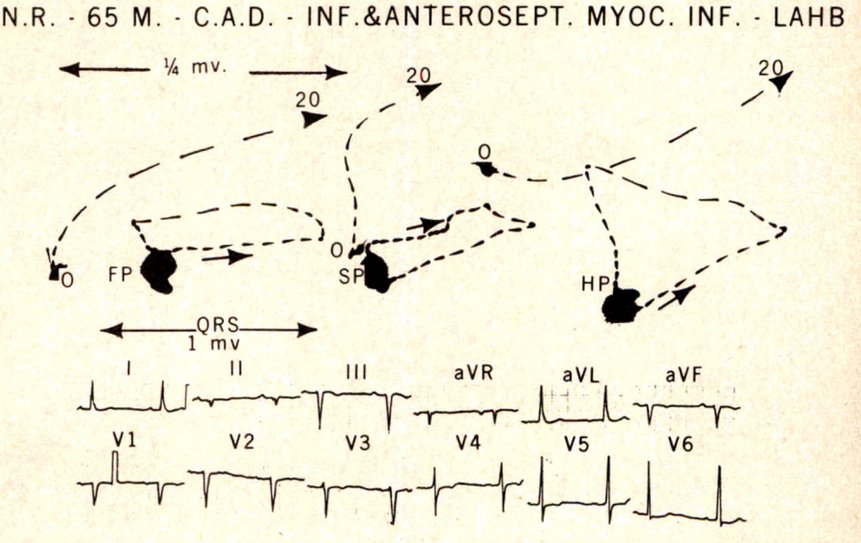

FIGURE 12. Vectorcardiogram and electrocardiogram in a 65 year old man with coronary artery disease (C.A.D.) and documented inferior (INF.) and anteroseptal (ANTEROSEPT.) wall myocardial infarctions. The frontal plane initial 20 msec QRS vectors rotate in a clockwise fashion and are displaced superiorly, a finding diagnostic of inferior wall infarction. The terminal QRS forces rotate in a counterclockwise manner with terminal delay, indicating coexisting left anterior hemiblock (LAHB). Horizontal plane initial 20 msec QRS vectors are directed posteriorly as a result of anteroseptal myocardial infarction. The electrocardiogram shows small r waves in leads III, aVF and V_2. There is abnormal left axis deviation. These small r waves do not permit satisfactory electrocardiographic diagnosis of either inferior or anteroseptal wall myocardial infarction.

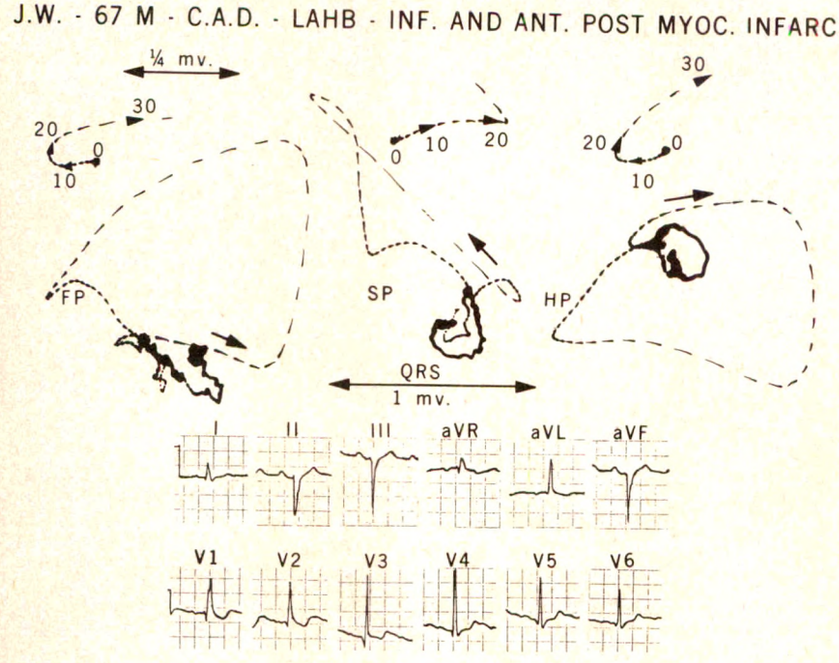

FIGURE 13. Vectorcardiogram and electrocardiogram in a 67 year old man with coronary artery disease (C.A.D.), left anterior hemiblock (LAHB) and complete right bundle branch block. The frontal plane initial 32 msec QRS vectors rotate clockwise and are directed superiorly, a finding diagnostic of inferior wall myocardial infarction. In the horizontal plane, initial 25 msec QRS forces are oriented posteriorly, indicating an anterior (ANT.) wall myocardial infarction. Complete clockwise rotation and major anterior displacement of the horizontal plane QRS loop are suggestive but not diagnostic of posterior wall infarction. The electrocardiogram shows Q waves in leads V_2 through V_6 and rS complexes in leads II and III.

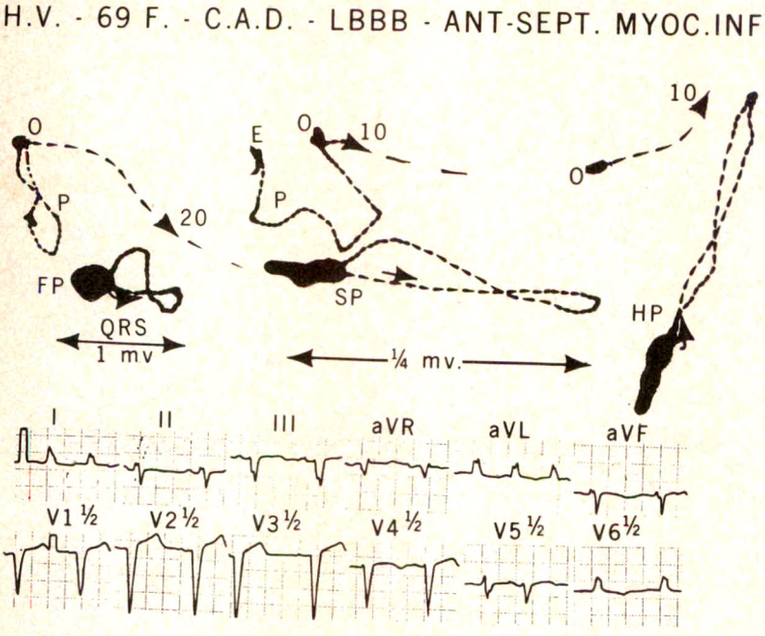

FIGURE 14. Vectorcardiogram and electrocardiogram in a 69 year old woman with documented triple vessel coronary artery disease and anterior wall dyskinesis. The vectorcardiogram and electrocardiogram reveal left bundle branch block (LBBB). Horizontal plane and sagittal plane initial 10 msec QRS vectors are directed posteriorly and thus diagnostic of anterior wall myocardial infarction.

superiorly directed 10 to 20 msec QRS vectors.[46,47] Delayed activation of the inferior wall results in clockwise rotation and right axis deviation of the frontal plane QRS loop. When left posterior hemiblock occurs in conjunction with inferior wall myocardial infarction, the Q waves in scalar leads II, III and aVF may appear small in relation to the tall R waves that follow.[48] In such cases, the initial 30 msec QRS vectors will be directed superiorly, suggesting inferior wall infarction. We have observed diminution of the Q wave voltage over a 1 year period in subjects with these combined abnormalities. It is possible that transient or altering degrees of left posterior fascicular block account for these changes, and further investigation of this phenomenon is warranted. Gaum et al.[49] reported distinctive rightward and inferiorly directed QRS vector loops in patients with supravalvular aortic stenosis and aortic coarctation. They postulated that this vectorcardiographic pattern might be attributable to selective posterobasal left ventricular hypertrophy or left posterior hemiblock.

Fernandez et al.[50] recorded Frank vectorcardiograms in patients undergoing selective coronary arteriography. Left coronary arteriography resulted in frontal plane QRS loop alterations similar to those described for left anterior hemiblock. Right coronary arteriography produced configurations of left posteri-

or hemiblock. In subjects with initial QRS vector changes of myocardial infarction, terminal QRS loop changes compatible with associated fascicular block developed. These angiographically induced QRS loop changes may be based on "peripheral" rather than isolated unifascicular block since there are usually no initial QRS vector shifts in patients without associated infarction.

Bifascicular block: The vectorcardiographic manifestations of bifascicular block[51] have recently been described in detail.[52–56] Left anterior hemiblock combined with complete right bundle branch block results in a more superior frontal plane maximal QRS vector than does isolated right bundle branch block or left anterior hemiblock.[52] It has been noted that a significant number of subjects with electrovectorcardiographic features of combined left fascicular and right bundle branch block manifest anteriorly directed or clockwise rotating horizontal plane QRS loops.[52] These major anterior vector forces may be based on (1) preferential initial posterior left ventricular wall depolarization, (2) coexisting posterior wall myocardial infarction, (3) associated right ventricular hypertrophy, or (4) more advanced "degree" of left fascicular and complete right bundle branch block. Kulbertus et al.[53] hypothesized that gradation from posterior to anterior horizontal plane QRS direction might indicate progressive damage to the conduction system. Cerqueira-Gomes et al.[55] observed that complete atrioventricular block had a greater tendency (75 percent) to occur in patients with anteriorly directed horizontal plane QRS loops. Furthermore, they could not predict the horizontal plane maximal QRS vector by examination of the 12 lead electrocardiogram. Lichstein et al.[56] concluded that the relation of horizontal plane QRS configuration to clinical course was not close enough to predict the course of an individual patient or aid in clinical management. Variance in such studies may be based on differences in underlying cause of the bilateral bundle branch block, which cannot be ascertained by examination of these papers. When left anterior hemiblock and complete right bundle branch block coexist with myocardial infarction, the vectorcardiogram is an elegant method of diagnosis (Fig. 13).

Left bundle branch block: When left bundle branch block is operative, the vectorcardiogram affords a method whereby coexisting myocardial infarction may be detected. The most reliable criteria for diagnosis of these combined abnormalities include a shift of horizontal plane QRS loop rotation from figure of eight to clockwise[57] and posterior orientation of the initial 10 msec QRS vectors[58] (Fig. 14).

Cardiac Arrhythmias

Timed vectorcardiogram: The timed vectorcardiogram ("running loop") is as useful as the scalar electrocardiogram in the surface analysis of cardiac arrhythmias.[9,58] All previously mentioned advantages of the still loops are equally in force in the timed vectorcardiogram. In addition, virtually every possible

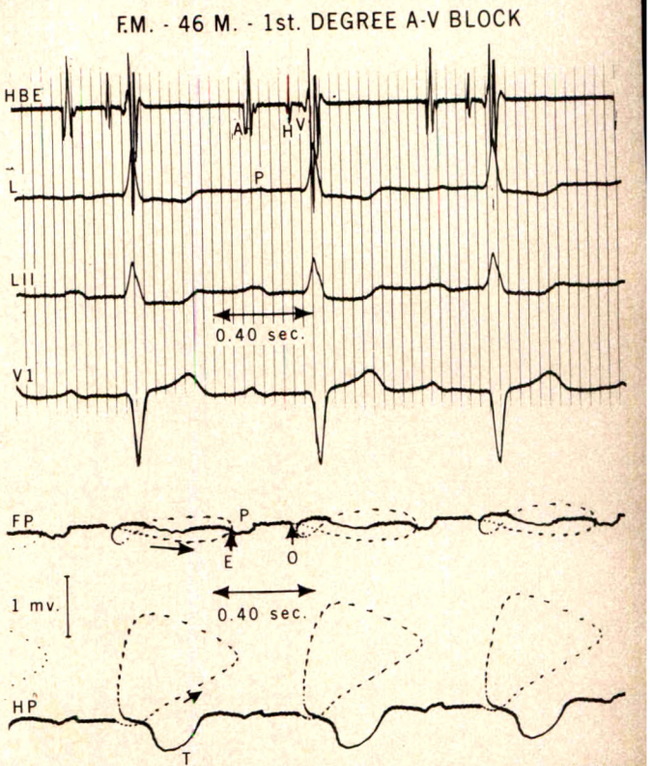

FIGURE 15. Simultaneously recorded His bundle electrogram (HBE), leads I, II and V_1 of the electrocardiogram, with frontal and horizontal plane timed vectorcardiograms in a 46 year old man with idiopathic first degree atrioventricular (A-V) block. The A-H interval is prolonged to 180 msec, thus indicating conduction delay at the level of the A-V node. All surface features of the electrocardiogram relating to A-V and intraventricular conduction are clearly discerned on the biplane vectorcardiogram. A 0.06 second difference between the onset of scalar and vector surface potentials is due to recording in two separate oscilloscopic devices.

combination of bundle branch blocks and variations thereof are easily perceived by recording frontal and horizontal plane running loops simultaneously.[59] Persistence of abnormal frontal plane QRS loop left axis deviation during isolated left anterior fascicular block and intermittent "complete" left bundle branch block suggests that, in the occasional case, QRS loops of posterior orientation and greater than 140 msec duration may be based on various degrees of left bundle bifascicular block.[60] Pathologic identification of fibrotic or degenerative changes in the proximal left bundle branch does not in any way cast discredit on this hypothesis, and definitive examination of the distal fascicular system in such cases will eventually resolve the issue.

Ventricular arrhythmias: Zoneraich and Zoneraich[61] analyzed vectorcardiograms in subjects with bundle branch block patterns arising as a result of ventricular ectopic beats. They recognized distortions of the QRS loops in association with diseases that render the myocardium fibrotic. Interestingly, these investigators[62] have also demonstrated right ventricular pacemaker-induced QRS loop patterns akin to those described for naturally occurring left bundle branch block and myocardial infarction in experimental animals and human subjects. The fact

that these changes were observed in patients with documented acute myocardial infarction lends credence to the proposition that the vectorcardiogram is of practical value for diagnosis when these disturbances occur in combination.

Atrial arrhythmias: High fidelity atrial vectorcardiograms have been recorded in patients with atrial flutter[63] and "left atrial"[64] and "inferior atrial"[65] rhythms. Such studies have been descriptive in nature but, combined with His bundle and intraatrial recordings, may prove useful in the future for delineating the sequence of atrial activation during various rhythm disturbances. Simultaneous recording of the timed vectorcardiogram and His bundle electrogram is feasible in human subjects[58,66] (Fig. 15) and has been applied for evaluation of ventricular depolarization sequences in patients with preexcitation.[67]

Pacemaker Analysis, Single Plane Projection and Computer Application

Gordon[68] presented data that indicated the advantages of pacemaker stimulus artifact analysis using Frank vectorcardiograms. Location, orientation and output of the pacemaker can be established by this technique. Kinoshita and Kobayashi[69] devised a unique method for determining the Y axis deflection in a single horizontal plane QRS loop projection. Representing superior-inferior deflection vectors in the form of colored dashes facilitates the diagnosis of inferior wall infarction by inspection of the horizontal plane QRS loop.

Computer analysis of the vectorcardiogram: Computer analysis has been applied to the diagnosis of numerous cardiac abnormalities, including left ventricular overload[70] and myocardial infarction.[71] During the 1960's some enthusiastic proponents of computer technology suggested that individual analysis of the electrocardiogram and vectorcardiogram would soon be replaced by "rapid-fire" digital printouts. Practical experience over the past decade has not confirmed these speculations. Visual inspection of the P, QRS and T loops is still desirable for definitive interpretation of the vectorcardiogram in the individual case. Superficial and completely qualitative examination of either the XYZ leads or vector loops is to be condemned and has been a pitfall. Careful attention should be directed to the magnitude, duration, rotation and orientation of the critical initial and maximal deflection vectors before diagnostic conclusions are reached. Such analysis permits maximal utilization of information contained in planar loop projections and precludes major individual interpretive variation, which has been documented in the past.[72] Visual inspection or measurement and computer analysis are in no way mutually exclusive, and both techniques in combination are useful for clinical application and research purposes.

In conclusion, our experience, and that of other investigators, has confirmed the practical value of clinical vectorcardiography. It is suggested that this technique be used in all laboratories where the comprehensive noninvasive diagnosis of cardiac disease is undertaken.

Pseudomalfunction of a Beall Mitral Valve Prosthesis in the Presence of Paravalvular Aortic Regurgitation

Premature closure of a Beall mitral valve prosthesis is described in a patient with aortic prosthetic paravalvular regurgitation. Differentiation from valvular malfunction and diagnostic confirmation by means of cinefluoroscopy and simultaneous electrocardiography are discussed.

As a result of increasing surgical success in valvular heart surgery, the number of patients with prosthetic valves requiring follow-up care is increasing. Evaluation of the function of valve prostheses is complicated by variability in structural characteristics of the prostheses, location of the valves replaced and underlying cardiac function. Detection of malfunction may be quite difficult and requires a thorough knowledge of the auscultatory, echocardiographic and fluoroscopic findings of the prosthesis under evaluation.

This paper describes a patient with both aortic and mitral valve prostheses who had an abnormal prosthetic sound in mid to late diastole. Valve cinefluoroscopy was used to confirm the mitral origin of the sound and to distinguish valve malfunction from early prosthetic closure secondary to paravalvular aortic regurgitation.

Case Report

A 32 year old Negro male alcoholic was admitted to Temple University Hospital on October 2, 1973 with a diagnosis of pneumonia and acute bacterial endocarditis involving both the aortic and mitral valves. The responsible organism in both instances was found to be a type 35 pneumococcus. Despite large dose penicillin therapy, the patient had frank heart failure with an inadequate response to digitalization and diuresis. On November 5, he underwent a limited cardiac catheterization that demonstrated severe mitral and aortic regurgitation with elevation of left ventricular end-diastolic pressure (left ventricle 140/48 mm Hg) and all right heart pressures (right ventricle 80/25, pulmonary arterial wedge 45 mm Hg). These findings and deterioration of the patient's clinical condition prompted emergency valve replacement. At operation, subtotal destruction of both valves and an endocardial abscess of the high ventricular septum were found. The abscess was drained and the valves were replaced with a no. 21 Bjork-Shiley prosthesis in the aortic area and a medium Beall prosthesis in the mitral area.

Postoperatively, the murmurs of aortic and mitral regurgitation were evident. Because of these murmurs, excessive hemolysis and persistent evidence of moderate heart failure, a second cardiac catheterization was undertaken on December 3. At this time, significant paravalvular insufficiency involving both prostheses was identified. Surgical correction was considered but deferred pending improvement in the patient's general condition. On December 13, concern was generated for the patient's continued hemodynamic stability by the appearance of increased intensity of the murmur of aortic regurgitation, a diminished mitral prosthetic closure sound and a mid to late diastolic sound of prosthetic origin. This combination of findings suggested premature closure of the mitral valve prosthesis in association with increasingly severe aortic insufficiency. Prosthetic valve malfunction or detachment, or both, was an additional serious possibility. Valvular cinefluoroscopy was used in an attempt to clarify the diagnosis.

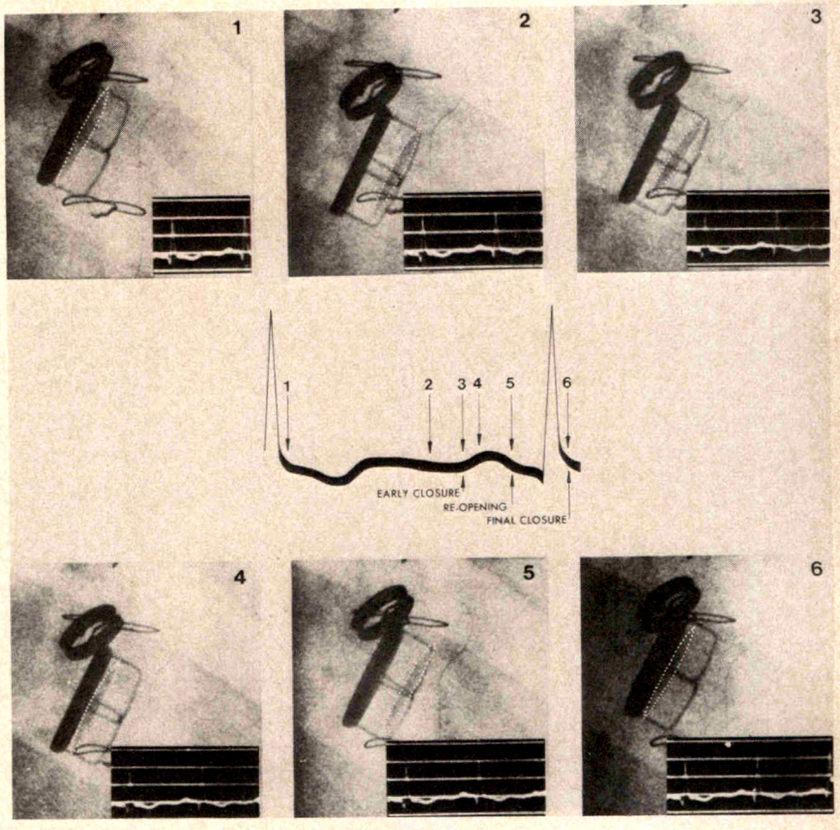

FIGURE 1. Selected sequential frames from the cinefluorogram of a single cardiac cycle with an artist's rendering of the superimposed, simultaneous electrocardiogram. The frames show the valve closed in systole (frame 1) and open in diastole (frame 2), premature closure in later diastole (frames 3 and 4), reopening at the time of atrial contraction (frame 5) and final closure with ventricular systole (frame 6).

Valvular cinefluoroscopy: With use of a Siemens image intensifier with 6-inch magnification mode, the patient was examined in both the right anterior oblique and left anterior oblique positions with the prosthetic base perpendicular to the X-ray beam. Thirty-five millimeter cine films were taken at a rate of 60 frames/sec. An electrocardiogram (lead II) was superimposed on each cine frame (Cinetrace, Electronics for Medicine). Aortic valve motion appeared normal. Although the base of the mitral prosthesis was stable, frame by frame analysis of disc motion and the electrocardiogram revealed that the valve closed prematurely in mid-diastole, reopened with atrial systole and closed again at the time of ventricular contraction (Fig. 1). The simultaneous electrocardiogram demonstrated normal sinus rhythm at a rate of 72/min with a P-R interval of 0.14 second and QRS duration of 0.09 second. It was assumed that premature closure was the result of a significant increase in the amount of paravalvular aortic regurgitation and prompt surgical intervention was undertaken.

At operation, the aortic and mitral paravalvular leaks were oversewn. Postoperatively, mitral prosthetic function returned to normal as determined by auscultation and cinefluoroscopy. The patient was discharged in improved condition 14 days after his second operation.

Discussion

In sinus rhythm, the hemodynamics of closure of a mitral valve prosthesis are similar to those of the normal mitral valve, being influenced directly by the left atrial-left ventricular pressure gradient and mitral valve flow. Closure is initiated shortly after atrial systole and is in part a result of atrial augmentation of left ventricular pressure. Valve closure is then completed by the pressure developed by left ventricular contraction.[1] However, in the presence of prolonged atrioventricular conduction or atrial fibrillation with a long R-R cycle length, the valve may float softly back to partial or complete closure before the onset of ventricular contraction.[1,2] Variation in the intensity or location of the mitral closing sound may represent prosthetic malfunction[3] or indicate a variation in the gradient across the valve orifice secondary to one of several factors including alteration in the rate or character of atrial contraction, underlying ventricular function and pattern of cardiac conduction. In our patient a decrease in the intensity of the mitral closure sound developed with an abnormal sound occurring in mid to late diastole. The association of these findings in a patient with known prosthetic paravalvular aortic regurgitation suggested premature mitral valve closure. This diagnosis was confirmed and prosthetic malfunction excluded using cinefluoroscopy with a simultaneous electrocardiogram imposed on each cine frame. In the selected sequential photographs of valve motion in Figure 1, premature valve closure is clearly visible in frames 3 and 4. Reopening of the valve with atrial contraction and final closure at the time of ventricular contraction is also demonstrated (frames 5 and 6).

Premature closure of mitral valve in severe aortic regurgitation: In sudden severe aortic insufficiency, early closure of the mitral valve has been demonstrated to occur in both experimental animals and clinical situations. Diastolic ventricular pressure is determined by both rate and volume of ventricular

filling, cavity size and wall compliance. In acute severe aortic insufficiency, the ventricular diastolic capacity is exceeded by a combination of forward flow from the left atrium and regurgitant flow across the aortic valve. There is insufficient time for the ventricular cavity to dilate in response to this increased volume load, and further volume results in marked elevation in ventricular pressure. In severe cases, the diastolic pressure exceeds left atrial pressure, resulting in premature closure of the mitral valve.[4,5] Clinical recognition of this entity is of great importance since the prognosis of the patient with severe aortic insufficiency with left ventricular failure is poor without surgical intervention.

Although this phenomenon has not previously been described in a patient with a Beall mitral prosthesis, Agnew and Carlisle[6] described its occurrence in three patients with a Starr-Edwards ball valve prosthesis. In their patients, the valve closed prematurely and did not reopen after atrial systole, a situation more closely representing acute aortic insufficiency with a nondistensible ventricle and high diastolic pressures. In our patient, atrial systole caused reopening of the mitral valve. This finding suggests only moderate elevation of late diastolic pressure, which may represent partial conditioning of the ventricle to larger diastolic volumes or some moderation in the amount of regurgitant flow. It further demonstrates that premature closure with subsequent reopening by atrial systole is a variation in the spectrum of this syndrome and connotes a less serious but still dangerous clinical situation.

Value of cinefluoroscopy of prosthetic valve: We suggest (1) that variation in the intensity or location of the mitral prosthetic closing sound be investigated by use of cinefluoroscopy, and (2) that the patient with a prosthetic valve undergo valve cinefluoroscopy early after operation and at yearly intervals thereafter. Comparison of these serial observations with cinefluoroscopic findings at the time of suspected prosthetic malfunction will facilitate differentiation of normal from abnormal valve motion. Further help in determining the timing of valve motion may be necessary and, as in our case, a superimposed frame by frame simultaneous electrocardiogram may be useful.

Limitations of the Surface Electrocardiogram in Diagnosis of Atrial Arrhythmias

Further Observations on Dissimilar Atrial Rhythms

DELON WU, MD

Electrophysiologic studies with recordings of multiple intracavitary electrograms were performed in two patients with atrial dysrhythmias. In Case 1 the arrhythmic pattern in the surface electrocardiogram resembled atrial flutter. Electrophysiologic studies revealed the arrhythmia to be paroxysmal left atrial tachycardia, with separation of left and right atrial components of the P wave by an isolectric period secondary to marked interatrial conduction delay. In Case 2 the surface electrocardiogram indicated paroxysmal atrial tachycardia with block. Electrophysiologic studies revealed right atrial standstill with atrial inexcitability and two dissimilar rhythms involving the left atrium. The electrocardiograms did not accurately reflect atrial arrhythmias in these two patients and only multiple direct recordings permitted the correct diagnoses. New electrophysiologic observations concerning intraatrial block and dissimilar atrial rhythms are presented.

Atrial dysrhythmias are usually easily recognizable in the surface electrocardiogram with the type and timing of P waves reflecting underlying atrial activity. However, in some patients, direct recording techniques are necessary for accurate and complete diagnosis. Zipes and DeJoseph[1] recently reported on several patients with dissimilar atrial rhythms that required direct recording techniques for diagnosis. In this study, we present further observations concerning the limitations of surface electrocardiography in patients with atrial dysrhythmias. In one of our patients, the electrocardiographic pattern resembled atrial flutter, whereas electrophysiologic studies revealed the arrhythmia to be paroxysmal atrial tachycardia with marked left to right interatrial block. In the second patient electrocardiograms suggested paroxysmal atrial tachycardia, whereas direct studies revealed multiple (three) dissimilar atrial rhythms.

Methods

Electrophysiologic studies were performed in two patients with atrial dysrhythmias. Informed consent was obtained before the studies. Two electrode catheters (one bipolar and one quadripolar) were percutaneously passed to the right heart chambers and utilized for one or more of the following: (1) recording of right atrial electrograms from multiple sites, (2) right atrial stimulation, (3) recording of coronary sinus (left atrial) electrograms, and (4) recording of His bundle electrograms. A bipolar electrode catheter was also passed to the esophagus and used to record left atrial electrograms.

Standard leads I, II, III and V_1 and multiple atrial electrograms were recorded simultaneously on a multichannel oscillosopic recorder (Electronics for Medicine DR-16) at paper speeds of 100 and 200 mm/sec. Electrical stimuli were provided by a digital programmable pulse generator (constructed by

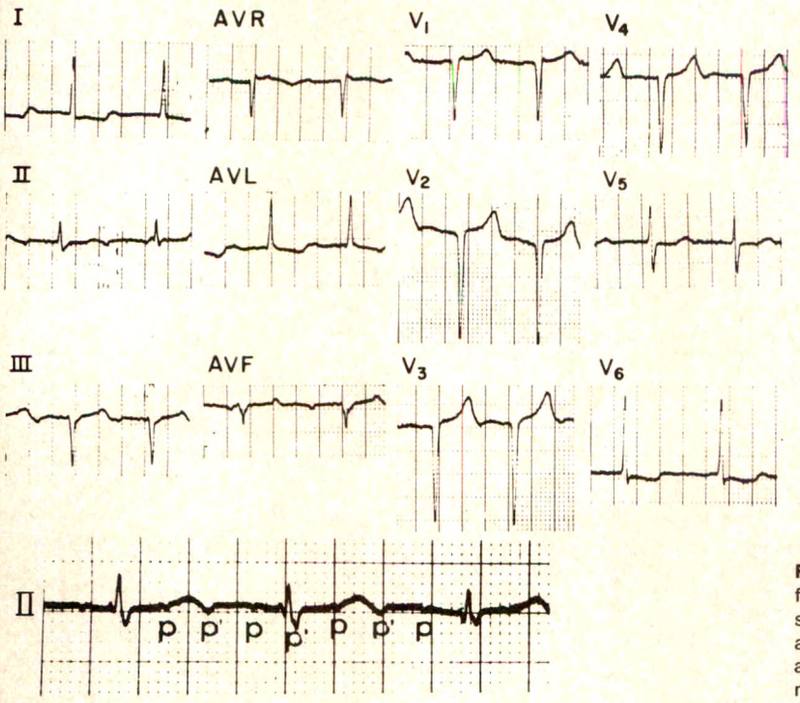

FIGURE 1. Case 1. Electrocardiograms reveal "atrial flutter" (rate 340/min), with irregular ventricular response and nonspecific ST-T wave changes. There is alternation of smaller (P) and larger (P′) waves, which are both inverted in leads II, III and aVF. An enlargement of the rhythm strip is shown at bottom.

M. Bloom, Philadelphia, Pa.). Refractory periods were measured with the extrastimulus technique.[2,3] The test stimulus (S_2) was introduced after every eighth driven stimulus (S_1). The S_1-S_2 interval was decreased in 10 msec increments. Conduction intervals and refractory periods were defined and measured as previously described.[2,3]

Results

Case 1

This was a 68 year old man with chronic obstructive lung disease with cor pulmonale and thyroglossal tumor. He was not taking cardiac medications. Electrocardiograms were interpreted as revealing atrial flutter (rate 340/min), with varying atrioventricular (A-V) block and nonspecific ST-T wave changes. Close inspection of the electrocardiogram (Fig. 1) revealed alternation of atrial activity between smaller and larger atrial complexes both of which were inverted in leads II, III and aVF.

Electrophysiologic studies with simultaneous recording of multiple surface leads, left atrial electrograms (from the esophagus) and right atrial electrograms revealed the rhythm to be atrial tachycardia at half the rate of the previously interpreted flutter rate (162/min) (Fig. 2A). Activation of the atria appeared to be from left to right, the interval between left (A_L) and right atrial (A_R) electrograms being 165 msec. The smaller atrial complexes (P_L) in the surface electrocardiogram coincided with the onset of the left atrial electrogram, whereas the larger surface atrial complex (P_R) coincided with the onset of the right atrial electrogram (Fig. 2A). Thus, the apparently alternating flutter waves in the surface electrogram reflected the left and right atrial components of a single P wave with a duration of 220 msec, secondary to marked interatrial block. His bundle recordings revealed varying A-V block with the site of block proximal to the His bundle.

The atrial tachycardia was transiently converted to normal sinus rhythm after sudden cessation of rapid high right atrial pacing at a rate of 428/min (cycle length 140 msec) (Fig. 2B). P waves after conversion revealed an atrial activation sequence of right to left, with a duration of 205 msec. The interval between the right and left atrial electrograms (A_R-A_L) was 150 msec. Normal sinus rhythm lasted for only several beats and was followed by immediate resumption of the left atrial tachycardia.

Atrial extrastimuli were introduced at a driving cycle length of 310 msec, which constantly captured the atria (Fig. 3). Conduction time between the right and left atria (A_R-A_L interval) increased progressively as coupling intervals were decreased (Fig. 3, A and B). Left atrial tachycardia resumed immediately after each capturing extrastimulus with a returning interval of 240 msec, thereby suggesting that an ectopic focus was discharged and reset by the premature atrial stimulation. The atrial functional and effective refractory periods were 150 and 140 msec, respectively (Fig. 3, B and C). Although these periods seem short, there are no comparable normal data in man for the driven cycle length of 310 msec.

Comments: Our findings suggest that paroxysmal atrial tachycardia with marked interatrial block can mimic atrial flutter in the surface electrocardiogram. Direct recording techniques were necessary for proper delineation of the rhythmic disturbance. This tachycardia in our patient appeared to be ectopic rather than reentrant since single extrastimuli appeared to reset it. In this patient there was also a marked discrepancy between interatrial conduction time, which was long, and atrial refractory periods, which were short.

Case 2

This was a 64 year old man, admitted to the University of Illinois Hospital because of dyspnea and leg edema. For the past 2 years, he had been taking digoxin (0.25 mg/day)

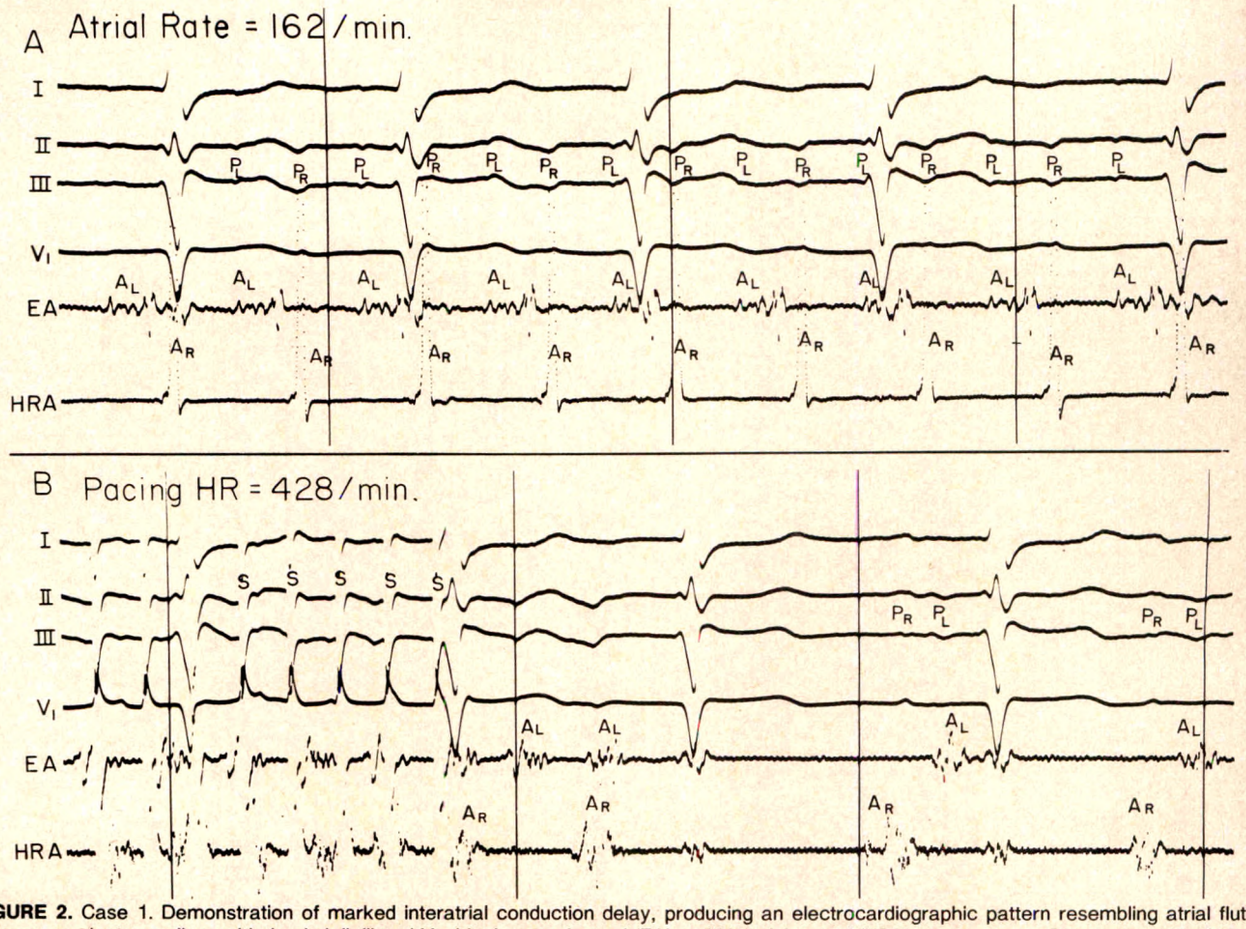

FIGURE 2. Case 1. Demonstration of marked interatrial conduction delay, producing an electrocardiographic pattern resembling atrial flutter. Shown are electrocardiographic leads I, II, III and V_1, bipolar esophageal (EA) and high right atrial (HRA) electrograms. Paper speed is 100 mm/sec, and time lines are at 1-second intervals in this and subsequent illustrations. **Panel A** discloses paroxysmal left atrial tachycardia (rate 162/min), with left (A_L) to right (A_R) atrial activation sequence. Note that the smaller and the larger P waves (P_L and P_R) in the surface electrocardiograms coincided with the onset of the left (A_L) and right (A_R) atrial electrograms, respectively. **Panel B** reveals conversion of tachycardia to sinus rhythm with rapid atrial stimulation (S) at a rate of 428/min. The two beats on the right are sinus. Note the change in P wave configuration and atrial activation sequence after conversion. HR = heart rate.

and diuretic agents for congestive heart failure. Chest X-ray examination revealed marked cardiomegaly with enlargement of all four chambers.

Electrocardiograms revealed atrial tachycardia (170/min) with varying block and periods of A-V dissociation, and complete left bundle branch block (QRS interval = 0.12 second) (Fig. 4). The P waves were inverted and seen clearly only in lead V_1. Values for serum electrolytes, creatinine and enzymes (glutamic oxaloacetic transaminase [SGOT], lactic dehydrogenase [LDH] and creatine phosphokinase [CPK]) were normal. Despite discontinuance of digoxin, paroxysmal atrial tachycardia with block persisted.

Electrophysiologic studies were performed 1 week after admission. Surface lead V_1 revealed the previously noted atrial tachycardia with an atrial rate of 162/min (cycle length 365 msec) (Fig. 5). Intraatrial recordings from the high, mid and low lateral right atrium revealed absence of atrial activity (atrial standstill) despite maximal signal amplification (Fig. 5). Recording of left atrial electrograms from the coronary sinus revealed a left atrial tachycardia, with irregular irregularity. The cycle lengths of left atrial complexes ranged from 220 to 380 msec (Fig. 5). These coronary sinus atrial electrograms bore no apparent relation either to P waves in the surface electrocardiogram or to QRS complexes. His bundle electrograms revealed sporadic, very low amplitude, atrial potentials with His bundle potentials preceding each QRS complex (H-V intervals 100 msec). R-R intervals ranged from 585 to 775 msec with a mean heart rate of 90/min. Atrial pacing was attempted from multiple right atrial sites. The atria were totally inexcitable, despite a maximal stimulus amplitude of 22 milliamperes.

On the day after electrophysiologic study, a bipolar electrode catheter passed to the esophagus revealed a regular atrial rhythm, with a rate of 324/min (cycle length 182 msec) (Fig. 6). This rhythm had a 2:1 relation to the atrial tachycardia recorded in the surface electrocardiogram.

Comment: In this patient, surface electrocardiograms revealed chronic paroxysmal atrial tachycardia with varying block. Direct recording techniques from both the right and left atria revealed no electrogram with a 1:1 correspondence to this rhythm. However, direct recording techniques revealed the following additional multiple dissimilar atrial rhythms: (1)

right atrial standstill with atrial inexcitability; (2) left atrial tachycardia with irregular irregularity, recorded from the coronary sinus; and (3) left atrial flutter with twice the rate of the surface paroxysmal atrial tachycardia, recorded from an esophageal lead 1 day after the initial electrophysiologic study. Presumably, paroxysmal atrial tachycardia recorded in the surface electrogram reflected 2:1 intraatrial block of this flutter. The portion of the atria responsible for the surface paroxysmal atrial tachycardia could not be determined.

It is not known whether the coronary sinus and esophageal electrodes sampled similar portions of the left atrium, and since the two left atrial rhythms were recorded on different days, it is uncertain whether there were two simultaneous dissimilar rhythms involving the left atrium or two different left atrial rhythms on different days. Because of the 2:1 relation of the flutter and the paroxysmal atrial tachycardia, and because the paroxysmal atrial tachycardia persisted at the same rate on both days, it is likely that the arrhythmia recorded with the esophageal lead was present although not recorded during the initial electrophysiologic study.

In summary, this patient had at least three and possibly four simultaneous dissimilar atrial rhythms.

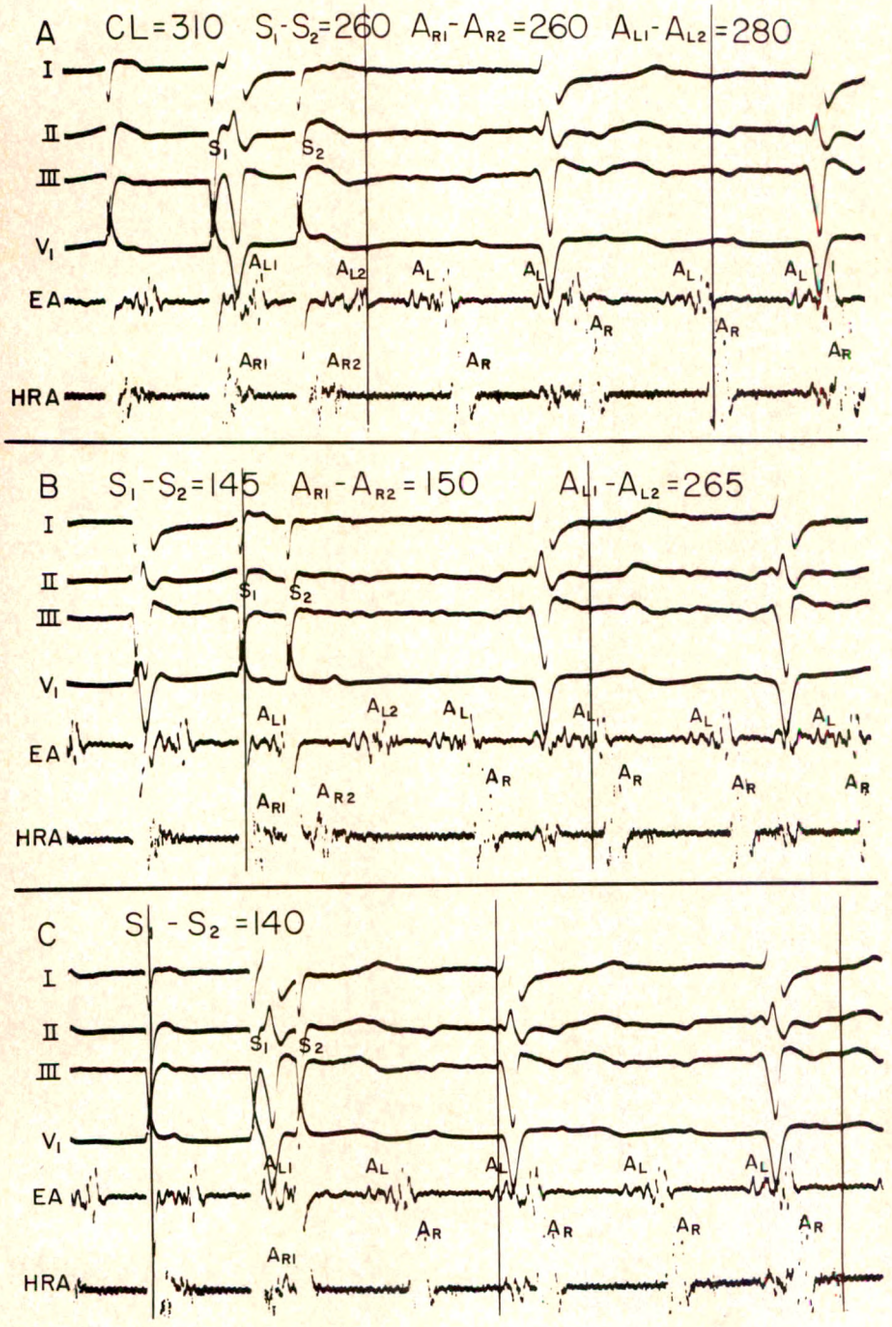

FIGURE 3. Case 1. Recording disclosing refractory periods of the atrium. S_1, A_{L1}, and A_{R1} indicate, respectively, stimulus artifact and left and right atrial electrograms of the driven beats; S_2, A_{L2} and A_{R2} indicate, respectively, stimulus artifact and left and right atrial electrograms of the test beats. The driving cycle length (CL) was 310 msec. In **Panel A,** S_1-S_2 and A_{R1}-A_{R2} were both 260 msec; A_{L1}-A_{L2} was 280 msec and A_{L2}-A_L 240 msec. In **Panel B,** S_1-S_2 was 145 msec, A_{R1}-A_{R2} was 150 msec and A_{L1}-A_{L2} lengthened to 265 msec because of increased interatrial conduction delay. The atrial functional refractory period was 150 msec. A_{L2}-A_L was again 240 msec. In **Panel C,** an atrial effective refractory period of 140 msec was achieved. Note the resumption of paroxysmal tachycardia immediately after the extrastimulus.

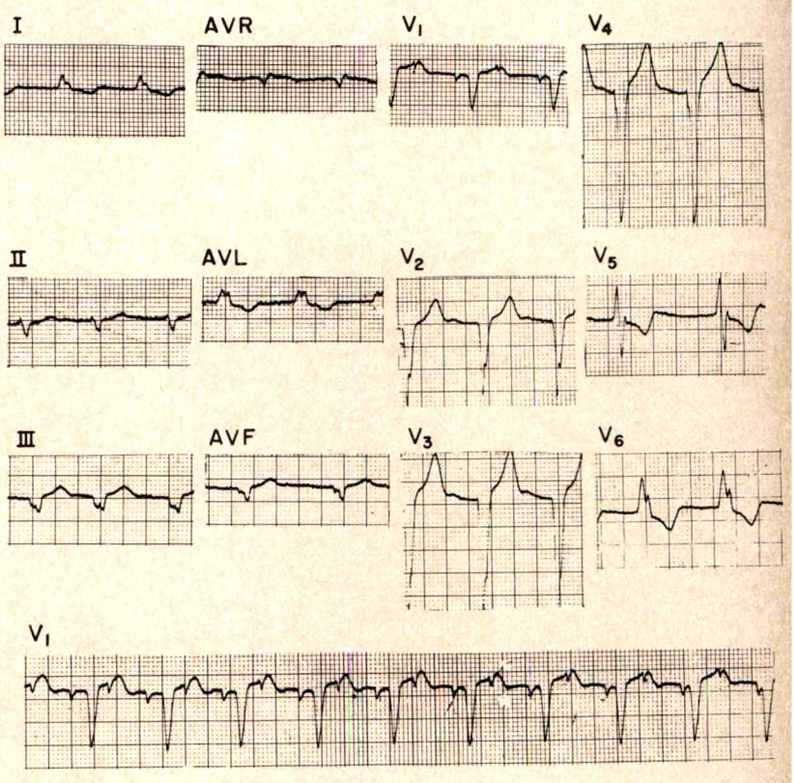

FIGURE 4. Case 2. Electrocardiogram discloses paroxysmal atrial tachycardia (rate 170/min) and varying A-V block with periods of junctional tachycardia and complete left bundle branch block.

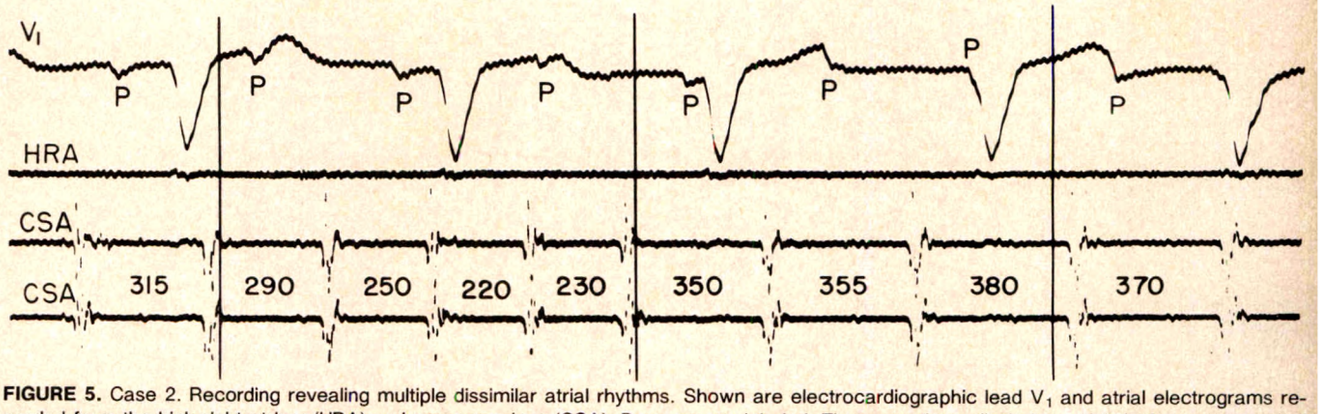

FIGURE 5. Case 2. Recording revealing multiple dissimilar atrial rhythms. Shown are electrocardiographic lead V_1 and atrial electrograms recorded from the high right atrium (HRA) and coronary sinus (CSA). P waves are labeled. There are three dissimilar atrial rhythms: paroxysmal atrial tachycardia (V_1), right atrial standstill (HRA) and a rapid irregular left atrial rhythm of varying cycle lengths (220 to 380 msec) (CSA).

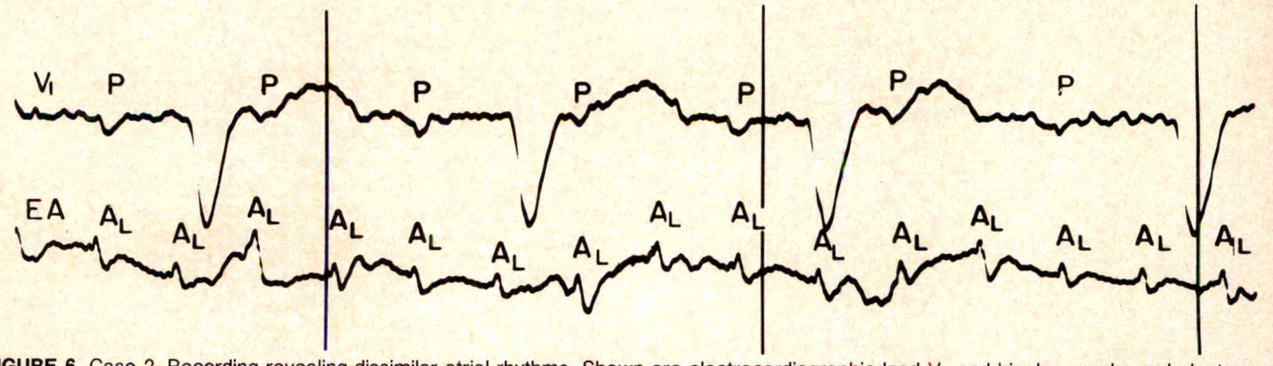

FIGURE 6. Case 2. Recording revealing dissimilar atrial rhythms. Shown are electrocardiographic lead V_1 and bipolar esophageal electrogram (EA). Lead V_1 shows paroxysmal atrial tachycardia, whereas the esophageal electrogram shows atrial flutter. The atrial electrogram (A_L) has a 2:1 relation to the P waves in lead V_1.

It was impossible to determine which atrial rhythm controlled the ventricles.

Discussion

The mode of impulse transmission between the sinus node, atria and A-V node is still a matter of debate. Sir Thomas Lewis,[4] in studies of the canine heart, suggested that the electrical impulse in the normal heart originates in the sinus node and spreads through both atria in a radial or syncytial wave form to reach the A-V node. Studies by Spach et al.[5] and others[6,7] support this view. On the other hand, many workers[8-14] have suggested the existence of specialized or preferential pathways in the atria. James[15] and other investigators[16–26] have provided anatomic and electrophysiologic evidence supporting the existence of preferential atrial conduction. Their studies demonstrated three internodal tracts (anterior, middle and posterior) connecting the sinus and A-V nodes. In addition, an extending branch to the left atrium (Bachmann's bundle) arising from the anterior internodal tract was also demonstrated.

Intraatrial and Interatrial Block

Intraatrial or interatrial block is characterized by abnormally wide P waves during sinus rhythm or by changes in P wave configuration during sinus rhythm or after a premature beat.[18,27,28] James and Sherf[18] suggested that the blocks occur in the internodal tracts. Recent experiments in canine hearts by Waldo et al.[26] demonstrated that P wave duration increased significantly whereas P wave configuration and polarity remained unchanged after the anterior internodal tract was cut close to the sinus node. A lesion placed in the Bachmann's bundle adjacent to the interatrial septum produced significant changes in P wave polarity, configuration and duration resembling "P mitrale." These studies suggested that the specialized atrial tracts were functionally significant in activation of the atria.

The diagnosis of intraatrial or interatrial blocks can be facilitated by direct intracavitary recordings. In Case 1, with severe interatrial block, several interesting electrophysiologic phenomena were seen. First, the degree of interatrial delay was such that the two components (left and right atrial) of the P wave were separated by an isoelectric period, producing an electrocardiographic pattern resembling atrial flutter. Second, the interatrial delay prolonged the P wave duration to 220 msec. Third, despite severe interatrial delay, the atrial functional refractory period was only 150 msec. This short atrial functional refractory period almost certainly reflected the short driving cycle length, since atrial functional refractory period decreases as cycle length shortens.[3] Although refractory periods were not measured at multiple sites, this result also suggests a major discordance between intraatrial conduction time and refractory period in this patient. A similar discordance between long conduction time and short refractory period in the diseased His-Purkinje system was recently described by Wu et al.[29] Finally, Case 1 is another instance of direct demonstration of left atrial rhythm by intracavitary recordings.[30]

Atrial Dissociation

Atrial dissociation of the right and left atria, with two independent P waves, has been reported in both human and animal hearts.[31–35] This occurrence has usually been attributed to complete intraatrial or interatrial block. The basic rhythm is usually sinus, but may be an ectopic atrial rhythm, junctional rhythm or even atrial fibrillation or flutter. The dissociated rhythm may be a slow escape rhythm, atrial tachycardia or fibrillation or flutter, and it is not conducted to the ventricles. The atrial complexes of the ectopic dissociated rhythm are usually smaller than those of the basic rhythm, probably because a smaller portion of the atrium is depolarized. Despite electrocardiographic observations, the true existence of this phenomenon was questionable, since direct intracavitary recordings were rarely performed. Recently, Zipes and DeJoseph,[1] using multiple intracavitary recordings, demonstrated dissimilar atrial rhythms with fibrillation in one atrium and a slower, more regular activity in the other. Their results suggested that the slower, more regular rhythm in one atrium was a result of constant filtering of the fibrillatory waves coming from the other atrium, due to a fairly fixed refractory period in the latter.

In our Case 2, with multiple dissimilar atrial rhythms, the electrophysiologic findings could be explained by postulating right atrial standstill and multiple ectopic foci in the left atrium. For this to occur, protective entrance and exit block in various ectopic foci must also have been present, since multiple foci would interfere with each other if there were no block. An alternative and more plausible explanation, as suggested by Zipes and DeJoseph,[1] was right atrial standstill and a rapid firing focus in the left atrium. Diverse refractory periods of atrial muscles in various sites of the atrium resulted in multiple atrial rhythms. Right atrial standstill presumably reflected advanced right atrial disease.

Both of our cases suggest that, under unusual circumstances, the surface electrocardiogram may not accurately portray atrial activation, particularly in the presence of advanced atrial disease. Manifestation of atrial rhythms at various recording sites including the surface electrocardiogram is dependent on the mass of atrial depolarization and proximity of the recording electrodes to the atrial mass.

"Paradoxical" Prolongation of Sinus Nodal Recovery Time After Atropine in the Sick Sinus Syndrome

JAMES A. REIFFEL, MD
J. THOMAS BIGGER, MD, FACC
ELSA-GRACE V. GIARDINA, MD

New York, New York

A case of symptomatic sick sinus syndrome is presented with confirmation of sinus nodal dysfunction established by functional testing. The validity of such provocative testing and the criteria for abnormality are discussed. A newly recognized, seemingly "paradoxical" and potentially detrimental effect of atropine noted in this patient is examined. Despite an increase in sinus rate and an improvement in sinoatrial conduction time after administration of atropine, a markedly prolonged sinus recovery time after rapid atrial pacing occurred, and atrial quiescence for more than 10 seconds was seen. Possible electrophysiologic mechanisms for this phenomenon, such as decreased atriosinus entrance block, concealed sinoatrial reentry or enhanced intranodal depolarization, are discussed and potential clinical correlates are made.

The "sick sinus syndrome" has been recognized with increasing frequency since 1968 when Ferrer[1] called attention to a group of related disorders whose signs and symptoms stem from sinus nodal dysfunction. The various clinical manifestations of these disorders have been well described.[1–7] and methods of documenting or quantitating the functional defects are improving. Ambulatory monitoring, one useful means of documenting such defects, allows observation of the electrocardiographic pattern during symptomatic periods. Pharmacologic interventions and provocative testing with atrial stimulation are additional useful tools for demonstrating otherwise latent or intermittent dysfunction. These advances in diagnostic technology have resulted in increased recognition of sinus nodal dysfunction and consequently in more frequent attempts at therapy, generally with permanent pacemaker implantation.[2,4] Pharmacologic therapy such as vagal blockade is employed less frequently and has often been unsuccessful. It may also be potentially detrimental. We recently studied a patient with the sick sinus syndrome in whom administration of atropine "paradoxically" lengthened the sinus nodal recovery time after atrial pacing. This occurred despite an increase in sinus rate and improvement in sinoatrial conduction after administration of the drug. The results of functional testing and our explanation for the response of the sinus recovery time to atropine form the basis of this report.

Case Report

A 55 year old woman was referred for functional testing of the sinus node. She had no cardiovascular symptoms until the onset of increasingly frequent "skipped beats" 4 years before admission. At that time sinus bradycardia was first noted. One year before admission, she first experienced exertional dyspnea and light-headedness that became progressively more severe. At no time did she experience true syncope, angina, congestive heart failure or rapid palpitations.

On hospital admission, blood pressure was 100/70 mm Hg and pulse 53 beats/min with occasional pauses; respirations were 16/min and temperature was normal. Cardiac examination revealed normal size and thrust, normal sounds, a functional systolic ejection murmur but no gallop or rub. Routine laboratory data were unremarkable except for the electrocardiogram, which

disclosed a mean sinus rate of 48 beats/min. A Valsalva maneuver caused the pulse rate to decrease to 40 beats/min where it remained until glottal release. Twenty-four hour dynamic electrocardiography revealed sinus bradycardia, moderately frequent supraventricular premature beats, repeated episodes of sinoatrial Wenckebach phenomena, as well as 3 to 5 second periods of asystole. Electrophysiologic studies were then performed to quantitate the severity of sinoatrial dysfunction and to assess the response to vagolytic drugs.

Electrophysiologic Methods

The patient was studied in the cardiac catheterization laboratory in the resting, nonsedated postabsorptive state. Under fluoroscopic monitoring a no. 6F tripolar catheter used to record the His bundle electrogram was passed percutaneously by way of the right femoral vein to the right atrium to lie across the tricuspid valve, and a no. 6F quadripolar catheter, one pair of electrodes for stimulating and one pair for recording, was passed through a right antecubital vein into the right atrium. The stimulating electrodes were positioned along the lateral wall of the mid-right atrium and the recording electrodes at the junction of the superior vena cava and the right atrium. Signals from the atrial and His bundle electrodes and the body surface electrocardiogram were displayed simultaneously on an Electronics for Medicine multichannel oscillograph and recorded on frequency-modulated magnetic tape. Control recordings of spontaneous rhythm were obtained before the initiation of atrial stimulation. Premature atrial stimuli were introduced by means of the stimulating electrodes during spontaneous sinus rhythm. The atrial electrogram was used to initiate a programmable Ortec stimulator. In this way, atrial premature stimuli of twice diastolic threshold intensity and 2 msec in duration were introduced by means of an isolation transformer after every eighth spontaneous sinus cycle and moved in 20 msec increments. The entire atrial diastolic period was scanned twice. Rapid atrial pacing at cycle lengths of 1,000, 900, 800, 700, 600, 500 and 400 msec was performed four times at each atrial cycle length with use of the same electrode pair. By means of the Electronics for Medicine recorder, the data were transferred to photographic paper for analysis at a paper speed of 100 mm/sec.

When rapid pacing was performed, the following were measured: (1) the interval from the last driven atrial depolarization to the next spontaneous depolarization of any type, and (2) the interval from the last driven atrial depolarization to the next spontaneous P wave if this interval was different from the first. Sinus recovery time was defined as the interval from the last driven atrial depolarization during rapid atrial pacing to the next spontaneous P wave if it was of sinus origin.

When the spontaneous sinus cycle was interrupted by an atrial premature depolarization, the following were measured: (1) the interval between the last two spontaneous P waves preceding the atrial premature depolarization, that is, the spontaneous sinus cycle length (A_1-A_1); (2) the interval between the last spontaneous sinus P wave and the atrial premature depolarization, that is, the test cycle (A_1-A_2); (3) the interval between the atrial premature depolarization and the following spontaneous P wave, that is, the return cycle (A_2-A_3); and (4) the spontaneous sinus cycle immediately following the return cycle, that is, the postreturn cycle (A_3-A_4).

Rapid atrial pacing and atrial premature stimulation were subsequently repeated 5 minutes after the administration of 1 mg of atropine intravenously when the pulse rate stabilized at a new level.

Results

The electrophysiologic data obtained at the time of catheterization were as follows:

Control Studies

Rhythm and rate: Sinus arrhythmia with atrial cycle lengths ranging from 1,025 to 2,507 msec was the predominant rhythm throughout the 60 minute testing period. Brief periods of junctional escape beats were noted, some with retrograde atrial depolarization (Fig. 1). The mean sinus cycle length (1,200 beats) was 1,479 msec.

Rapid atrial pacing: The values for sinus recovery time were generally similar at a given frequency of stimulation, and all postpacing pauses were terminated by sinus impulses (Fig. 2). In three of the four trials, the value of sinus recovery time rose to a peak at a pacing interval of 700 msec, with a maximum of 2,632 msec, and then decreased progressively. When the driven atrial cycle length was 400 msec in these three trials, the mean sinus recovery time was 1,543 msec (Fig. 2, point A, and Fig. 3A). However, in the fourth trial, the sinus recovery time at a paced cycle length of 400 msec was 3,325 msec, thus suggesting that 2:1 sinoatrial exit block had occurred (Fig. 2, point B, and Fig. 3B).

Premature atrial stimulation: An estimated mean sinoatrial conduction time was calculated from the plot of A_2-A_3 versus A_1-A_2 (Fig. 4A) using previously published principles.[13] The vertical line seen in this display represents an A_1-A_2 interval equal to the mean of all spontaneous atrial cycle lengths in sinus rhythm whereas the lower horizontal line represents an A_2-A_3 interval also equal to the mean spontaneous atrial cycle length. The upper horizontal line represents an A_2-A_3 interval equal to two spontaneous atrial cycle lengths. Points falling on the middle diagonal line represent nonreset of the sinus nodal pacemaker by the atrial premature depolarization (A_2). These late diastolic premature depolarizations do not have time to penetrate and reset the sinus node before it fires spontaneously and thus are followed by a fully compensatory pause. For these points, A_1-A_2 plus A_2-A_3 = $2(\overline{A_1\text{-}A_1})$. Atrial premature depolarizations elicited earlier in atrial diastole yield A_2-A_3 intervals that fall below and to the left of the middle diagonal line as sinus pacemaker reset occurs; that is, when the premature depolarization penetrates and depolarizes the sinus node before its next expected spontaneous firing, the sinus pacemaker is reset. The return cycle is no longer fully compensatory but is greater than one spontaneous sinus cycle length.

The value of A_2-A_3 represents the duration of conduction from the induced atrial premature depolarization into the sinus node, at which point reset occurs, plus the time until the next spontaneous sinus depolarization occurs (presumed equal to $\overline{A_1\text{-}A_1}$) plus the duration of conduction out of the sinus node to the atrium, when the next atrial depolarization occurs. Thus, A_2-A_3 equals $\overline{A_1\text{-}A_1}$ plus conduction time

into and out of the sinus node. Therefore, A_2-A_3 minus A_1-A_1 (which is represented by the distance of these points above the lower horizontal line) equals twice the sinoatrial conduction time. The mean of all A_2-A_3 intervals in this zone was determined and a mean sinoatrial conduction time was calculated from the formula $[(\overline{A_2\text{-}A_3}) - (\overline{A_1\text{-}A_1})]/2$.

Despite the borderline normal value of 83 msec so obtained, several return cycles were compatible with 2:1 sinoatrial exit block. These points, not used in calculating the mean sinoatrial conduction time, are also seen in Figure 4A. When 2:1 sinoatrial exit block occurs, A_3 is delayed by a time equal to one sinus cycle length; that is, the curve shifts upward a dis-

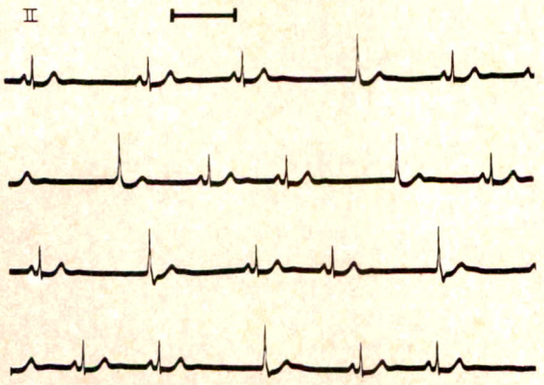

FIGURE 1 (above). Lead II rhythm strip at the onset of electrophysiologic testing revealing sinus rhythm with junctional escape beats. Time bar equals 1 second.

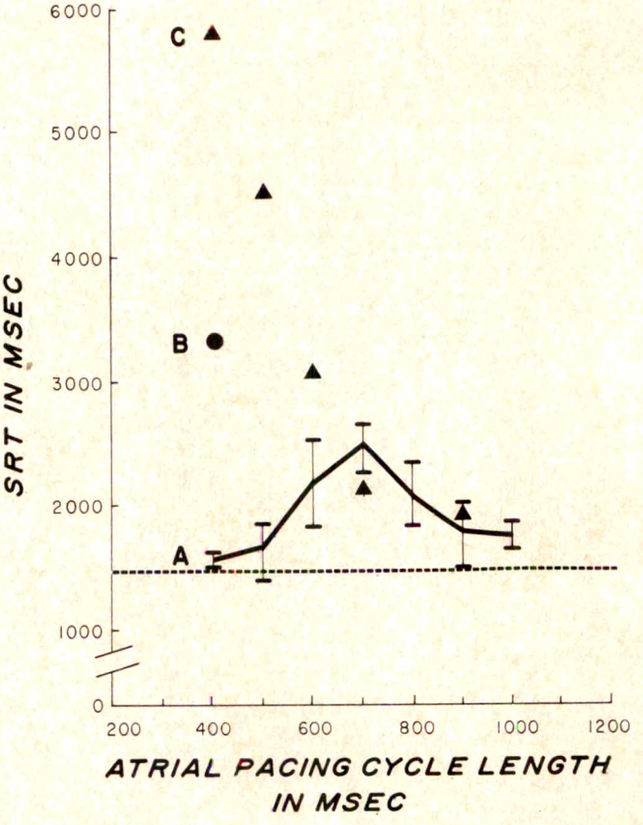

FIGURE 2 (right). Rapid atrial pacing. Postpacing pauses (sinus recovery times, SRT) are plotted against driven atrial cycle length. Bars represent range of pauses at each pacing frequency in control state (see text). **Continuous line** connects mean values. **Triangles** indicate pauses at corresponding pacing frequencies after administration of atropine. **Point A** = mean sinus recovery time at a driven atrial cycle length of 400 msec for three of four trials in the control state. **Point B** = pause representing probable 2:1 sinoatrial exit block in the fourth trial at a driven atrial cycle length of 400 msec in the control state. **Point C** = junctional escape beat without retrograde conduction to the atria at a driven atrial cycle length of 400 msec after administration of atropine. **Dashed horizontal** line represents mean sinus cycle length.

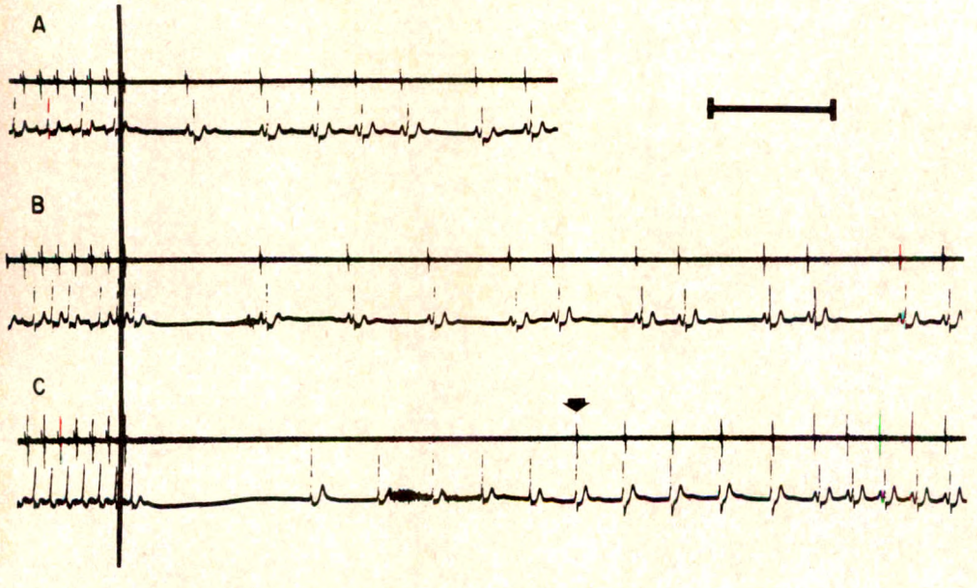

FIGURE 3. Termination of atrial pacing at driven atrial cycle lengths of 400 msec. **Panel A,** indicating results in three of four trials in the control state, corresponds to point A in Figure 2. **Panel B,** indicating 2:1 sinoatrial exit block in the fourth trial in the control state, corresponds to point B in Figure 2. **Panel C,** indicating results after administration of atropine, corresponds to point C in Figure 2. Note the absence of atrial activity for 10,920 msec. **Arrow** indicates earliest atrial complex after pacing. The first five P waves to return result from atrial activation from junctional escape beats. Sinus P waves follow. Time bar equals 3 seconds.

tance equal to A_1-A_1. Points then fall on the upper diagonal line or below and to the left of it, depending on the prematurity of the atrial premature depolarization. The lower diagonal line in this figure indicates where return cycles following interpolated atrial premature beats would have occurred. The mean post-return cycle (A_3-A_4), not shown on this plot, was not significantly different from the mean of all other sinus cycles.

Atrioventricular conduction: A-H and H-V intervals were normal, however, A-H Wenckebach phenomenon appeared with a paced atrial cycle length of 500 msec.

After Atropine

Rhythm and rate: The mean atrial cycle length shortened to 953 msec in the steady state after administration of atropine.

Rapid atrial pacing: On all but one occasion the postpacing pauses were lengthened by comparison with the mean value of sinus recovery time at equivalent pacing rates before administration of atropine

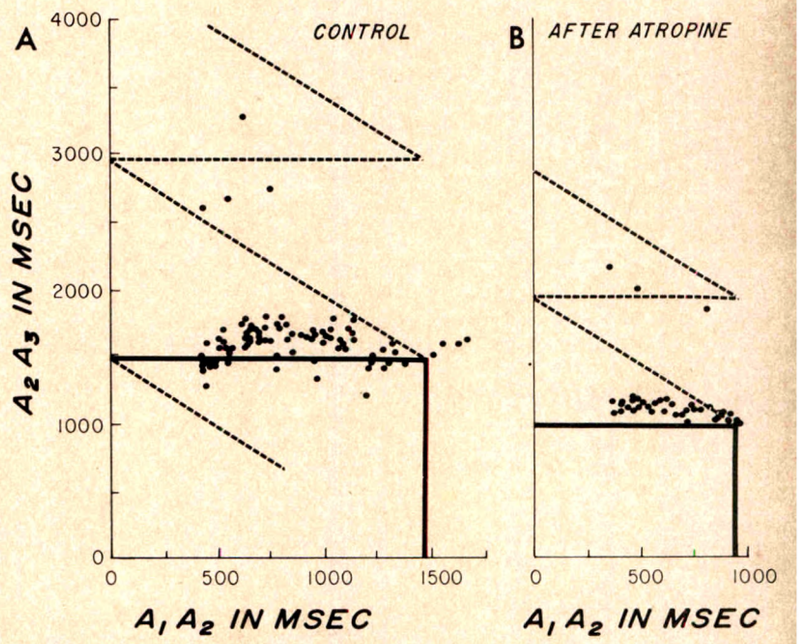

FIGURE 4. The return cycle (A_2-A_3) plotted as a function of the test cycle (A_1-A_2) during atrial premature stimulation. **Panel A** = control state; **Panel B** = state after administration of atropine. See text for details.

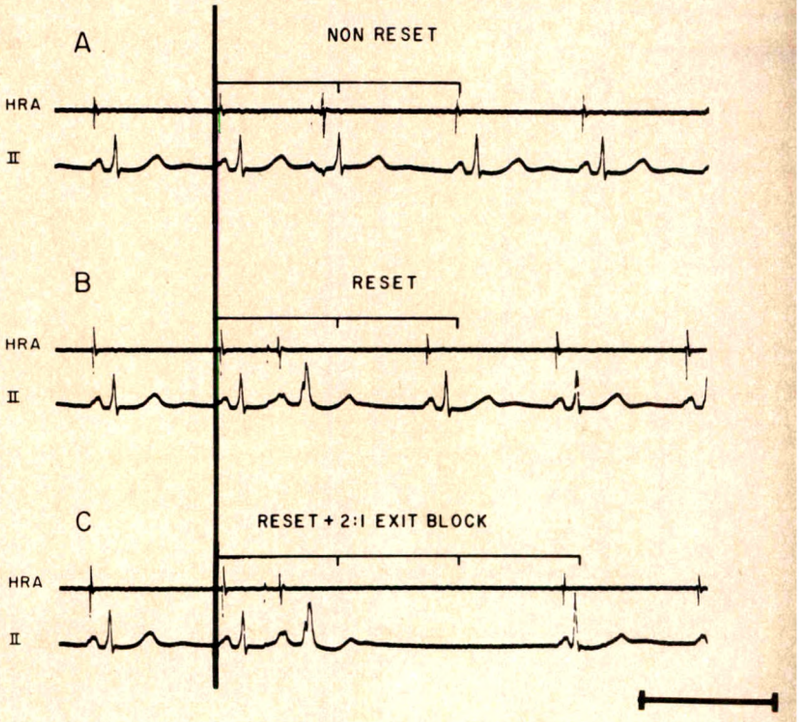

FIGURE 5. Lead II and high right atrial electrogram (HRA) during atrial premature stimulation. **Panel A,** nonreset of sinus node (points fall on the middle diagonal line in Figure 4). **Panel B,** reset of sinus node (points fall above the lower horizontal line but to the left of and below the middle diagonal line in Figure 4). **Panel C,** reset with 2:1 sinoatrial exit block (point falls above the upper horizontal line but to the left of and below the upper diagonal line in Figure 4). In each panel, the brackets represent a distance equal to the mean A_1-A_1 cycle length. In **Panel A,** A_1-A_2 plus A_2-A_3 equals two brackets and therefore equals two times $\overline{A_1\text{-}A_1}$. In **Panel B,** A_1-A_2 plus A_2-A_3 is less than two times $\overline{A_1\text{-}A_1}$. In **Panel C,** A_1-A_2 plus A_2-A_3 is one cycle length longer than in Panel B because of the lengthening of A_2-A_3 by a distance of approximately one $\overline{A_1\text{-}A_1}$. Time bar equals 1 second.

(Fig. 2). Only two pauses were terminated by beats of sinus origin. With a paced atrial cycle length of 500 msec, the postpacing pause was terminated by a junctional depolarization after 4,524 msec. With a paced atrial cycle length of 400 msec, the postpacing pause was terminated by a junctional depolarization without retrograde atrial conduction at 5,794 msec (Fig. 2, point C, and Fig. 3C). No atrial activity was seen until a junctional beat with retrograde atrial depolarization occurred after 10,920 msec. The sinus recovery time was therefore even greater than 10,920 msec.

Premature atrial stimulation: An estimated mean sinoatrial conduction time of 75 msec was calculated from the plot of A_2-A_3 versus A_1-A_2 (Fig. 4B). Rare recovery cycles demonstrating 2:1 sinoatrial exit block were again seen. The reference lines in this plot have the same meaning as in Figure 4A. Frames showing examples of nonreset, reset and 2:1 sinoatrial exit block after reset during atrial premature stimulation are shown in Figure 5.

Atrioventricular conduction: A-H and H-V intervals were again normal. A-H Wenckebach phenomenon occurred only with a paced atrial cycle length of 400 msec.

Discussion

Our patient clearly manifested several features of symptomatic sinus nodal dysfunction classically a part of the sick sinus syndrome.[2–7] Light-headedness, exertional dyspnea and supraventricular ectopic beats were all associated with inappropriately slow sinus rates as revealed by ambulatory monitoring. Provocative testing allowed further documentation and quantitation of the degree of sinoatrial dysfunction. Such testing[3,8–15] rests upon the principles of overdrive suppression by rapid atrial pacing, assessment of sinoatrial responses to atrial premature stimulation and manipulation of autonomic balance by pharmacologic means.

Sinoatrial recovery time: Gaskell[16] in 1884 first demonstrated the depression of intrinsic pacemaker rate that results from driving the heart at a rate faster than that of the dominant pacemaker. Further in vitro and in vivo support for overdrive suppression followed,[17–19] although the necessary and possible pacing frequencies varied from species to species. In recent years, the response of the sinus node to rapid atrial pacing has become one clinical method of provocative testing for sinoatrial dysfunction.[9,11,12,15] The length of time required for the sinus node to resume impulse formation after overdrive suppression—that is, the sinus recovery time—has been thought to reflect in large part the automatic properties of the node. However, conduction from the atrium to the sinus node during pacing and sinoatrial conduction after pacing must be considered in assessing the catheter-recorded postpacing recovery interval.

Values for the sinus recovery time have been described for normal persons and have been contrasted with those obtained in patients with sinus bradycardia or the sick sinus syndrome.[2,9,11,12,15] Unfortunately, the criteria for separating normal from abnormal values have varied. Rios et al.[15] found that the sinus recovery time averages 108 percent of the prepaced sinus rate in normal subjects and 113 percent in patients with the sick sinus syndrome, whereas Rosen et al.[3] stated that, in normal patients, cessation of rapid atrial pacing does not produce asystolic periods lasting 1.4 seconds. Narula et al.[11] first suggested correction of the sinus recovery time for heart rate. In 27 of 28 of their normal subjects, the value for sinus recovery time minus sinus rate, was 110 to 525 msec (15 to 59 percent of sinus cycle length). However, 16 of 28 patients with sinus bradycardia also had corrected sinus recovery times in this range. Mandel et al.[9] noted that 3 patients with the sick sinus syndrome had a longer sinus recovery time (4,732 ± 67 [standard error of the mean] msec) than did 43 normal subjects (1,041 ± 56 msec) and subsequently reported[12] that 29 of 31 patients with symptomatic sick sinus syndrome had a mean maximal postpacing pause of 3,164 ± 334 msec, whereas the normal mean was 1,073 ± 67 msec. In their normal subjects this represented a maximal pause of 106 to 128 percent of control sinus cycle length, the exact percentage depending on the pacing rate used. Ferrer's review[2] states that for a sinus cycle length of 1,000 msec a pause of 125 percent of the control cycle length is strongly suggestive whereas at sinus rates of 42 beats/min (a cycle length of 1,420 msec) a pause of 1,700 msec or more is diagnostic of sinus nodal dysfunction although this value is only 120 percent of the control cycle length. In our patient the maximal sinus recovery time in the control state was 2,632 to 3,325 msec, which is well in excess of 160 percent of the control sinus cycle length and exceeds any of the cited criteria of abnormality.

Sinoatrial conduction time: Estimation of sinoatrial conduction time by examining the sinoatrial response to premature atrial stimulation is also, in our opinion, useful in assessing sinoatrial function. Recent use of this principle stems from the observations of Langendorf et al.[20] on the behavior of sinus rhythm interrupted by atrial parasystolic beats and the subsequent application of these observations.[10,13,14,21–24] As with rapid atrial pacing, in vitro work has supported the principles and revealed some of the pitfalls of this technique.[25–27] Although the mean sinoatrial conduction time in our patient was only mildly prolonged when compared with values generally obtained at the same heart rate,[28] the documentation of 2:1 sinoatrial exit block indicates a severe disturbance of conduction.

Atropine: Provocative testing of sinus nodal function by pharmacologic means has been less extensively analyzed. Although considerable data exist concerning the response of normal subjects to graded doses of atropine,[22,29–38] only recently have the responses in patients with sinoatrial dysfunction been examined.[2,3,12,21,39,40] These responses suggest that a blunted acceleration in heart rate after administration of vagolytic agents indicates sinoatrial dysfunc-

tion. Mandel et al.,[12] for example, reported that after administration of 0.025 mg/kg of atropine the average increase in heart rate was only 23 percent (52 to 64 beats/min) in 31 patients with sinus bradycardia. Narula[39] found that 2 mg of atropine intravenously caused the sinus cycle length to decrease to less than 1,000 msec in only 3 of 75 patients with sinus bradycardia, and Rosen et al.[3] found that although 8 of 11 patients with symptomatic sinus node disease had an increase in heart rate of 25 to 125 percent after 1 mg of atropine intravenously, none had a sinus rate of more than 90 beats/min. Although our patient's sinus rate increased by 54 percent in response to 1 mg of atropine intravenously, a dose greater than those reported to induce a paradoxical sinus bradycardia[22,29–34,37,38,40] with an accompanying paradoxical increase in sinus recovery time,[22] this increase represented a peak post-drug rate of only 63 beats/min.

Far less has been written concerning the effects of vagolytic agents on the sinus recovery time and the mean sinoatrial conduction time. Engel et al.[21] and Mandel et al.[12] have stated that atropine can shorten a prolonged sinus recovery time, although Narula et al.[11] indicated that the sinus recovery time will not necessarily shorten to normal and suggested that nonsinus escape beats are more likely to terminate the postpacing pause after atropine. In view of the increased sinus rate and improved sinoatrial conduction seen in our patient in response to atropine, it seems surprising that rapid atrial pacing in the postmedication state resulted in significant lengthening of the postpacing pauses with markedly prolonged atrial quiescence on two occasions. In fact, similar although less dramatic findings have previously been reported on only one occasion to our knowledge.[41]

Mechanisms of paradoxical response to atropine: This seemingly paradoxical increase in the sinus recovery time after atropine may have resulted from: (1) alterations in sinus nodal automaticity, (2) alterations in sinoatrial conduction time, and (3) possible alterations in intra-sinoatrial nodal conduction. First, a primary change in sinus nodal automatic function must be important, although it is inseparably linked with alterations in sinoatrial conduction time. When the latter is decreased by atropine, there may be better penetration of the sinus node by atrial paced beats at any frequency of pacing than during the control state. If more paced impulses propagate to the sinus node per unit of time, sinus suppression might increase, thereby prolonging the sinus recovery time. This explanation assumes that (1) the mean sinoatrial conduction time is improved enough after administration of atropine to allow more atrial stimuli to reach the sinus node; (2) maximal sinus recovery time occurs at the atrial pacing rate that allows the maximal frequency of sinus nodal penetration per unit of time (which may not always be true); and (3) in spite of the increase in spontaneous automatic firing rate after administration of atropine, the sinus node remains highly sensitive to overdrive suppression of automaticity. If this latter assumption is true, it implies that sinus nodal suppression and sinus recovery time might be even more severely prolonged if the node were penetrated by an equivalent number of atrial impulses per unit of time before the administration of atropine, when the spontaneous firing rate was slower.

Second, a disturbance in sinoatrial conduction could explain the increase in sinus recovery time after administration of atropine. Since the sinoatrial junction functions somewhat analogously to the atrioventricular junction, disturbances in sinoatrial conduction can promote reentrant rhythms[42] in the perinodal fibers.[43] Reentrant beats have been demonstrated in the region of the sinus node in both animal[44,45] and human[46,47] studies, and concealed conduction in this tissue has also been noted.[48] There is no reason to believe, therefore, that repetitive concealed conduction such as has been shown to occur in the atrioventricular nodal region[49] could not occur in the sinus nodal region as well. It is thus possible that a reentrant rhythm in the perinodal fibers with concealed sinoatrial conduction, causing repetitive resetting of the sinus node but antegrade conduction block to the atria, could account for the apparently prolonged sinus recovery time in our patient after administration of atropine.

Third, it is known that conduction of impulses within the sinus node is relatively poor.[27,50] Conduction of impulses from the atrium to the sinus node is not necessarily associated with resultant depolarization of the entire node. Furthermore, the automatic properties of all P cells within the node are not identical. Therefore, the possibility exists that sinus impulse initiation after atrial premature stimulation or atrial pacing may not be by the same cell or at the same rate as existed before the atrial initiated beat. If intranodal conduction is influenced by vagotonia, then the possibility exists that such conduction could be enhanced by atropine, resulting in more uniform and complete depolarization of sinus nodal P cells when stimulated by an impulse arising in the atrium. This theoretical effect of atropine could conceivably enhance the suppression of sinus nodal automaticity by atrial pacing.

Clinical implications: Atropine may have therapeutic effects in patients with the sick sinus syndrome. It is capable of increasing sinus rate and improving sinoatrial conduction in some symptomatic patients, but in an as yet undetermined percentage of such patients, it may be potentially detrimental. As functional testing in our case demonstrated, the tendency to post-tachycardia asystole may be enhanced by the very agent proposed for therapy. Whether a prolongation of the sinus recovery time during provocative testing correlates precisely with the frequently observed period of severe bradycardia or asystole that may follow termination of spontaneous atrial tachyarrhythmias in the bradycardia-tachycardia form of the sick sinus syndrome has not yet been fully evaluated, but there is evidence that this is the case.[11,47] Regardless of the mechanism, an increase in

post-tachycardia bradycardia produced by atropine could increase the severity of symptoms in these patients. We therefore recommend that provocative electrophysiologic testing be repeated after potentially therapeutic pharmacologic agents are administered to patients with sinus nodal dysfunction since this may be the only means of demonstrating the possible detrimental effects of such therapy.

Acknowledgment

We are indebted to Dr. M. I. Ferrer for referring her patient for these electrophysiologic studies.

Demand Pacemaker Arrhythmias Caused by Intermittent Incomplete Electrode Fracture

Diagnosis with Testing Magnet

PHILIPPE COUMEL, MD
JACQUES MUGICA, MD
S. SERGE BAROLD, MB, FRACP, FACC

Saint-Cloud, France
Rochester, New York

This report describes how the testing magnet was used to diagnose intermittent and incomplete electrode fracture in two patients with an implanted demand pacemaker. During fixed-rate pacing the interval between two consecutive pacemaker spikes intermittently doubled in length, suggesting that the pulse generator was continuing to fire on time into a transiently disrupted circuit. Attenuated pacemaker spikes occurring at the anticipated time of pacemaker discharge also provided a diagnostic clue. Ventricular electrograms from the defective electrodes registered small false signals.

The widespread use of demand pacemakers from a proliferating number of manufacturers has added a new dimension to clinical electrocardiography and has made the evaluation of pacemaker function increasingly difficult. This report describes use of a testing magnet to diagnose intermittent and incomplete electrode fracture in two patients with an implanted demand pacemaker. Such problems will undoubtedly become more frequent as the longevity of pulse generators continues to increase.

Case Reports

Case 1

The bundle of His in a 35 year old woman was surgically ligated because of intractable reciprocating supraventricular tachycardia in association with the Wolff-Parkinson-White syndrome.[1] Epicardial pacing electrodes were sutured on the diaphragmatic surface of the heart (one on the left and one on the right ventricle) and connected to a Medtronic bipolar demand pulse generator, model 5842. Pacing and sensing remained normal for about 20 months; about 22 months after implantation the patient was hospitalized because of the recent onset of syncope. The electrocardiogram revealed a complex pacemaker arrhythmia (Fig. 1 and 2).

Analysis of electrocardiograms (Fig. 1 and 2): The basic automatic interval (on demand) is 960 msec. The arrhythmia is characterized by:

1. *Irregular prolongation of the spike to spike (S-S) interval* to less than twice the automatic interval (960 to 1,460 msec). The S-S intervals of 1,080 and 1,120 msec (Fig. 2, bottom and top, respectively) suggest partial recycling of the pulse generator because they are significantly shorter than the sum of one automatic interval (960 msec) and the delivery (paced) refractory period of this pulse generator (that is, the earliest time after a pacemaker spike that sensing can occur—about 250 to 300 msec for this unit).[2,3]

2. *Apparent irregular prolongation of escape intervals.* The escape interval, conventionally measured from the onset of the surface QRS complex, may vary according to the pattern of ventricular depolarization, that is, time of sensing.[4] This slight variation is clearly shown in Figure 2, where beats with a narrow QRS complex (beats A) recycle the pulse generator with an escape interval of 980 to 1,000 msec, whereas Wolff-Parkinson-White beats with a broad QRS complex (beats B) initiate an escape interval of 1,080 msec (Fig. 1). However, the escape intervals seem to lengthen beyond the accept-

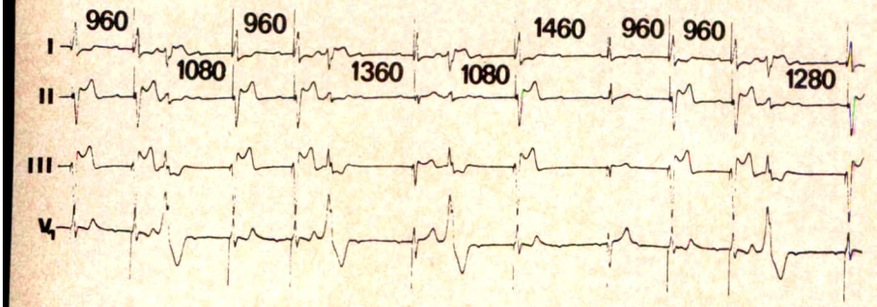

FIGURE 1. Case 1. **Top,** leads I, II, III and V_1 recorded simultaneously. **Bottom,** leads V_4, V_5 and V_6 recorded simultaneously. In this and subsequent figures the duration, in milliseconds, of the interval between two consecutive pacemaker spikes appears above the top tracing in each panel and the apparent duration, in milliseconds, of the escape intervals is indicated below the top tracing. The apparent escape intervals for beats B (Wolff-Parkinson-White beats with a broad QRS) range from 1,080 to 1,360 msec (3rd, 5th, 7th and 12th beats, top panel). See text.

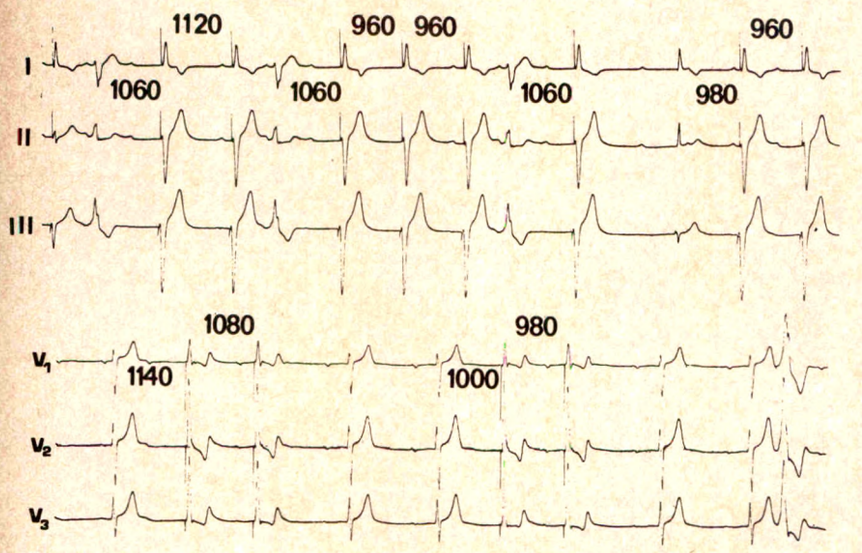

FIGURE 2. Case 1. **Top,** leads I, II and III recorded simultaneously on a day different from that shown in Figure 1. **Bottom,** leads V_1, V_2 and V_3 recorded simultaneously. The escape intervals for beats A (beats with narrow QRS) (third last beat, top panel, first and fifth beats, bottom panel) range from 980 to 1,140 msec. The S-S intervals of 1,080 and 1,120 msec suggest partial recycling of the pulse generator. See text.

able range; the escape intervals for beats A range from 1,080 to 1,360 msec (Fig. 1), whereas those for beats B range from 980 to 1,140 msec (Fig. 2).

3. *Irregular pauses after paced or spontaneous beats.* These pauses were shorter than two automatic intervals and were terminated by a spontaneous beat (Fig. 2). No cardiac cycles were lengthened to more than twice the duration of the automatic interval of the pulse generator.

Electrocardiograms were recorded for long periods with the magnet over the pulse generator (Fig. 3). The automatic interval was immediately shortened to 940 msec, a normal response for this pulse generator.[4] The amplitude of the pacemaker spike did not change with respiration, but the duration of the S-S interval doubled to precisely twice that of the automatic interval about once in every 50 pacemaker spikes. The 1,880 msec S-S intervals contained diminutive ineffectual pacemaker spikes (arrows) at the anticipated time of pacemaker discharge, that is, 940 msec after the last pacemaker spike (Fig. 3).

Multiple X-ray films of the pacing electrodes failed to reveal any fractures.

The pulse generator was surgically disconnected and electrograms were obtained from the pacing electrodes with the V lead of an electrograph (Siemens Mingograph, frequency response 400 hertz). The first electrode recorded a large ventricular electrogram free of artifact (Fig. 4, top); unipolarization of the pacing system, using this electrode as the cathode, resulted in normal sensing and pacing with a threshold of 2 milliamperes (tested with an external Medtronic pacemaker, model 5880). Electrograms from the second electrode (Fig. 4, bottom) revealed small artifacts (arrows), usually near the end of the T wave. Unipolarization, using this electrode as the cathode, reproduced the pacemaker arrhythmia previously seen, and the pacing threshold was 6.5 milliamperes.

A new pulse generator, model 5943, was then connected to the first electrode. The pulse generator that had been removed (model 5842) was suitably modified and used as an external pacemaker in another patient. No evidence of malfunction was noted, and this finding was subsequently confirmed by the manufacturers, who observed only the anticipated battery depletion for a generator of this age.

Case 2

An epicardial Medtronic demand pacemaker, model 5942, was implanted in a 63 year old man with complete

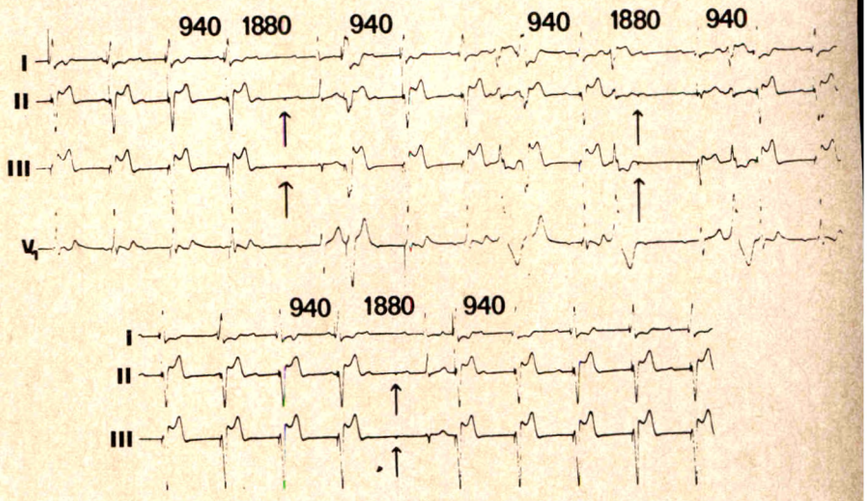

FIGURE 3. Case 1. Application of the magnet. **Top,** leads I, II, III and V_1 recorded simultaneously. **Bottom,** leads I, II and III recorded simultaneously. The S-S interval lengthens intermittently to precisely double the duration of the automatic interval. Note the occurrence of small ineffectual pacemaker spikes at the anticipated time of pacemaker discharge, that is, 940 msec after the last pacemaker spike **(arrows).** See text.

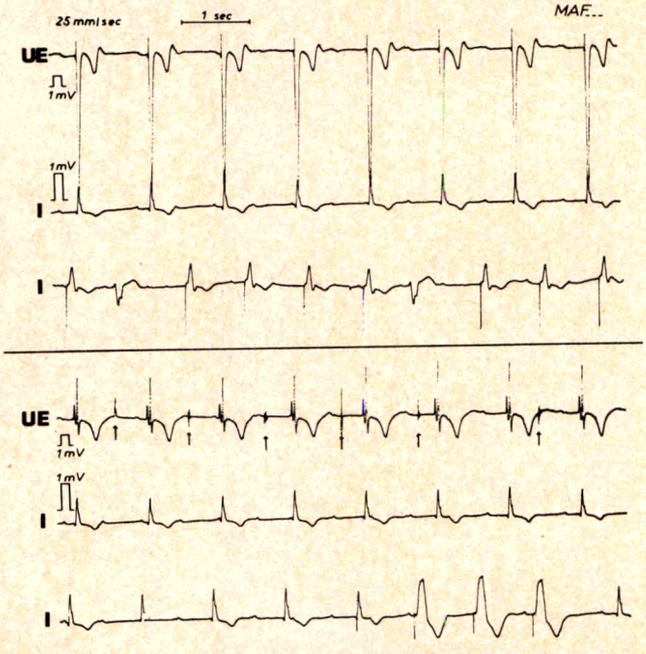

FIGURE 4. Case 1. **Top,** unipolar electrogram (UE) from the normal electrode recorded simultaneously with lead I **(middle strip).** The **lower strip** shows normal unipolar demand ventricular pacing with this particular electrode as the cathode. **Bottom,** unipolar electrogram (UE) from the defective electrode, recorded simultaneously with lead I **(middle strip).** Note the intermittent occurrence of false signals (1 to 3 mv) near the end of the T wave. The **lower strip** shows abnormal unipolar demand pacing by a Medtronic pulse generator, model 5943, when the defective electrode was the cathode.

atrioventricular block. Sensing and pacing with an automatic interval of 840 msec remained normal until 10 months after implantation when a routine electrocardiogram revealed intermittent prolongation of the S-S interval to 1,380 msec (Fig. 5). Deep respiration or change in posture did not significantly influence the size of the pacemaker spike in simultaneously recorded leads I, II, III and V_1.

These leads were then simultaneously recorded with the magnet over the pulse generator, but there was no evidence of malfunction during the recording of more than 1,500 paced ventricular beats; the S-S interval remained constant (about 830 msec) and the few observed spontaneous beats were consistently followed by a spike of normal size falling within the absolute refractory period of the heart (Fig. 6A, left panel). Further recordings with the magnet were obtained to observe the effect of critically timed spontaneous beats upon the size of the subsequent pacemaker spike. The pacemaker spikes of paced ventricular beats remained consistently normal in size during a recording of 5,000 beats, but the amplitude of the spike was strikingly diminished when it coincided with the T wave of some premature spontaneous beats (Fig. 6, A [right panel] and B to D). Note the complete disappearance of the pacemaker spike in Figure 6D with doubling of the S-S interval to precisely twice the length of the automatic interval.

Multiple X-ray films of the pacing electrode failed to reveal any fractures.

The pulse generator was surgically disconnected. The bipolar electrogram recorded intermittent small artifacts (arrows) related to the T wave (Fig. 7, top). Unipolar electrograms from the two electrodes were then recorded simultaneously (Fig. 7, UE1 and UE2). Electrograms from the first electrode displayed intermittent artifacts (UE1, arrows). Unipolarization of the pacing system using this electrode as the cathode revealed a pacing threshold of more than 25 milliamperes (tested with an external Medtronic pacemaker, model 5880). The electrogram from the second electrode (UE2) was entirely free of artifact. The pacing threshold was 1 milliampere when the system was unipolarized using the second electrode as the cathode.

A new unipolar Medtronic pulse generator, model 5943, was connected to the second electrode. The new system has functioned well during several months of follow-up. The pulse generator that had been removed, model 5942, was returned to the manufacturers, who found no evidence of malfunction.

Discussion

Abrupt changes in resistance within a pacing system produce corresponding voltage changes between the anode and cathode and may generate false signals that can be sensed by a demand pulse generator.[5–8] These signals generally occur at random and their presence should be suspected whenever demand pacing assumes a chaotic pattern as in Case 1. Case 2 illustrates how a defective electrode may induce rhythmic recycling of a demand pacemaker if mechanical systole creates false signals by making and breaking the circuit. The timing of such an abnormality would be electrocardiographically indistinguishable from T wave sensing.

Factors affecting amplitude of pacemaker spike: Barring small physiologic variations with respiration, the amplitude of the pacemaker spike in a bipolar pacing system may diminish in the following circumstances: (1) Pulse generator failure, which was ruled out in both cases. (2) Short circuit between the electrodes, which was excluded by the electrographic recordings and successful conversion to long-term unipolar pacing. (3) Defective electrode insulation. The size of the pacemaker spike is a function of the distance between the electrodes and the current density. Because an insulation break creates an alternative

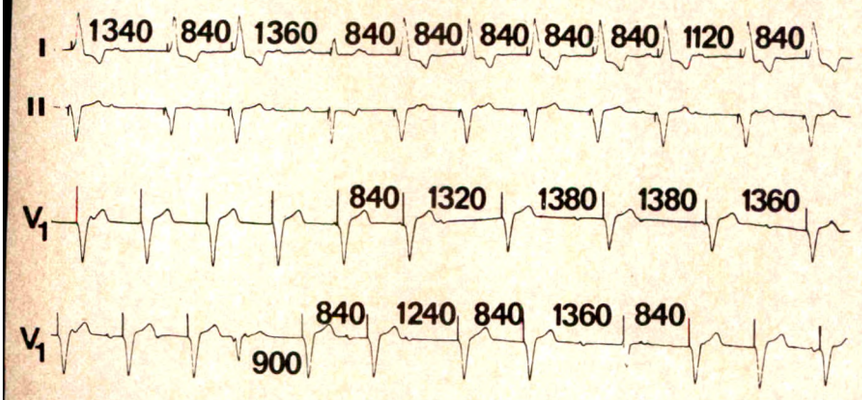

FIGURE 5. Case 2. Leads I and II recorded simultaneously. The S-S interval lengthens intermittently from 840 msec (automatic interval) to a value never higher than 1,380 msec. The **bottom strip** shows normal sensing of a spontaneous beat by the pulse generator.

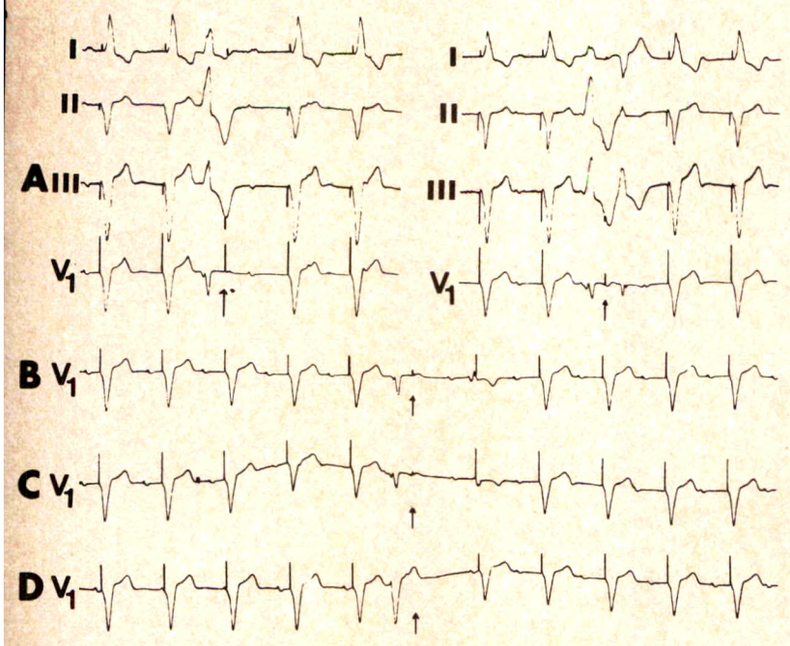

FIGURE 6. Case 2. Application of the magnet causes a slight shortening of the automatic interval to about 830 msec.[4] **A,** leads I, II, III and V_1 recorded simultaneously. In the left panel there is no evidence of pacemaker malfunction. The third pacemaker spike is normal in amplitude and falls within the refractory period of the heart. In the right panel, note the reduced size of the third pacemaker spike, also falling within the refractory period of the heart. **B to D,** lead V_1. Various reductions in spike amplitude after spontaneous beats **(arrows).** In **D,** duration of the S-S interval increases to precisely twice that of the automatic interval, and the pacemaker spike disappears. Generalized reduction of the pacemaker spike was also seen in leads I to III (not shown) recorded simultaneously with lead V_1.

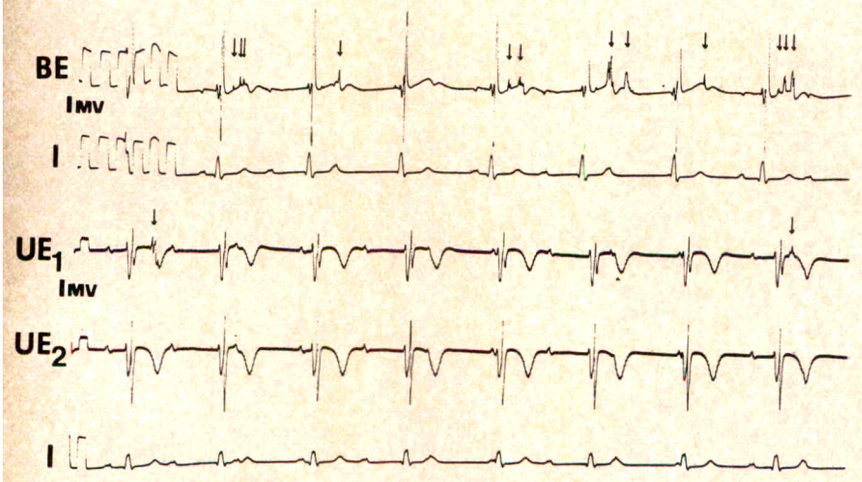

FIGURE 7. Case 2. **Top,** bipolar electrogram (BE) and surface lead I. **Bottom,** simultaneous recording of unipolar electrograms from the two electrodes (UE_1 and UE_2) and surface lead I. Note the small artifacts at the **arrows.** Calibration = 1 mv.

path for current flow,[9] the electrical dipole of the leakage current from a small insulation defect close to the proximal electrode could theoretically reduce or cancel the resultant dipole and therefore the amplitude of the pacemaker spike. Clinically, however, insulation defects in bipolar systems almost invariably increase the amplitude of the pacemaker spike,[10,11] making this possibility highly unlikely but not altogether impossible in our two cases. (4) A partial wire fracture with a fluid bridge.

Testing magnet for diagnosing intermittent partial electrode fracture: The testing magnet for contemporary pacemakers is valuable in the evaluation of pacemaker function because its use eliminates all arrhythmias related to oversensing.[12] This report shows how the magnet may also be used to diagnose intermittent partial electrode fracture. In this situation, long electrocardiographic records are essential because firing of the pulse generator must coincide with the momentary increase in electrode resistance. Pacemaker spikes usually disappear in the presence of an electrode fracture but the attenuated spikes so clearly seen in Figures 3 and 6 provided a striking and relatively uncommon diagnostic clue of a transient increase in electrode resistance.

When the magnet was placed over the pulse generator, the S-S interval intermittently lengthened to precisely double the duration of the automatic interval in contrast to its irregular prolongation during demand pacing. During fixed-rate pacing (that is, while the magnet is being used), pacemaker pauses that are exact multiples of the automatic interval suggest that the pulse generator is continuing to fire on time into a transiently disrupted circuit.[13] When the spontaneous rhythm is faster than the preset rate of a demand pacemaker this finding may be the only diagnostic clue to intermittent electrode fracture because false signals will remain undetectable.

The electrogram from the defective electrodes registered small false signals of borderline voltage for sensing.[14] Although these relatively small signals may partially recycle contemporary implantable Medtronic pulse generators,[3] it is unlikely that they were responsible for the shortened escape interval after paced beats in Figure 2 because interruption of the pacing circuit shortly after a pacemaker spike disturbs the high residual polarization voltage at the myocardial-electrode interface and generally creates much larger signals.[4,13] The signals responsible for partial recycling after a paced beat probably were quite large but fell within the relative refractory period of the pulse generator (the short recovery period after the delivery refractory period) when comparatively larger signals may also partially recycle an implantable Medtronic pulse generator.[2,4,13] This possibility reemphasizes the importance of fully understanding the specifications of normally functioning pulse generators since seemingly erratic behavior may not necessarily indicate failure.

Sensing of concealed ventricular extrasystoles: Massumi et al.[15] recently suggested that a demand pacemaker could sense intracardiac voltage generated by concealed ventricular extrasystoles (depolarization confined to the His-Purkinje system and invisible in the 12 lead electrocardiogram[16]). Several authors[17–19] have since accepted this concept despite cogent alternative explanations[8] for these observations. The electrocardiograms in our report resemble those described by Massumi et al.[15] and, in this context, spurious signals recorded from defective electrodes should not be interpreted as originating from the heart. The concept of sensed concealed ventricular extrasystoles should remain speculative and highly improbable on electrophysiologic grounds; consideration of this possibility in the differential diagnosis of a complex pacemaker arrhythmia might detract attention from a potentially more serious problem such as an intermittent electrode fracture.

Etiology of the Mitral Valve Prolapse-Click Syndrome

ROBERT M. JERESATY, MD, FACC

Hartford, Connecticut

The syndrome of mitral valve prolapse with associated auscultatory and electrocardiographic findings has recently generated considerable interest.[1–25] Its frequency has been documented in several large series.[1–3,8] Ours currently stands at 200 patients, with angiographic confirmation of the mitral valve prolapse in 60. Two main theories have been advanced to explain the etiology of this syndrome: The first stresses mitral valve abnormality and the second, myocardial involvement as demonstrated by left ventriculography and hemodynamic studies.

1. The Valvular Theory

According to this theory, myxomatous degeneration of the mitral valve is the underlying mechanism responsible for the mitral valve prolapse.[2,3,15,16,21] The loss of the normally dense collagenous supporting structure allows stretching of the cusps by normal ventricular pressure and results in redundant and ballooned leaflets. Fibrous friction lesions of the left ventricular endocardium with adhesions of the chordae tendineae and collagenous prolongation into the subjacent myocardium have been described.[23] Papillary muscle fibrosis in the absence of coronary atherosclerosis has been demonstrated.[3,24] In all but one reported series,[1] rheumatic heart disease was not evident.

The valvular theory attempts to explain the various manifestations of the click syndrome. The chest pain is thought to be due to excessive stretching of the papillary muscles.[1,3,25] According to the Laplace law, the chordae tendineae, attached to a voluminous billowing leaflet that by overshooting the other leaflet no longer has its support, are under increased tension. Such forceful traction on the papillary muscle interferes with its rather tenuous vascular supply and may produce papillary muscle and subendocardial fibrosis. The electrocardiographic changes and the ventricular arrhythmias are secondary to papillary muscle and endocardial ischemia and subsequent fibrosis. Sudden death is believed to be arrhythmic in origin. The click, which coincides with maximal prolapse,[26] is probably due to "sudden tensing of the everted valve leaflets," the "snapping of a sail" phenomenon.[27] The late systolic murmur is attributed to the initially competent valve becoming incompetent as prolapse develops.[26,28] Response of the click and murmur to various maneuvers is explained by changes in the left ventricular volume.[3] The sharp systolic retraction seen in apex cardiograms is ascribed to abnormal tension on the papillary muscle resulting in the base of the muscle being drawn inward.[2,6] The indentation along the inferior border of the left ventricle[29] may be due to the same mechanism.[3]

Pathologic changes in mitral valve: In several recent reports, myxomatous degeneration was demonstrated in patients who had midsystolic clicks. Altogether, nine cases of this association have been documented,[5,7,14,17,30–32] including a recent case observed by our group and two cases kindly reported in a personal communication from Edwards and Guthrie.[32] To my knowledge, these nine cases represent the only available adequate pathologic studies in patients with nonejection clicks. Their importance lies in the demonstration of redundant myxomatous cusps in each instance. Despite the absence of oculoskeletal manifestations, Read et al.[15] have ascribed myxomatous degeneration of the mitral valve to a forme fruste of Marfan's syndrome. At present, there is no evidence to warrant such generalization.[3]

2. The Myocardial Theory

This theory is based primarily on angiographic and hemodynamic findings without pathologic correlations. Although some workers have implicated coronary artery disease,[33,34] most advocates of the myocardial theory have postulated a cardiomyopathy unrelated to this disease. Their disparate findings are as follows:

1. *Abnormal systolic protrusion of the inferior aspect of the left ventricle.*[29] This results in elevation of the papillary muscles; the chordae tendineae become slack, allowing the posterior leaflet to balloon into the left atrium.

From the Section of Cardiology, Department of Medicine, St. Francis Hospital, Hartford, Conn., and the Department of Medicine, University of Connecticut School of Medicine, Farmington, Conn.

Address for reprints: Robert M. Jeresaty, MD, Section of Cardiology, St. Francis Hospital, 114 Woodland St., Hartford, Conn. 06105.

· 2. *Noncontraction or late systolic expansion of the inflow tract of the left ventricle* with significant reduction in the extent and mean velocity of fiber shortening in this segment.[9] The same group[11] has reported congenital absence of the atrioventricular (A-V) groove branch of the left circumflex coronary artery, postulating that this absence may be responsible for the segmental myocardial dysfunction.

3. *Left ventricular asynergy.* Gooch et al.[8] have described asynergistic contractions or relaxations in 17 of their patients; 16 had an anterior convex bulging during late systole or early diastole, and eight of these also had systolic bulging of the inferoposterior wall of the ventricular cavity. One patient had apical akinesia. The same group[10] have subsequently described five types of abnormal left ventricular systolic contraction patterns: (a) "ballerina foot" pattern (vigorous posteromedial contractions with anterior convexity); (b) "hourglass" pattern (vigorous ring-like traction involving the middle portion of the left ventricle); (c) inadequate shortening of the long axis; (d) posterior akinesia; and (e) pattern of cavity obliteration.

4. *Hemodynamic disturbances.* We have described a constrictive pattern of the left ventricular pressure curves in 5 of our original 32 cases.[25] In the absence of severe mitral regurgitation, hemodynamic studies have generally shown no abnormalities.[3,10] However, Gulotta et al.[35] reported in 20 of their 26 patients left ventricular dysfunction documented by either elevated left ventricular end-diastolic pressure, low resting cardiac index or inappropriate rise in cardiac index during exercise.

3. Critique of the Myocardial Theory

A. Relation between coronary artery disease and the mitral valve prolapse-click syndrome: Papillary muscle dysfunction resulting from coronary artery disease has been held by a few workers[33,34] to be responsible for this syndrome. I believe this represents a coincidental rather than causal association of two common diseases.[3,13,36] We have observed only four instances of proved coronary artery disease in 45 of our patients who underwent coronary cinearteriography (mild to moderate coronary stenosis in two patients and severe stenosis in two). Other authors[3,8–10,30] have reported on the results of selective coronary arteriography in more than 200 patients and have documented coronary artery disease in only 2 to 3 percent. Furthermore, since October 1971, the date of publication of the article by Steelman et al.[33] we have been searching for midsystolic clicks among patients admitted to our coronary care unit (approximately 700 patients annually). We encountered no patients who manifested clicks de novo in the course of acute myocardial infarction. A click was heard in only six patients, four of whom underwent cardiac catheterization; mitral valve prolapse was demonstrated in all and coronary artery disease in only two. Late systolic murmurs can be due to papillary muscle dysfunction,[37–39] but it must be proved that midsystolic clicks as such can be caused by this disorder, an association that is not evident in three comprehensive reviews of papillary muscle disease.[37–39] It is unfortunate that some cardiologists, including the authors of a well respected textbook,[40] have accepted the unproved concept of causal linking between coronary artery disease and the click syndrome. The available evidence does not warrant suspicion of coronary artery disease when a click is heard and supports the converse view, that the finding of a click in a patient with atypical chest pain and ST-T wave changes makes coronary artery disease unlikely.

Review of the coronary arteriograms in our 45 patients revealed congenital absence of the A-V groove branch of the left circumflex artery[9] in only 8 patients, 7 of whom had a large posterolateral branch of the right coronary artery to compensate for this absence.

B. Nonischemic cardiomyopathy: The angiographic abnormalities range from akinesia[9] to hypercontractility,[10,29] from hypokinesia of the inferior wall[9] to abnormal systolic protrusion of the same wall[29] and from asynergy of the anterior wall with systolic bulging[8,35] to vigorous contraction involving the same area.[10] To explain these contradictory findings disparate causes of the same syndrome have to be postulated, thus prompting a search for an explanation for these discrepancies. The angiographic abnormalities may be factitious and due to the effect of premature ventricular contractions induced during the injection of dye.[41] In one of our patients who underwent two angiographic studies 4 years apart, marked asynergy associated with a run of premature ventricular contractions was noted during the first study but not during the second study, which was free of arrhythmias. Even if one assumes that abnormalities of the left ventricular contraction are genuine, they do not necessarily indicate a primary myocardial disease. Rigidity of various segments of the left ventricle, particularly near the inflow tract, may be due to fibrotic friction lesions[23]; fibrosis of the papillary muscles and adjacent endocardial areas resulting from excessive traction may explain localized akinesia or hypokinesia. Excessive contractility may be due to aneurysmal ballooning of the easily distensible cusps reducing the volume of blood encompassed by the muscular element; this would mimic the effect of mitral insufficiency, decreasing myocardial afterload and increasing the velocity and extent of fiber shortening.[42] The sum of all these factors may result in a spectrum of angiographic manifestations.

The hemodynamic disturbances, when present, may be due to endocardial, subendocardial and papillary muscle ischemia and fibrosis. The decreased compliance would explain the "constrictive" pattern.

4. Future Directions

Implicating myxomatous degeneration of the mitral valve as the underlying mechanism in this syndrome poses further etiologic problems. The main

question to be solved is: What is myxomatous degeneration? What causes it? Shift of emphasis from the myocardial to the valvular theory would focus attention on this pathologic abnormality and the nature of mucopolysaccharide infiltration. Only in a few reported cases[3,19,20] was this syndrome found to be genetically determined. No definite correlation with age was demonstrated by Pomerance,[21] who suggested a nonspecific tissue reaction resulting from many possible etiologic processes.

Gross and microscopic studies are needed to elucidate the etiology of the click syndrome and to confirm the valvular theory of myxomatous degeneration. Since coronary artery disease does not induce myxomatous degeneration, the demonstration of a nonejection click in a patient with coronary artery disease and a nonmyxomatous mitral valve would be the only convincing evidence linking these two entities.

In conclusion, the mitral valve prolapse-click syndrome can be termed an entity in search of a raison d'être. It is my contention that further research into the nature of the myxomatous process is, to quote Sutton's law, "where the money is."

Addendum

After submission of this editorial, Cobbs and King reported a case of mitral valve prolapse with "abnormal inward motion at the site of the posterior papillary muscle" (Cobbs BW, King SB: Mechanism of abnormal ventriculogram and ECG associated with prolapsing mitral valve [abstr]. Circulation 49, 50 Suppl III:III-7, 1974). Mitral valve replacement was carried out for intractable ventricular arrhythmias and one episode of ventricular fibrillation. Postoperatively, the left ventriculogram promptly returned almost to normal. This interesting case adds further support to the valvular theory and disproves theories postulating an abnormal contraction ring.[9,10]

Left Ventricular Volume Measurement by Echocardiography: Fact or Fiction?

JOSEPH W. LINHART, MD, FACC*

Measurement of left ventricular volume in man necessitates certain assumptions regardless of the method used. These assumptions tend to be forgotten as the method grows in popularity. Even though the originators of the technique of echocardiographic volume measurement admitted the inaccuracies in their assumptions, echocardiography is currently an accepted method for measuring ventricular volume. It is appropriate, therefore, to reevaluate critically this original and widely used technique and to emphasize not only the original assumptions but also the many problems that heretofore may not have been considered by the clinician.

Possible Errors in Echocardiographic Measurements

The clinical applications of reflected ultrasound for volume measurement as performed by simultaneously visualizing the interventricular septum and the left ventricular posterior wall have been described by several investigators.[1–6] However, they disagree on the anatomic correlate of this measurement. Feigenbaum,[1,5] Popp[2] and Murray[6] and their co-workers have stated empirically that these measurements represent an oblique section through the left ventricle. Pombo et al.[3] and Fortuin et al.,[4] on the other hand, have presented evidence that the echocardiographic measurement represents the left ventricular minor axis. The probable answer to this seeming paradox is that ultrasound is not measuring the same dimension in all patients.

Errors in measuring minor axis: The geometry of the left ventricle, the size and shape of the mitral leaflets, the orientation of the left ventricle within the chest cavity and the location of the acoustical window vary. Although these landmarks allow the echocardiographer to measure the same dimension in the same patient from day to day, individual differences can result in deviations from the "ideal" measurement in both the longitudinal and transverse directions. With use of a simplified geometric model of the left ventricle within the chest cavity (a model that, because of its geometric regularity, minimizes the effect of any deviation), it can be calculated that a 10° or 1 cm discrepancy between the ultrasonic beam and the minor axis can result in a 5 to 10 percent error in measurement of the minor axis. This is an even greater problem in ventricles that are larger and more spherical than normal: First, as a ventricle enlarges, its major axis becomes longer, and the true minor axis is displaced apically away from the tips of the mitral valve leaflets. Second, an oblique chord through an ellipse is more likely to approximate its minor axis than a chord through a sphere is likely to approximate its diameter. When the erroneous single dimension is extrapolated to three dimensions and when these measurements are applied to stroke volume determination, this error becomes most significant.

Errors in measuring distance: Assuming, though, that it is possible to standardize measurement of the minor axis, we must next consider the error involved in making any echocardiographic measurement of distance. One measures distances with ultrasound by assuming that the distance from the transducer to an object is proportional to the time it takes for the beam to be reflected back from the object to the transducer. Because there is a random error in transmission velocity through a nonhomogeneous medium and because measured distance is a function of transmission "time," there is a random error in distance measurement that varies directly with the distance measured. It is obviously impossible to define exactly the magnitude of this error. For example, even if this error is only ±1 percent of the distance, then (also allowing for the 0.1 cm resolution) the approximately 5 cm distance between the transducer and the interventricular septum would

From the Division of Cardiology, Departments of Medicine, The Chicago Medical School, Chicago, Ill. and Hahnemann Medical College and Hospital, Philadelphia, Pa.

have an error of ±0.15 cm. If the distance to the posterior wall is 10 cm, the error is ±0.2 cm. Because these errors are random, they are added when the distances are subtracted, and the echocardiographic dimension becomes 5 ± 0.35 cm. (If it were possible to place the transducer on the interventricular septum, then the dimension would be 5 ± 0.15 cm.) The greater the distance from the chest wall to the heart (for example, in patients who are obese or who have chronic obstructive pulmonary disease), the greater is the error associated with this method of measurement. These error brackets must, of course, be added to the problem of locating the "right" dimension.

Errors in translating minor axis dimension into volume determination: If the left ventricular minor axis is known, is it possible to translate this linear dimension into a three-dimensional volume? It is possible if the following assumptions are true: (1)

TABLE I

Comparison of Methods for Calculating End-Diastolic (EDV) and End-Systolic (ESV) Volumes from the Appropriate Ultrasonic Dimensions (Ud and Us)

* All authors reported statistically significant relations. Murray et al. did not derive regression equations for EDV vs. Ud^3, ESV vs. Us or ESV vs. Us^3. Feigenbaum et al. derived, but did not report, a regression equation for ESV vs. Us^3; the equation listed was derived from their data.

d = end-diastolic; s = end-systolic; *P* = probability; SEE = standard error of the estimate; U = left ventricular axis measurement by echocardiography.

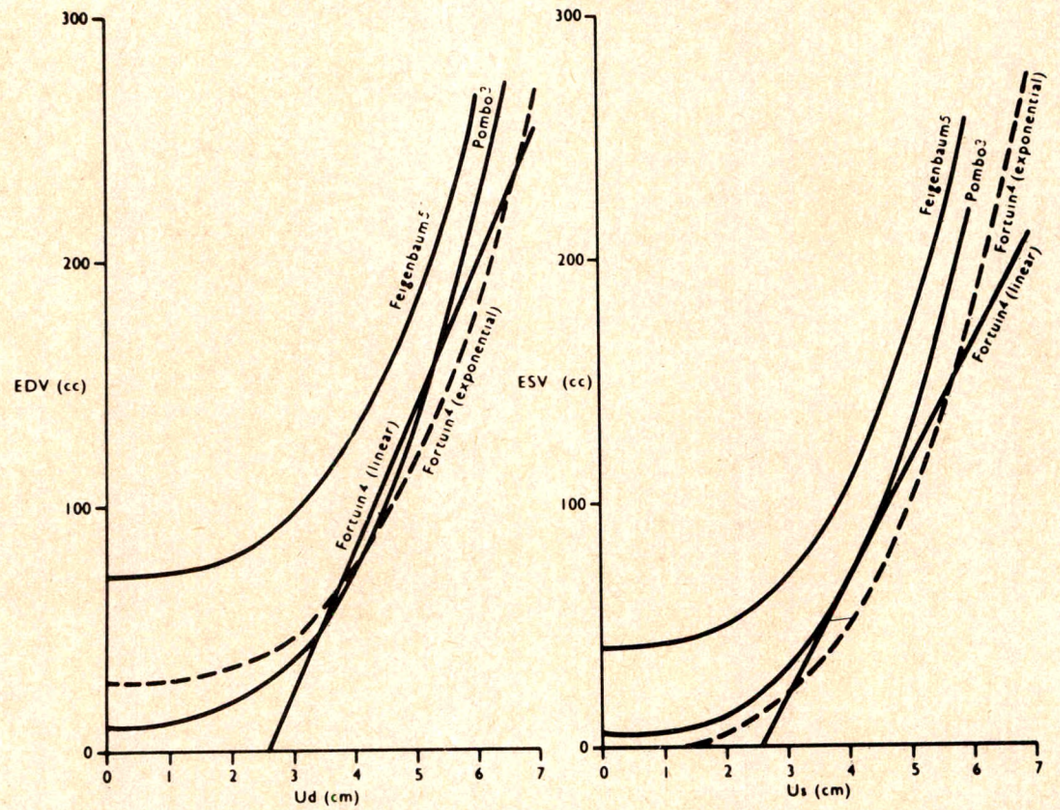

FIGURE 1. Graphic representation of the formulas of Table I. The regression equation of Murray et al.[6] for end-diastolic volume (EDV) vs. Ud is similar to that derived by Fortuin et al. (linear) and is not represented separately. For any given left ventricular axis measurement in diastole (Ud) or systole (Us), there is a whole range of formulas and volumes from which to choose.

that the longitudinal cross-sectional geometry of the left ventricle is known and is the same in all persons (present thinking assumes it to be an ellipse); (2) that its three-dimensional shape is this two-dimensional figure rotated on its major axis (that is, an ellipsoid of revolution in which all longitudinal cross sections are the same); (3) that these two conditions are true in both systole and diastole, in volume overload and in pressure overload states, in ischemic heart disease and in primary myocardial disease; and (4) that the major axis of the left ventricle is constant or is a constant known multiple of the minor axis in all patients in systole and in diastole. Unfortunately, none of these assumptions are true—especially the last, and especially within the large group of patients with coronary heart disease.

Certain known facts about ventricular geometry are applicable to this situation. Normal ventricular

The linear formula of Fortuin et al.[4] was based on their formulas for end-diastolic and end-systolic volume, and is shown in terms of these variables and in terms of U.

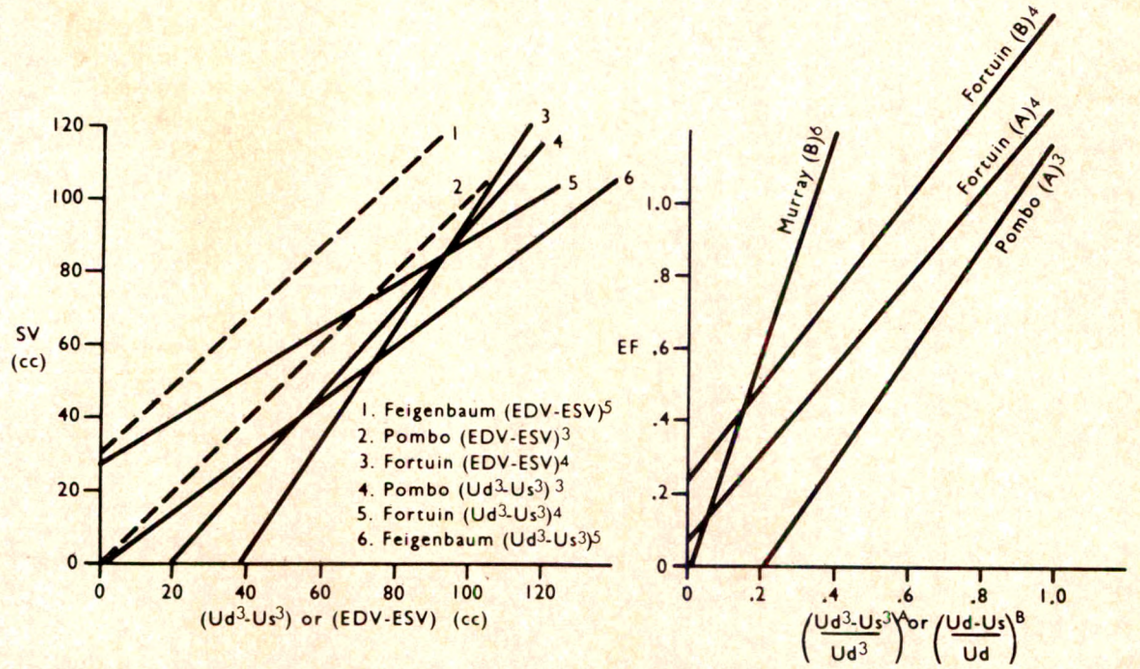

FIGURE 2. Graphic representation of the various formulas for calculating stroke volume (SV) and ejection fraction (EF). **A,** also shown are graphs that are derived if stroke volume = end-diastolic volume (EDV) minus end-systolic volume (ESV) according to the equations for EDV and ESV published by Feigenbaum et al.[5] and Pombo et al.[3] This is analogous to the method used in angiographic calculations and, although not strictly comparable, serves to demonstrate further the inaccuracy and inconsistency of the ultrasonic method. The formula of Murray et al.[6] is not plotted because $(Ud-Us)^3 = Ud^3 - 3Ud^2Us + 3UdUs^2 - Us^3$ and, therefore, cannot be compared with $Ud^3 - Us^3$. **B,** the ejection fraction formulas of several authors who used either $(Ud^3 - Us^3)/Ud^3$ (called A) or $(Ud - Us)/Ud$ (called B). Because of the different exponents involved, it is impossible to compare "A" and "B" equations.

shape *does* approximate an ellipsoid of revolution. As it enlarges, a ventricle becomes more spherical. During ejection, the left ventricle becomes more spherical. During ejection, the left ventricle does not contract concentrically. The minor axis shortens 10 to 35 percent while the major axis shortens by only 1 to 5 percent.[7] At end-systole the ratio between the major axis and the minor axis is greater than at end-diastole. As the ventricle enlarges, the minor axis enlarges more than the major axis, and the ratio between the two axes becomes less.

Correlation of Echocardiographic and Angiographic Measurements

Despite these problems, four studies[3–6] have reported statistically significant correlations between the ultrasonic left ventricular axis (U) and left ventricular volume. Pombo et al.[3] assumed that the major axis is twice the size of the minor axis in all patients in systole and in diastole. They then related left ventricular volume to U^3. Feigenbaum et al.[5] also used U^3 because of its statistical superiority over U^2 or U. Fortuin et al.[4] compared the ventricular volume with U and U^3 and demonstrated similar statistical correlation with both U and U^3 in normal-size ventricles but better correlation with U in larger ventricles. Murray et al.[6] were not able to demonstrate a statistically significant difference. Table I and Figure 1 compare the findings of these investigators. The wide variations in the regression formulas derived from their data indicate the extent to which their results differ. To emphasize this point further, if all the data reported in these four studies were plotted on the same graph, an echocardiographic diastolic dimension of 5 cm would be associated with angiographic volumes of 125 to 250 cm^3 and an end-systolic dimension of 4 cm would be associated with angiocardiographic volumes of 50 to 150 cm^3. Similarly, normal angiocardiographic volumes were reported in patients who had abnormally small, normal or abnormally large echocardiographic dimensions.

The scatter of angiographic volumes associated with any given ultrasonic dimension increased as the dimension increased. This is consistent with our two previous considerations. The difficulty in standardizing the echocardiographic dimension increases as the ventricle becomes larger, and the error of measurement becomes larger as the ventricle enlarges. Just as the linear dimension is cubed to calculate volume, the error is also cubed. A dimension of 5 ± 0.35 cm becomes a volume of 125 ± 29 cm^3, a dimension of 6 ± 0.4 cm becomes a volume of 216 ± 46 cm^3 and a dimension of 7 ± 0.45 cm becomes a volume of 343 ± 73 cm^3. Once these error brackets are applied to volumes as predicted by the various regression formulas (Fig. 1), the possible range of volumes becomes huge. Accurate predictions are therefore impossible.

These considerations become even more important when applied to the determination of stroke volume and cardiac output. If it is impossible to predict accurately end-diastolic and end-systolic volume, it must be impossible to predict stroke volume by this method. Table II and Figure 2 demonstrate the published formulas for calculating these variables.

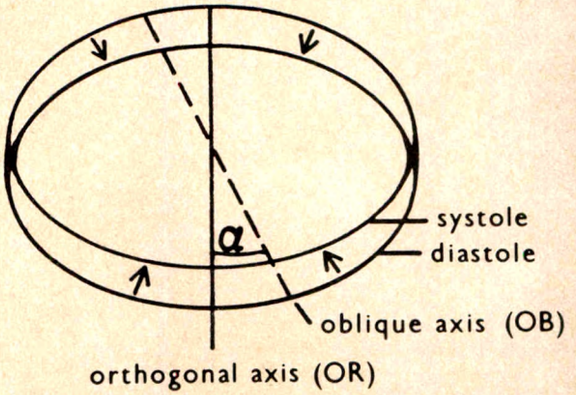

FIGURE 3. Relation of oblique section through the left ventricle (oblique axis) and the true left ventricular minor axis (orthogonal axis). Because the ejection fraction is a measure of the relative extent of shortening of the minor axis, ultrasound can accurately measure this variable. Furthermore, standardizing the ultrasonic measurement among individual patients is less important when measuring the ejection fraction. The oblique axis, the orthogonal axis and the constant angle approximate congruent triangles at end-diastole and at end-systole. As a result, the relative shortening of the oblique axis does accurately reflect the relative shortening of the orthogonal axis.

Clinical Status of Echocardiography

Following the clinical course: Where, then, is the place of ultrasound in measuring left ventricular volume and pump function? Because echocardiography can reproduce the same measurement in the same patient, it is most useful for following the clinical course of individual patients. For example, we have used echocardiography to follow changes in volume during atrial pacing; the absolute dimensions and the degree of shortening during contraction decrease at faster heart rates. When angina develops, the dimension increases, and the extent of shortening decreases even more. Premature ventricular contractions have smaller dimensions, and the postextrasystolic beats have larger diastolic and smaller systolic dimensions.

Similarly, the course of a patient with a myocardial infarction could be followed. A patient with recurrent chest pain of unknown cause could be studied to see whether the expected changes in ventricular size that accompany angina pectoris are manifest. The response of a patient to pharmacologic intervention could be evaluated objectively since many drugs (digitalis, diuretic agents, propranolol and nitroglycerin, for example) are effective because of their influence on ventricular volume. Also, pre- and postcoronary revascularization ventricular dimensions could be measured in all patients, and the occurrence of graft closure could be inferred because of deteriorated ventricular function even though the patient remained asymptomatic.

Left ventricular ejection fraction: The other use of echocardiography may be in measuring left ventricular ejection fraction (EF). Because contraction is a function of minor axis shortening:

$$EF = \frac{EDV - ESV}{EDV}$$

$$EF = \frac{\pi/6\ (Dd^2L) - \pi/6\ (Ds^2L)}{\pi/6\ (Dd^2L)}$$

$$EF = \frac{Dd^2 - Ds^2}{Dd^2}$$

where EDV is end-diastolic volume; ESV is end-systolic volume; Dd is the end-diastolic minor axis; Ds is the end-systolic minor axis, and L is the major axis. Therefore, it is *not* necessary to be able to measure volume in order to measure ejection fraction. More importantly, because the ejection fraction represents a relative shortening of the minor axis, it is not necessary to standardize the echocardiographic measurement. As shown empirically in Figure 3, an oblique section through the left ventricle maintains a constant ratio to the true left ventricular minor axis. The two chords form approximately congruent triangles in systole and in diastole. This is true not only for an "ideal" ellipse but also for the more irregularly shaped ventricle. If Ud = K Dd and if Us = K Ds, where K is a constant and Ud and Us are the ultrasonic left ventricular axes during diastole and systole, respectively, then

$$EF = \frac{Ud^2 - Us^2}{Ud^2}.$$

A decreased ejection fraction occurs because of generalized or localized abnormalities, or both, in ventricular contraction. Echocardiography may have its greatest value, in that regard, in measuring generalized changes that can occur as a primary defect or in response to more localized disease. Echocardiography cannot detect mitral regurgitation directly, and in patients with this condition the ejection fraction tends to be high. Similarly, if the echocardiographic beam visualizes a localized area of hypokinesis in the septum or the posterior wall, a spuriously low ejection fraction will be calculated. Two studies, one recently reported[8] and one recently completed in our laboratory, support some of these theoretical considerations. Although more studies are needed, this method may allow the physician to compare ejection fractions in the same patient and among groups.

Compound-B ultrasonography: Another approach to this problem is compound-B ultrasonography.[9] The advantage of this method over conventional echocardiography is that both the longitudinal and orthogonal axes of the left ventricle can be measured in a complete study. Ventricular volume at end-diastole and at end-systole may be calculated by the area-length method of Sandler and Dodge.[10] However, in individual cases it may be difficult to outline the anatomic apex of the left ventricle, and the volume will be underestimated. The compound-B ultrasonic ejection fraction measures the relative change in cross-sectional area just as the conventional echocardiographic ejection fraction measures the relative decrease in minor axis. Besides being able to detect generalized abnormalities of ventricular contraction, compound-B ultrasonography can also indicate localized asynergic motion of the septum, posterior wall or apex.[11]

LETTERS TO THE EDITOR

SURGICAL VS. MEDICAL THERAPY IN UNSTABLE ANGINA

The recently published preliminary report by Bertolasi et al.[1] of a prospective and randomized study of surgical versus medical therapy in unstable angina pectoris raises important questions that cast an element of doubt on the authors' conclusion that "... patients with the intermediate syndrome treated surgically appeared to have significantly reduced mortality."

In comparing medical with surgical therapy, it is important to define clearly the entire protocol of the medical therapy. The authors outlined only in very general terms medical treatment during the acute stage of the syndrome giving no details concerning long-term medical management except for a brief statement that: "... patients were evaluated at 4 month intervals." The data, as presented, thus appear to compare surgical treatment with, at best, variable medical therapy. Also, no information was provided for either group in regard to (1) length of stay in hospital, (2) frequency of follow-up visits and nature of medical treatment during the very important 3 or 4 months after onset of the intermediate syndrome, and (3) degree of physical activity permitted both groups during the same period.

In addition, the statement that "... those who survive surgery are in better clinical condition than the medically treated patients" is based on an interesting but arbitrary and potentially misleading index. No information was given concerning the circumstances of death, actual incidence of early and late myocardial infarction, episodes of acute coronary insufficiency and anginal status in the two groups at various times during the follow-up period.

Unless medically treated patients in such studies are subjected to specific protocols of treatment, comparison of the two groups gives rise to results that are of questionable validity, even in a preliminary report.

REPLY

Dr. Mizgala's questions allow us to update our preliminary report. The study, which ended in April 1973, included 146 patients with intermediate syndrome or progressive angina (cases with postinfarction angina are not considered here), 33 of whom were excluded for reasons mentioned in our article. The average hospital stay during the acute stage of the syndrome was 16.8 days; 100 percent of the included patients were followed up 13 to 47 months (average, 17.8). Each patient was studied every 4 months in order to obtain data, but of course was also examined as many times as required by his clinical course.

Of those patients with the intermediate syndrome, 28 were treated surgically; mortality rate and incidence of myocardial infarction were 10.7 percent and 14.2 percent, respectively. All deaths and infarctions occurred in the immediate postoperative period. Twenty-four patients were treated medically; mortality rate was 45.8 percent ($P < 0.005$) (the patients died, respectively, 2, 5, 7, 8 and 20 days after admission and in the 2nd, 3rd, 8th, 12th, 16th and 40th months of follow-up). Nine patients (37.5 percent, $P < 0.06$) had a myocardial infarction, six during the acute phase and three during the follow-up period.

Of those patients with progressive angina, 34 were treated surgically; mortality rate and rate of infarction were 8.8 percent and 11.7 percent, respectively. All deaths and infarctions occurred in the immediate postoperative period. Twenty-seven patients were treated medically; mortality rate was 7.4 percent ($P > 0.80$). The two deaths occurred, respectively, 2 days after admission and in the 12th month of follow-up; the rate of infarction was 7.4 percent ($P > 0.45$), one infarction occurring during the acute stage and the other during follow-up.

Deaths were attributed to ischemic heart disease (sudden death, myocardial infarction and cardiac failure) except for six deaths related to the surgical procedure (four occurring immediately after operation, one caused by renal failure and one due to sepsis). Two patients were excluded because their deaths were not related to heart disease or surgery (one due to gastric cancer and one to respiratory infection).

The medical treatment given has already been summarized in our paper, but we will comment briefly here on the anticoagulant therapy and the use of beta adrenergic blocking agents. Heparin was given in 25 percent of the cases, although our interest in that drug has lessened, especially since it has been postulated that thrombosis is frequently an epiphenomenon of the acute episode, particularly in cases of nontransmural necrosis without shock.[1] None of the patients received beta adrenergic blocking agents before coronary arteriography because of the increased risk to the patient. After the hemodynamic study propanolol or practolol was administered to 41 percent of the patients. These drugs were given when we suspected a "hyperkinetic state" or when they were not contraindicated by the left ventricular end-diastolic pressure or the left ventriculogram. We were not then aware of the report by Fischl et al.,[2] who obtained an excellent therapeutic response with doses of up to 400 mg of these drugs; however, in their group of patients, strictly defined according to criteria similar to ours, 14 were operated on with good results (one death), whereas the 9 who were treated medically had a mortality rate of 33 percent after 1 year, similar to the 37.5 percent rate recorded by us in the same period. These authors did not mention the complete medical protocol followed.

We followed no "specific protocol" for long-term treatment. We used isosorbide dinitrate, beta adrenergic blocking agents, diuretic agents and antiarrhythmic drugs for both medical and surgical groups. We did not use "metabolic" drugs or long-term anticoagulant agents. We evaluated the functional capacity of each patient through exercise testing.

Concerning our index, it is clearly the summary of the clinical results updated every 4 months. Figure 1, A and B,

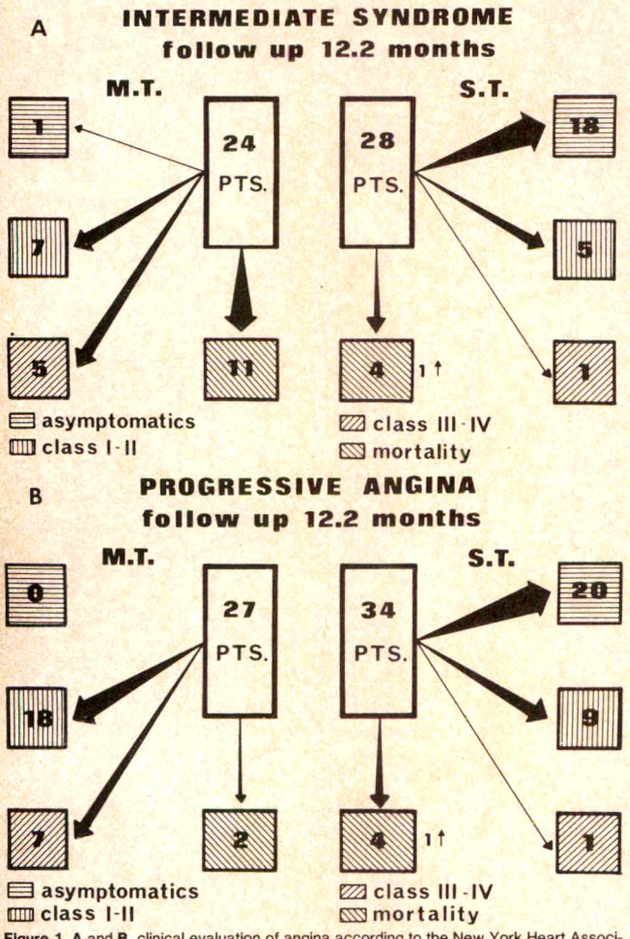

Figure 1. A and **B**, clinical evaluation of angina according to the New York Heart Association classification. One patient excluded (see text). M.T. = medical treatment. S.T. = surgical treatment; PTS = patients.

shows the results after 12 months of follow-up on the basis of symptoms of angina. These findings are supported by the identical results obtained in the more objective ergometric study.

Finally, it is possible that we did not place enough emphasis on the most important conclusion of our study. Among patients with unstable angina (excluding those with angina of recent onset and Prinzmetal's angina), there are two distinct groups: (1) those with the intermediate syndrome, and (2) those with progressive angina. Mortality rate and the incidence of myocardial infarction differ significantly in the two groups: 45.8 and 7.4 percent ($P < 0.002$) and 37.5 and 7.4 percent ($P < 0.01$), respectively. Theroux and Campeau[3] have reached similar conclusions.

The patients of Gazes et al.,[4] although not studied angiographically, were carefully selected and followed up during a 10 year period. These authors also identified two distinct courses for their patients and observed that after 1 year the mortality rate was 43 percent for the high risk group and 2 percent for the low risk group. Gazes et al. did not mention any specific treatment.

On the basis of the clinical pattern in patients with angina, we now identify several syndromes that have classically been known as preinfarction angina: (1) angina of recent onset with and without sudden loss of physical capacity; (2) Prinzmetal's angina; (3) intermediate syndrome; (4) progressive angina; (5) postacute myocardial infarction (angina within 1 month after an acute myocardial infarction); (6) acute persistent ischemia (this includes patients with the clinical findings of myocardial infarction [prolonged angina] without increased serum enzymes and with permanent modifications [more than 24 hours] in ventricular repolarization [T wave inversion]). We do not intend hereby to establish new classifications, which may increase confusion. Nevertheless, differences in the natural course of these patients suggest that it is wise to identify those in whom the therapeutic approach should probably differ.

LIFE UNITS IN CORONARY ARTERY DISEASE

The conflicting opinions concerning the efficacy of surgery and the tendency to delineate more and more subgroups of patients with coronary disease make it obligatory for the responsible physician to judge as best he can into which subgroup his patient falls. In my opinion there are almost as many subsets as patients. There is much more to predicting a patient's natural history than knowledge of the anatomy of his coronary arteries. Even when the questionable random trials are concluded, it will still be the duty of the physician to take all knowledge of the patient—his lifestyle, his biochemistry and his response to treatment as well as the anatomy of his coronary arteries—into account and predict his natural history, using the published guidelines of authorities.

I suggest that the term "life units" be used as the currency of evaluation. Life units represent the number of years a person lives multiplied by the quality of life, which for practical purposes can be related to functional heart classification. Class IV quality of life is rated 1; class III, 2; class II, 3; and class I, 4. Thus, 2 years lived at the class I level is equivalent to

$$2 \times 4 = 8 \text{ life units}$$

If the predicted life units before surgery are compared with the life units after surgery, in time we will gain some idea of the significance of surgery for a particular patient.

The term life unit would enable us to cope, using one measure, with the various ways that surgery can improve a patient's condition, namely, reduction of pain, improvement in exercise tolerance, prevention of infarction and increase in life span. Unscientific and "soft" as it is, it is a useful working term for the clinician. It need not have the same significance for every patient or doctor, and that is a strength rather than a weakness. It is the individual that a clinician is evaluating, not a group of individuals.

O. B. Tofler, MD
Royal Perth Hospital,
Perth, Western Australia

COMMENT

I share Dr. Tofler's view that there is, in essence, an infinite number of subsets of patients with coronary disease since

no two patients are identical. However, as physicians seeking to make the most rational judgments possible relative to major decisions affecting the life and health of our patients, we believe that it is necessary to cluster many of these subgroups on the basis of the best available information. Under essentially all circumstances, this judgment is based upon less than optimal information. However, this does not negate the value of meticulously performed studies of patients who can be clustered by one or several descriptors into reasonable population groups.

I am in complete sympathy with Tofler's desire to include the quality of life in any equation describing the outcome of alternative methods of treatment. His numerical quantitation is undoubtedly a severe oversimplification. Nevertheless, it has the attraction of simplicity and considerable validity presented in easily understandable quantitative units. Most physicians unconsciously apply some such thinking into their decision-making process. However, by expression in quantitative units, the relative merits of various treatments become more apparent. The hazard of such oversimplification is that greater emphasis may be placed upon the numerical product than is truly warranted. The application of such an equation to an analysis of patients is awaited with interest.

ECHOCARDIOGRAM IN *d*-TRANSPOSITION OF GREAT VESSELS

Dillon et al.[1] recently proposed that "the echocardiographic finding of superimposition of the great vessels without intervening crista together with simultaneous recording of the semilunar valves is diagnostic for transposition of the great arteries." The validity of this new diagnostic criterion was later challenged by Glaser et al.,[2] but the evidence presented was refuted by Dillon.[3]

We agree with Dillon that the recordings presented by Glaser et al. are inconclusive, although we believe that the latter's objection is valid. This belief is based on echocardiographic recordings that we recently obtained from two cyanotic newborn infants who were later proved to have normally related great vessels by cardiac catheterization and angiocardiography.

Figure 1, from one of these infants, unequivocally shows both semilunar valves, recorded simultaneously, parallel to each other and without an intervening crista. It can be seen from this recording that the posterior aortic valve closes before the anterior pulmonary valve (arrows), as expected. The left atrium is seen behind the aortic valve. Another recording revealed normal continuity between the posterior aorta and the mitral valve. Similar findings were obtained in the second patient.

Although it is also our experience that the semilunar valves can be recorded simultaneously in most patients with transposition of the great arteries, we believe that the evidence presented here shows that this finding is not diagnostic, at least in the newborn. We have found useful the criteria proposed by Gramiak et al.[4] to determine the relation of the great arteries. In the two cases discussed here, use of this technique indicated normal relation of the great vessels.

BOOK REVIEWS

CLINICAL CARDIAC RADIOLOGY, by Keith Jefferson and Simon Rees. Toronto, Canada, Butterworths, 1973, 326 pages, $57.75

The authors present a clinically oriented book of interest to both cardiologists and radiologists. The material is based on their personal experience with radiologic findings in some 1,500 patients with various forms of cardiac disease, in whom physiologic and anatomic "answers" were available.

The book is divided into two parts: Part I, general radiology, presents an overall view of radiographic changes that occur in heart disease. Heart size and variations in size of the cardiac chambers, the great vessels and the systemic veins are first described. Included are comments on the position of the heart and its component parts and on calcification in the cardiovascular system. The next section is devoted to the lungs, including changes of pulmonary vascularity, effects of pulmonary hypertension, effects of pulmonary thromboembolism, and infarction. A brief third section describes other systems affected by heart disease, such as the bony thorax, changes occurring in some hereditary syndromes and relations between general systemic diseases and the heart. Part II, clinico-radiological approach to heart disease, systematically presents radiologic appearances and findings in various cardiac diseases, including congenital heart disease, valvular diseases and myocardial and pericardial diseases.

The book is written in clear language and is very well illustrated. The 377 figures (many containing several parts) consist largely of reproductions of radiographs, but there are also many anatomic drawings, diagrams and angiocardiographic reproductions. Angiograms are used only to illustrate specific points; contrast radiography, as such, is not discussed. In addition to illustrative material, there are many tables showing data and explaining certain clinical-radiographic relations and probabilities. A bibliography contains an alphabetically arranged list of approximately 300 cited articles.

In contrast to electrocardiography, which is covered by a veritable plethora of textbooks, few books have been devoted to cardiovascular radiography. This one is outstanding, primarily because of its correlation of clinical and physiologic data with radiographic findings. Written by radiologists who have a deep understanding of the pathophysiologic processes that occur in cardiac diseases, this book places radiography in its proper perspective: a technique that does not merely depict images of altered anatomic structures of the heart and related organs, but that also reflects changes produced by specific functional processes. The reader not only will receive information on the expected radiographic changes in various cardiac diseases and their role in diagnosis, but also will come away with a better comprehension of the underlying disease process. This volume is highly recommended to cardiologists and radiologists alike.

Arthur Selzer, MD, FACC
San Francisco, California

President's Page: The College, Education and the Heart House Learning Center

The phrases "lifetime of learning," "prevention of obsolescence," "maintenance of professional competence" and other reminders of our professional obligation are heard daily by all of us. This emphasis on continued education is not new. Competent physicians have always recognized educational activities as an integral part of their professional life, the sole purpose of which has been to provide constantly improving, high quality patient care. However, because of the changes that are occurring so rapidly in medicine and cardiology, the educational aspects of professional life have reached crisis proportions. The potential for a very short "competency period" after completion of a training program is a source of frustration and, on occasion, panic. All too frequently, physicians are opting for early retirement, specialization in narrower areas of responsibility or, in other ways, are manifesting signs of failure to cope.

Widespread failure to cope with early obsolescence would be a tragedy for several reasons, not the least of which would be failure to discharge our responsibility to our patients. Failure on our part to provide guidelines and materials for continuing cardiologic education and failure to incorporate into the system methods for measuring achievement invites "outside" intervention. Regulatory controls imposed from without may be mediocre and therefore less acceptable than those we could devise for ourselves. In addition, provision needs to be made for a system that not only provides quality education for today but also investigates methods for continuing education of tomorrow in order that we avoid repetitive crises. Clearly, simple adherence to present educational methods will not suffice.

The recently formalized objectives for the Heart House Learning Center reflect the awareness of the College for the needs of today and the future and, as such, incorporate ongoing service functions as well as research in educational science. It seems appropriate to list these objectives:

1. To meet demonstrated and perceived educational needs of professional health personnel.
2. To construct a curriculum which will be responsive to changing needs, knowledge and teaching methods.
3. To establish a resource center for media and instructional techniques for intra- and extramural use.
4. To design improved methods of educational evaluation.
5. To establish improved teaching techniques.
6. To establish improved learning techniques.
7. To collaborate with other societies and institutions in accomplishing our educational goals.
8. To increase participation of health professionals in continuing medical education by assisting health professionals in designing learning experiences appropriate to their needs.
9. To provide for effective distribution of learning resources.
10. To monitor the total educational system with respect to cost-effectiveness and appropriate utilization.
11. To evaluate the degree to which the educational program has achieved the purpose of improving cardiovascular care.

Heart House is not just bricks and mortar. In addition to serving as the permanent headquarters for our College, it is an Institute for Research in Medical Education, a Learning Center and a Production Studio. The major goal is to provide a mechanism whereby the College members and others wishing to take advantage of the opportunity can be assured of being prepared for the delivery of quality cardiovascular care and assessment of that care which is surely forthcoming. Heart House is a continuous learning center. The need for "cramming" sessions should be minimal.

The College is committed to implementation of the above objectives.

American College of Cardiology

Norms for Use in the Peer Review of Selected In-Hospital Cardiovascular Diagnoses

Developed by the American College of Cardiology
Bethesda, Maryland
April 1, 1975*

FOREWORD

In 1974 the American College of Cardiology published (*American Journal of Cardiology* 33:697–709, 1974) norms for use in peer review of the quality of cardiovascular practice which were subject to periodic review. The American Medical Association (AMA) has since contracted with the Department of Health, Education, and Welfare (DHEW) to generate norms for use in PSRO. The present Norms represent a modification of the previous Norms to conform to a common format employed by all medical specialties. Along with the criteria developed by other medical specialties, these criteria will be submitted to DHEW for approval and dissemination to regional PSRO's. Regional PSRO's may accept these criteria for peer review, or they may generate their own local criteria.

According to the format developed by the AMA, Items I and II will serve for Concurrent Review; Items V and VI for Retrospective Review; Items III and IV, though intended primarily for Retrospective Review, may also serve for Concurrent Review.

The criteria to be published by DHEW will include specific instructions for their application. For example, it is assumed that all deaths will be reviewed; consequently, Item V (Discharge Status) makes no reference to death as a criterion for review. It should also be emphasized that the criteria were written to be as inclusive and straightforward as possible for use by paramedical clerks.

The official position of the American College of Cardiology toward PSRO is explained in the original publication.

DIAGNOSIS/PROBLEM:
CONGESTIVE HEART FAILURE
427.0 (Code Number)

I. *Justification for admission*
- A. Suspicion of or diagnosis of pulmonary edema
- B. Newly diagnosed CHF, to establish response to therapy
- C. Unresponsive to outpatient management (i.e., persistent or recurrent symptoms of dyspnea, weakness, edema)
- D. Diagnostic admission; i.e., to establish etiology, functional significance of lesion, anatomic or physiologic derangement (e.g., cardiac catheterization)

II. *Length of stay*
- A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
- B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
  1. Reasons for extending the initial length of stay
     - a. Persistent symptomatology; i.e., refractory heart failure
     - b. Pulmonary embolization
     - c. Renal insufficiency and/or electrolyte imbalance
     - d. Arrhythmia
     - e. Myocardial infarction

III. *Validation of:*
- A. Diagnosis
  1. Positive chest X-ray findings of pulmonary congestion; or
  2. Positive physical findings of gallop rhythm, or venous hypertension or edema or enlarged heart; or
  3. Improvement following digitalis or diuretics
- B. Reasons for admission
  1. Serious clinical disability (dyspnea, edema, weakness), I-C
  2. Invasive procedures based on suspicion of surgically remediable lesion, I-D

IV. *Critical diagnostic and therapeutic services*
- A. Electrocardiogram (100%)
- B. Chest X-ray (100%)
- C. Serum electrolytes and blood urea nitrogen or creatinine (100%)

V. *Discharge status*
- A. Improvement in symptoms (III B-1); and signs (III A-2)
- B. Documented plan of follow-up

VI. *Complications*
- A. Primary disease and treatment-specific complications
  1. Rising blood urea nitrogen
  2. New arrhythmia, interpreted as consistent with digitalis intoxication
  3. Digitalis toxicity (digoxin level >4 ng/ml; digitoxin level >40 ng/ml)
- B. Nonspecific indicators
  1. Surgery

DIAGNOSIS/PROBLEM: HYPERTENSION
(INCLUDE ACCELERATED, ENCEPHALOPATHY)
401.0 (Code Number)

I. *Justification for admission*
- A. Diastolic blood pressure in excess of 115 mm Hg
- B. Failure to respond to antihypertensive therapy
- C. Neurologic or sensorium abnormalities
- D. Suspicion of secondary cause of hypertension (e.g., renal disease, renal vasculature abnormality, adrenal disease)
- E. Uncontrolled congestive heart failure (see Congestive heart failure), renal failure (rising blood urea nitrogen)

II. *Length of stay*
- A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
- B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
  1. Reasons for extending the initial length of stay
     - a. Secondary cause of hypertension discovered (e.g., renal disease, renal vasculature abnormality, adrenal disease)
     - b. Unresponsive to initial antihypertensive therapy
     - c. Neurologic abnormalities
     - d. Congestive heart failure
     - e. Renal failure (rising blood urea nitrogen or creatinine)

III. *Validation of:*
- A. Diagnosis
  1. Diastolic blood pressure in excess of 90 mm Hg
- B. Reasons for admission
  1. Historical documentation of I-B

IV. *Critical diagnostic and therapeutic services*
- A. Blood pressure recorded daily, as a minimum (100%)
- B. Blood urea nitrogen or creatinine (100%)
- C. Electrocardiogram (100%)
- D. Fundoscopy (100%)
- E. Chest X-ray (100%)

V. *Discharge status*
- A. Anti-hypertensive therapy (e.g., salt restriction, antihypertensive medication)
- B. Documented plan of follow-up
- C. Resolution of reason for admission

VI. *Complications*
- A. Primary disease and treatment-specific complications
  1. None
- B. Nonspecific indicators
  1. Surgery

DIAGNOSIS/PROBLEM:
ARTERIOSCLEROTIC HEART DISEASE
(INCLUDE ANGINA PECTORIS AND "CHEST PAIN")
412.0 (Code Number)

I. *Justification for admission*

A. Suspicion of unstable angina pectoris, including new angina pectoris
B. Scheduled for coronary cineangiography

II. *Length of stay*
A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
1. Reasons for extending the initial length of stay
a. Persistent, recurrent angina pectoris
b. Additional diagnostic evaluation (coronary cineangiography)
c. Complications of diagnostic procedures (e.g., arterial occlusion, bleeding)
d. Myocardial infarction

III. *Validation of:*
A. Diagnosis
1. History is sufficient;or
2. Electrocardiographic confirmation of myocardial infarction; or
3. Stress electrocardiographic test positive or resting electrocardiogram during spontaneous angina positive; or
4. Coronary cineangiographic confirmation
B. Reasons for admission
1. Suspicion of angina or positive electrocardiographic findings of ischemia (rest or exercise), I-B

IV. *Critical diagnostic and therapeutic services*
A. Electrocardiogram (100%)
B. Chest X-ray (100%)

V. *Discharge status*
A. Patient's condition clinically stable or improving
B. Documented plan of follow-up

VI. *Complications*
A. Primary disease and treatment-specific complications
1. Complications of coronary cineangiography and catheterization (e.g., arterial occlusion, bleeding)
B. Nonspecific indicators
1. Surgery

DIAGNOSIS/PROBLEM:
MYOCARDIAL INFARCTION, ACUTE
410.0 (Code Number)

I. *Justification for admission*
A. Suspicion of or diagnosis of acute myocardial infarction
B. Suspicion of unstable angina pectoris

II. *Length of stay*
A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
1. Reasons for extending the initial length of stay
a. Persistent arrhythmia
b. Congestive heart failure or shock
c. Aneurysm, mitral regurgitation, ventricular septal perforation
d. Recurrent pain (including pericarditis)
e. Pulmonary embolization
f. Coronary bypass surgery

III. *Validation of:*
A. Diagnosis
1. Electrocardiographic interpretation of acute myocardial infarction; or
2. Elevation in serum cardiac enzymes (creatine phosphokinase, glutamic oxaloacetic transaminase, lactic dehydrogenase, etc); or
3. Classic history and hospital course even in absence of 1 and 2 (e.g., chest pain, interpreted as consistent with myocardial infarction. No specific modifiers required)
B. Reasons for admission
1. No entry necessary

IV. *Critical diagnostic and therapeutic services*
A. Monitoring of cardiac rhythm (100%)
B. Intravenous infusion line maintained (100%)
C. Coronary care unit, if available (100%)
D. Serial electrocardiograms (100%)
E. Serial cardiac enzymes (100%)

V. *Discharge status*
A. Pain-free
B. Documented plan of follow-up

VI. *Complications*
A. Primary disease and treatment-specific complications
1. Arrhythmia interpreted as consistent with digitalis intoxication
B. Nonspecific indicators
1. None

DIAGNOSIS/PROBLEM: ATRIAL FIBRILLATION (CRITERIA APPLICABLE TO OTHER ARRHYTHMIAS) 427.4 (Code Number)

I. *Justification for admission*
A. Newly diagnosed
B. Rapid rate requiring prompt slowing (or slow rate, with other arrhythmia)
C. Failure to respond to ambulatory antiarrhythmic therapy
D. Symptoms of chest pain, syncope, dyspnea, or embolization

II. *Length of stay*
A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
1. Reasons for extending the initial length of stay
a. Chest pain (angina → infarction)
b. Congestive failure or shock
c. Unresponsive to initial therapy

d. Serious ventricular arrhythmias
e. Pacemaker therapy

III. *Validation of:*
A. Diagnosis
1. Electrocardiographic documentation of rhythm disturbance
B. Reasons for admission
1. No entry necessary

IV. *Critical diagnostic and therapeutic services*
A. Electrocardiogram (100%)
B. Chest X-ray (100%)

V. *Discharge status*
A. Heart rate controlled within normal range
B. Free of chest pain, syncope, dyspnea

VI. *Complications*
A. Primary disease and treatment-specific complications
1. New rhythm disturbance interpreted as consistent with drug intoxication
B. Nonspecific indicators
1. None

DIAGNOSIS/PROBLEM:
VALVULAR HEART DISEASE
424.0 (Code Number)

I. *Justification for admission*
A. Scheduled for cardiac catheterization
B. Valvular heart disease complicated by heart failure, chest pain, syncope, hemoptysis or emboli
C. Suspicion of or diagnosis of aortic stenosis

II. *Length of stay*
A. Initial length of stay assignment for primary diagnosis or problem (numerical determinations to be established locally based on statistical norms)
B. Extended length of stay assignment (numerical determinations to be established based on the individual patient's condition at the end of the initial length of stay period)
1. Reasons for extending the initial length of stay
a. Arrhythmias
b. Bacterial endocarditis
c. Congestive heart failure
d. Thromboembolism
e. Hemodynamically significant valvular lesion warranting surgery

III. *Validation of:*
A. Diagnosis: Documentation of any of the following:
1. Characteristic physical findings
2. Cardiac catheterization confirmation
3. Compatible electrocardiographic interpretation
4. Compatible radiographic interpretation
5. Compatible echocardiographic interpretation
B. Reasons for admission
1. Presence of valvular heart disease complicated (e.g., congestive heart failure, chest pain, syncope, hemoptysis, or emboli) I-A,B

IV. *Critical diagnostic and therapeutic services*
A. Electrocardiogram (100%)
B. Chest X-ray (100%)

V. *Discharge status*
A. Anatomic diagnosis established
B. Patient's condition clinically stable or improving
C. Documented plan of follow-up

VI. *Complications*
A. Primary disease and treatment-specific complications
1. Complications of catheterization (eg, arterial occlusion, bleeding)
2. Bacterial endocarditis developing during hospitalization
B. Nonspecific indicators
1. Persistent fever

25th ANNUAL SCIENTIFIC SESSION
AMERICAN COLLEGE OF CARDIOLOGY

New Orleans, Louisiana **February 23–26, 1976**

- **Abstracts**
  Entries must be postmarked no later than September 22, 1975
- **Technical Exhibits**
  Deadline for requests for space: October 13, 1975
- **Scientific Exhibits**
  Deadline for requests for space: October 13, 1975
- **Young Investigators' Awards Competition**
  Entries must be postmarked no later than October 31, 1975

For application forms, write Patrick A. Ziarnik, Director, Annual Scientific Session Department, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

Calendar of Continuing Medical Education Programs

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists, educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Borys Surawicz, MD, FACC, Chairman
National Program Committee

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

1975

To be arranged individually — **Preceptorships in Cardiology.** Arthur Selzer, FACC, director. Pacific Medical Center, San Francisco, Calif.

AUG. 23–25 — **Tutorials in the Tetons (Cardiac Emergencies).** Robert S. Eliot, FACC, director and Robert J. Davis, FACC, Alan D. Forker, FACC, Vincent F. Miscia, FACC and Gerald L. Wolf, co-directors. Grand Teton National Park, Moran, Wyo.

SEPT. 8–9 — **Stress Electrocardiography.** Borys Surawicz, FACC, and Paul L. McHenry, FACC, directors. University of Kentucky Medical Center, Lexington, Ky.

SEPT. 22–26 — **Core Curriculum: Mechanisms and Therapy of Cardiac Arrhythmias.** Leonard S. Dreifus, FACC, director and Albert N. Brest, FACC, co-director. The Lankenau Hospital, Philadelphia, Pa.

SEPT. 30–OCT. 2 — **Advanced Echocardiography.** Harvey Feigenbaum, FACC, director and Betty C. Corya and James C. Dillon, FACC, co-directors. Indianapolis Hilton Hotel, Indianapolis, Ind.

OCT. 6–15 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC, director. Crown Center Hotel, Kansas City, Mo.

OCT. 8–9 — **Louis N. Katz Symposium—Coronary Artery Disease 1975: Dilemma, Dialogue and Decision.** Sylvan Weinberg, FACC, Leonard S. Dreifus, FACC, Herman Hellerstein, FACC and Herman Uhley, FACC, directors. Good Samaritan Hospital, Dayton, Ohio

OCT. 9–11 — **New Techniques and Concepts in Cardiology: Pathogenesis, Diagnosis and Treatment of Coronary Atherosclerosis.** Stephen E. Epstein, FACC, director. Washington Hilton Hotel, Washington, D.C.

OCT. 14–16 — **Ischemic Heart Disease: Current Concepts.** William J. Grace, FACC, director and Richard J. Kennedy, FACC and James T. Mazzara, FACC, co-directors. St. Vincent's Hospital and Medical Center of New York, New York, N.Y.

NOV. 6–8 — **Core Curriculum: Phonocardiography and Pulse Recording—Workshop.** Morton E. Tavel, FACC, director. The Methodist Hospital Graduate Medical Center, Indianapolis, Ind.

NOV. 12–14 — **Core Curriculum: Echocardiography, Phonocardiography and Pulse Tracings—A Basic Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

DEC. 7–9 — **Advances in Heart Disease 1976.** Dean T. Mason, FACC, director. Fairmont Hotel, San Francisco, Calif.

DEC. 7–10 — **Structure—Function Correlations in Cardiovascular Disease.** William C. Roberts, FACC, director. Williamsburg Conference Center, Williamsburg, Va.

DEC. 10 — **Colloquia in Cardiology—Number 8: Sudden Death and Myocardial Infarction: New Observations.** Robert W. Oblath, FACC, Ronald Danzig, FACC and Sam H. Stone, FACC, directors. Ambassador Hotel, Los Angeles, Calif.

DEC. 12–14 — **The Dwight E. Harken Symposium: Advances in the Prophylaxis and Therapy of Cardiovascular Disease.** Henry I. Russek, FACC, director. Americana Hotel, New York, N.Y.

1976

JAN. 11–13 — **Future Directions in the Management of Cardiac Disease.** John H. K. Vogel, FACC, director and Bruce C. Paton, FACC and James S. Forrester, co-directors. Snowmass-at-Aspen, Aspen, Colo.

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Number pages in sequence after last page of references.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals; Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

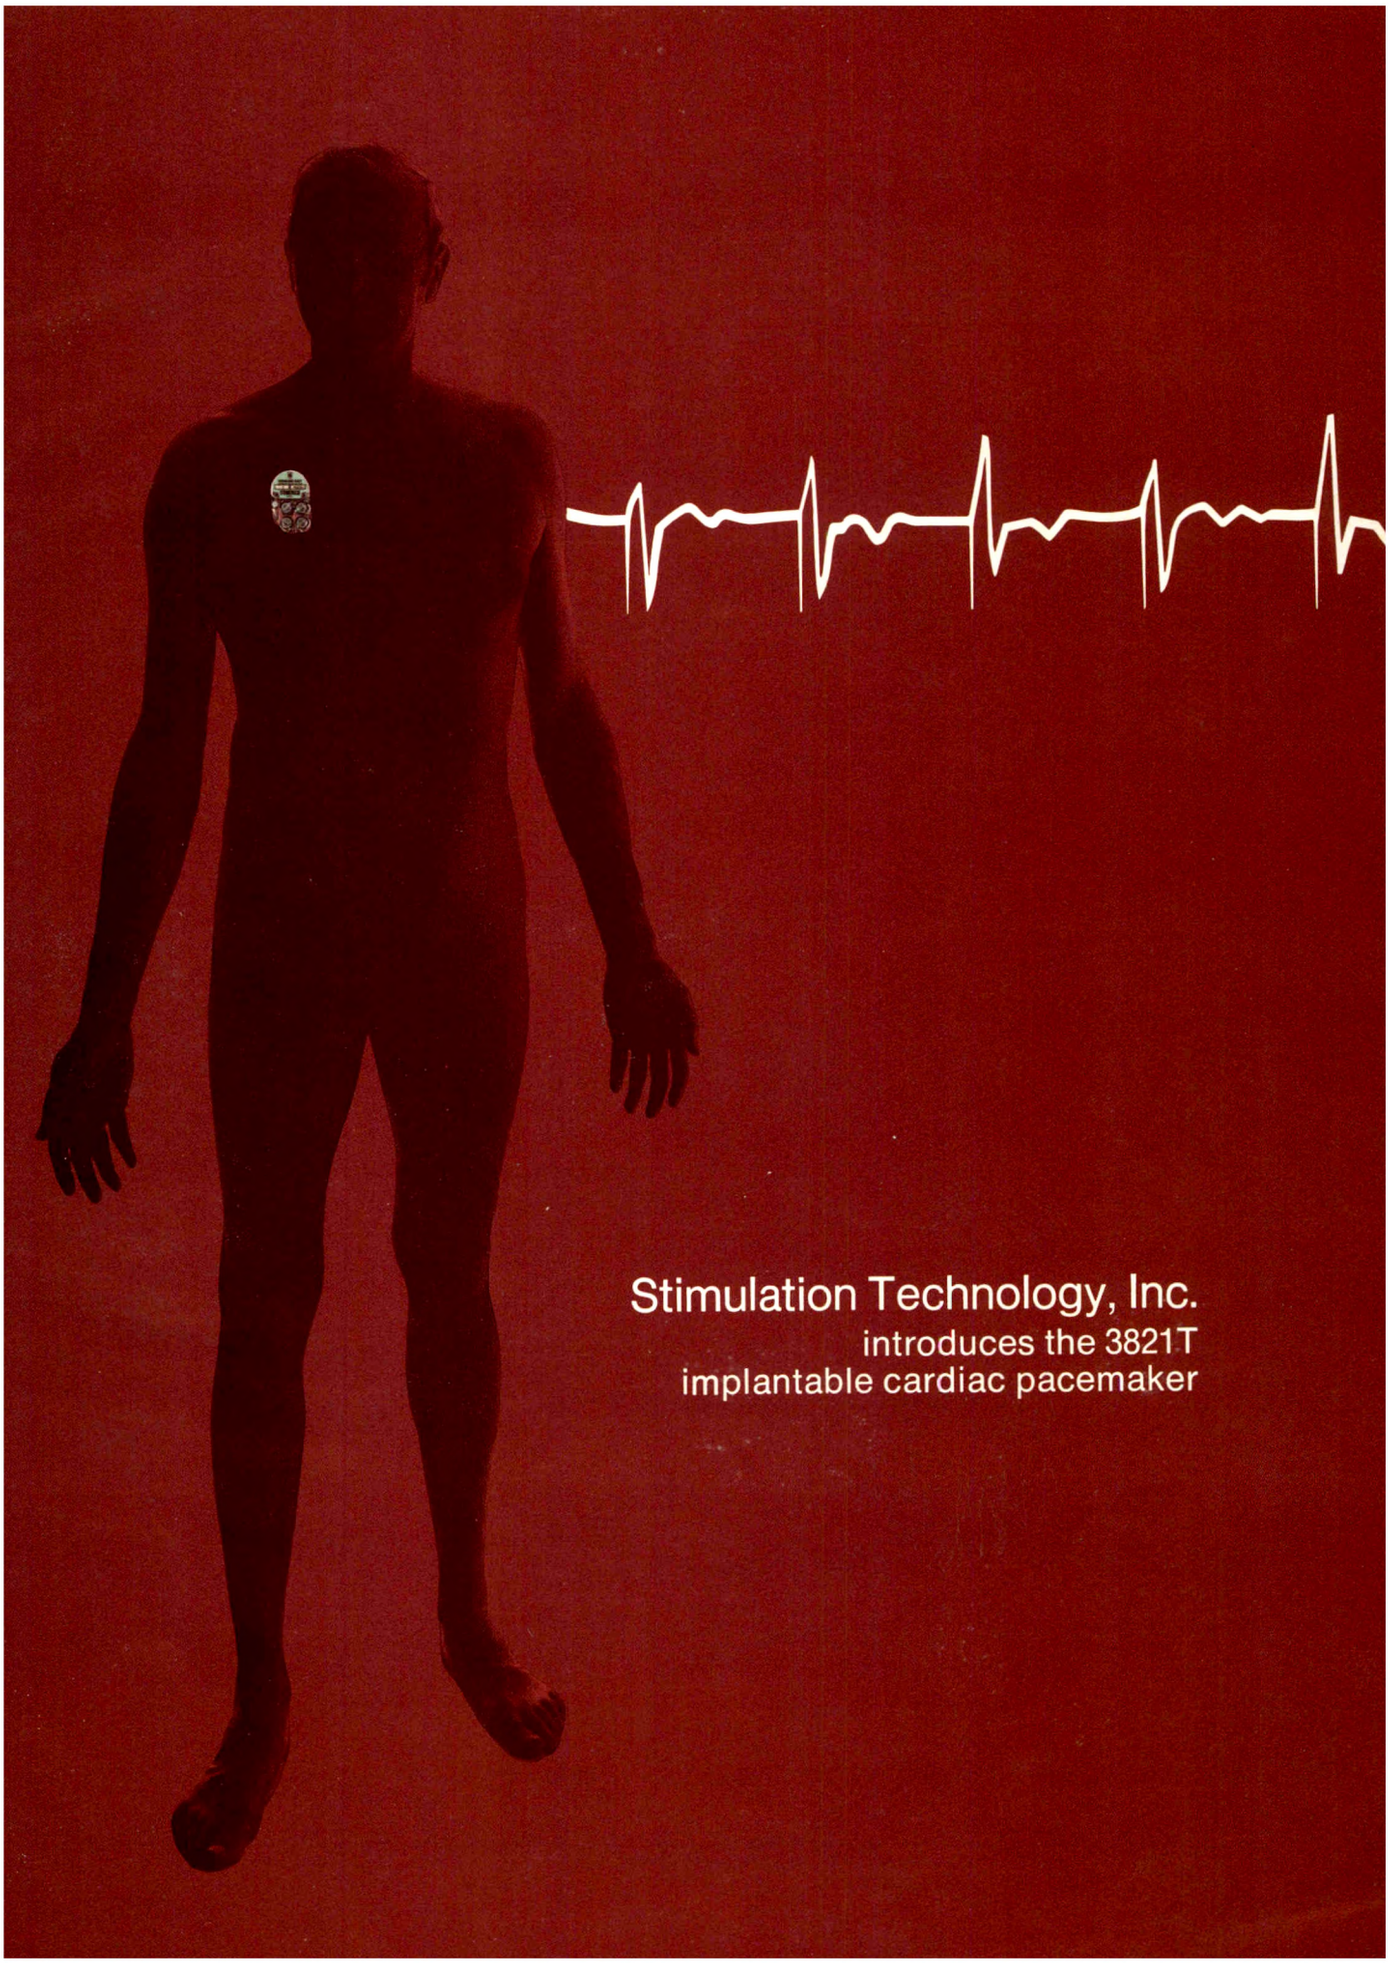
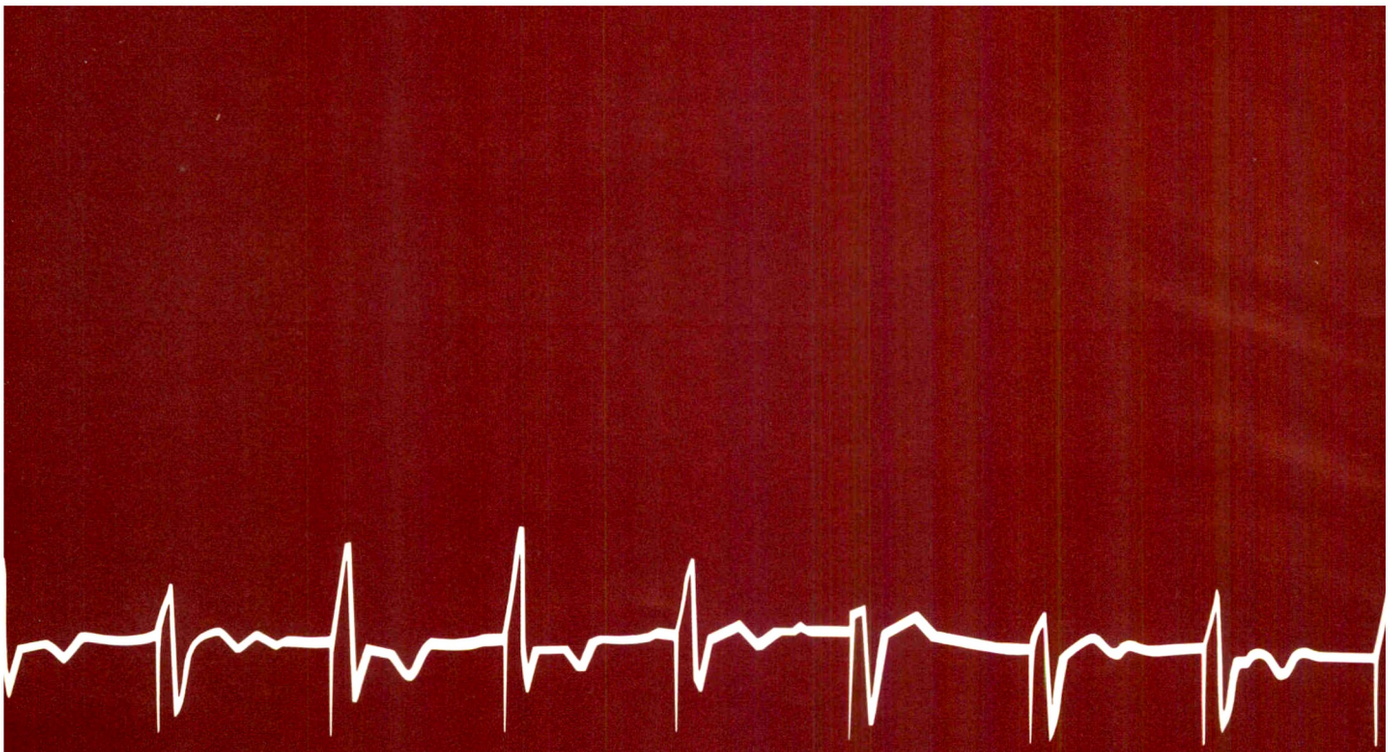
For books (with identical author and editor):

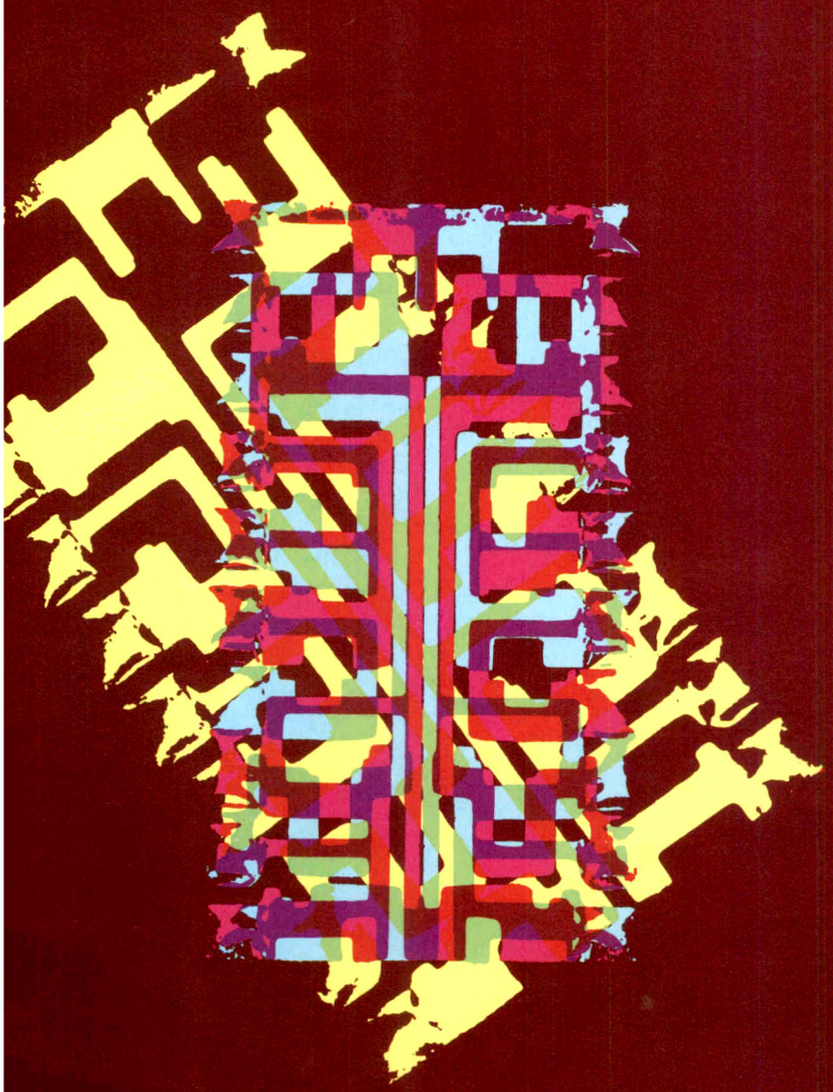
36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)

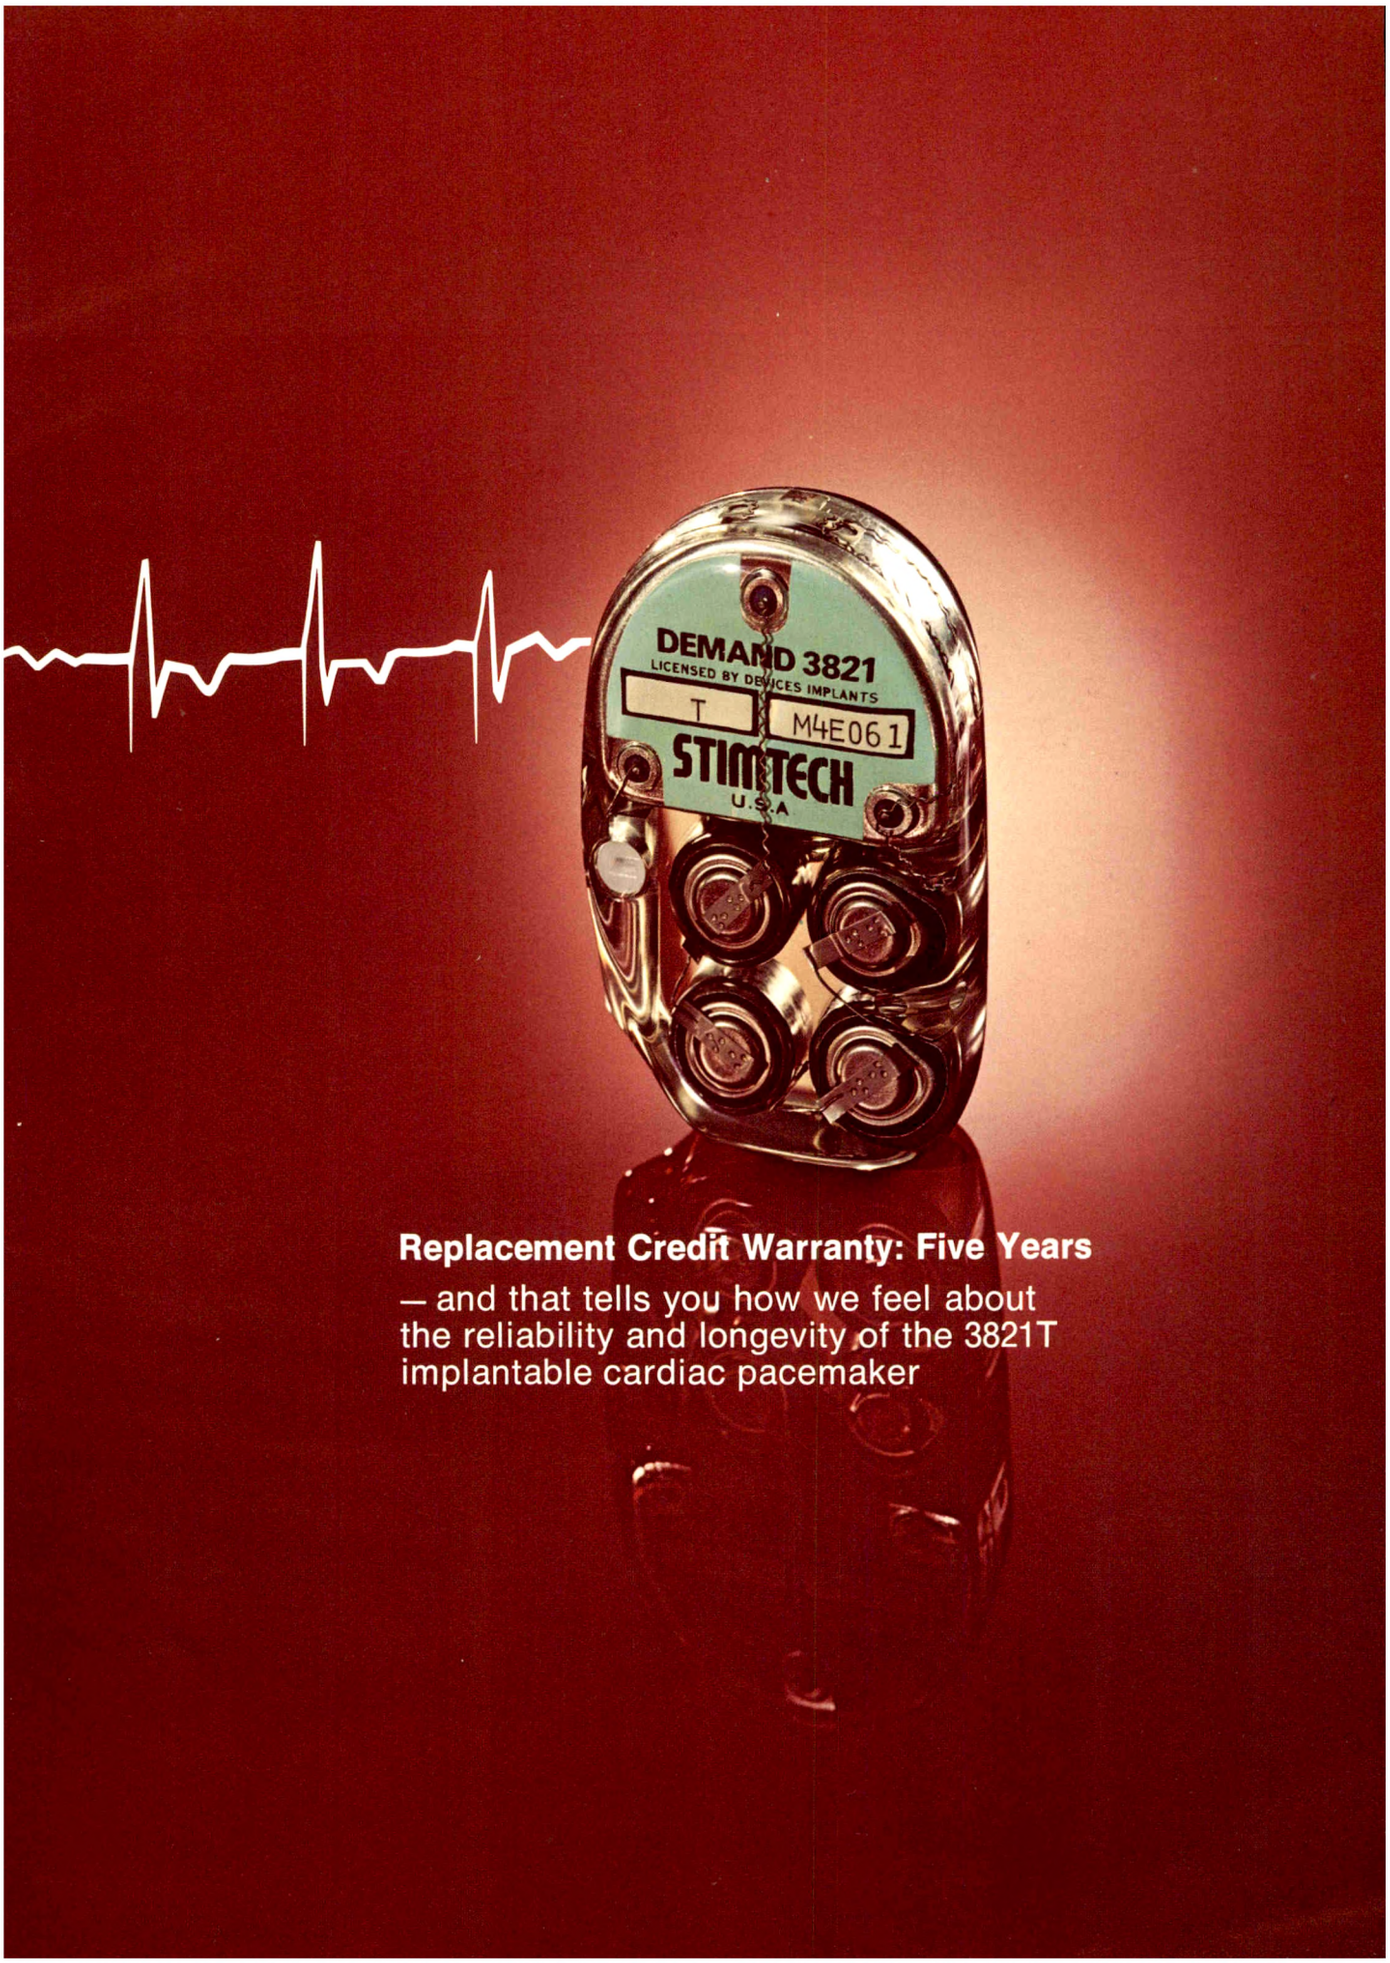


Stimulation Technology, Inc.
introduces the 3821T
implantable cardiac pacemaker





produced and distributed in the United States under license from Devices,Ltd. — for more than a decade one of the world's leading developers of cardiac pacemakers: first with hermetically sealed hybrid pacemaker circuitry



Replacement Credit Warranty: Five Years

— and that tells you how we feel about the reliability and longevity of the 3821T implantable cardiac pacemaker

The 3821T demand pacemaker

Actual Size

specifications:

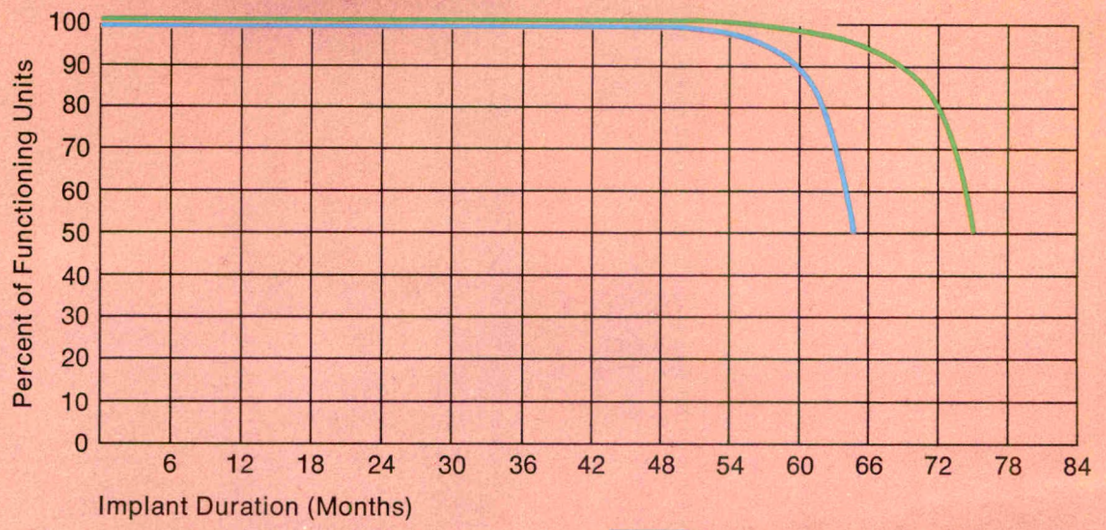
length	7.3 cm
width	4.7 cm
thickness	2.3 cm
weight	130 gm
basic rate	71 ± 4 ppm
hysteresis rate	60 ppm nominal
interference rate	105 ppm nominal
reed switch operated rate	105 ppm nominal

(Rates given apply to implanted (37° C) operation at normal battery voltage; exact rates, at room temperature, are shown on registration and information form enclosed with each pulse generator.)

features of the 3821T

- unipolar
- hybrid micro circuit construction
- battery depletion warning circuit
- unique interference handling capability
- hermetically sealed electronics
- small size
- lightweight

Pacemaker Battery -- Projected Longevity *



* These longevity projections are based on theoretical calculations for the pulse generator battery life only and do not account for pacemaker malfunction due to random component failure or events which have no relationship to time. The results therefore may not represent actual pacemaker longevity. The above projections are made on the basis of chemical capacities, self-discharge rates, and current drains measured using standard and micro electrodes, and no inhibition. Calculations include empirical data and extrapolations based upon actual battery life experience, projections from improvements in the new double separator cell and effects of one year pulse generator storage prior to implant.

Caution: U.S. federal law restricts this device to sale by or on the order of a physician.

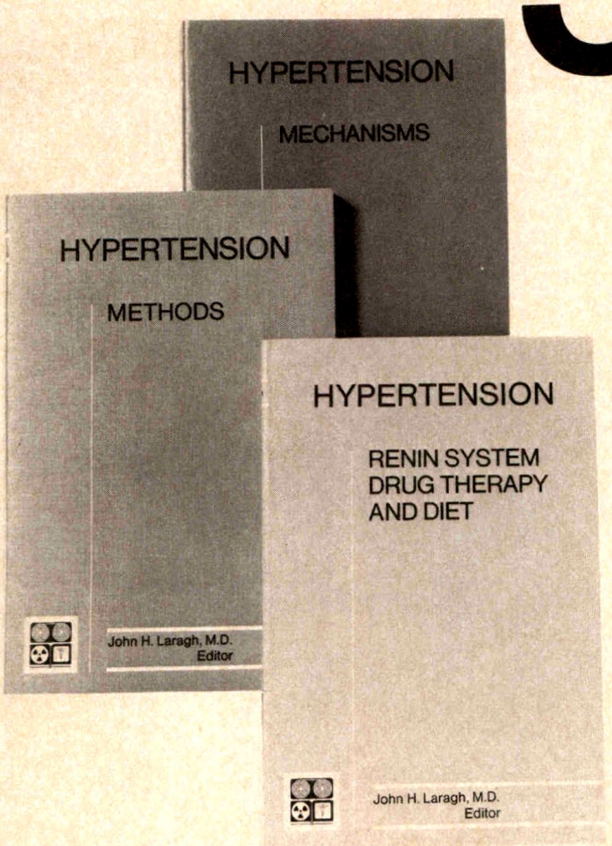
now available 1 2 3 complete selections from Laragh's HYPERTENSION MANUAL in paperback



Edited by John H. Laragh, M.D. The original Manual is already a classic treatise for understanding, diagnosing and treating Hypertension—the most definitive work on the subject to date.

SELECTIONS PRINTED AS FOLLOWS—FOR YOUR SPECIAL INTEREST

1 2 3 **1. HYPERTENSION/MECHANISMS—$12.50.**
500 pages—Contributors include—A.C. Guyton, L. Tobian, J.O. Davis, J.H. Laragh, J.E. Sealey, H.P. Dustan, J.N. Cohn, V. DeQuattro, H.R. Brunner, F.R. Bühler, J. Giese, A.R. Christlieb, L. Speroff, E.G. Biglieri, E.D. Vaughan, Jr., M.A. Schalekamp, J.C. Hunt and L. Baer.

1 2 3 **2. HYPERTENSION/METHODS—$7.50**
125 pages—Contributors include—D.R. Labarthe, K. Engelman, J.H. Laragh, J.E. Sealey, C.M. Hawkins, R.D. Remington, and F.R. Bühler.

1 2 3 **3. HYPERTENSION/RENIN SYSTEM, DRUG THERAPY AND DIET—$7.50**
110 pages—Contributors include—J.H. Laragh, E.D. Vaughan, I. Gavras, F.R. Bühler, H. Gavras, and L. Baer.

ORDER ALL THREE FOR $25.00 (a $2.50 savings)

in paperback complete selections from Laragh's HYPERTENSION MANUAL

Please send me
- ☐ Hypertension-Mechanisms for $12.50
- ☐ Hypertension-Methods for $7.50
- ☐ Hypertension-Renin System, Drug Therapy & Diet for $7.50
- ☐ All three for $25.00

☐ Full Payment enclosed (save handling charges) ☐ Bill me and add $1.00 for extra handling

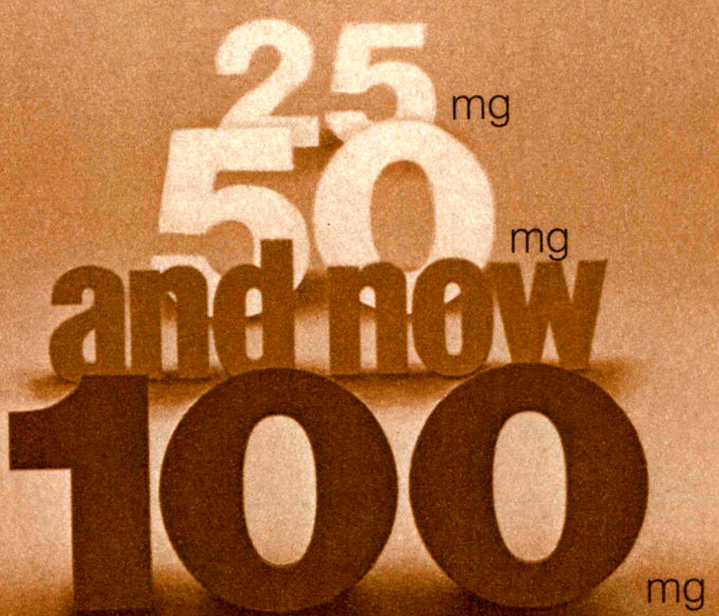
Merck Sharp & Dohme announces

a new dosage strength

TABLETS

HydroDIURIL® 100 mg

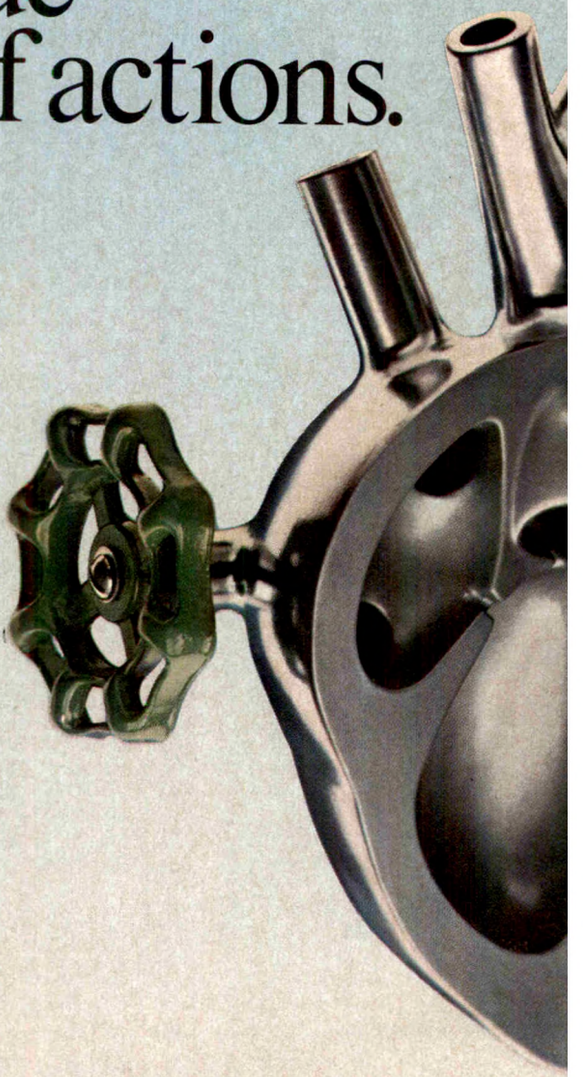
(HYDROCHLOROTHIAZIDE | MSD)



There are now three tablet strengths of HydroDIURIL – 25 mg, 50 mg, and the new 100 mg.

MSD MERCK SHARP & DOHME
DIVISION OF MERCK & CO., INC., WEST POINT, PA. 19486

INTROPIN® (dopamine HCl)
The only catecholamine with this unique combination of actions.



Intropin usually turns on:

Increased perfusion of vital organs

Multiclinic trials have demonstrated that Intropin provides adequate perfusion of vital organs. This is based upon a number of clinical parameters including an increase in urine flow which appears to be one of the better diagnostic signs of increased vital organ perfusion.

Increased urine output

Intropin significantly increases urine flow. This is in contrast to most other sympathomimetic amines, which usually cause little or no significant increase in urine output.

This increased urine output is due to increases in glomerular filtration rate and renal blood flow and is accompanied by increased sodium excretion. Intropin may also increase urine flow in patients whose urine output is within normal limits and may promote diuresis usually with no decrease in osmolality.

At doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage.

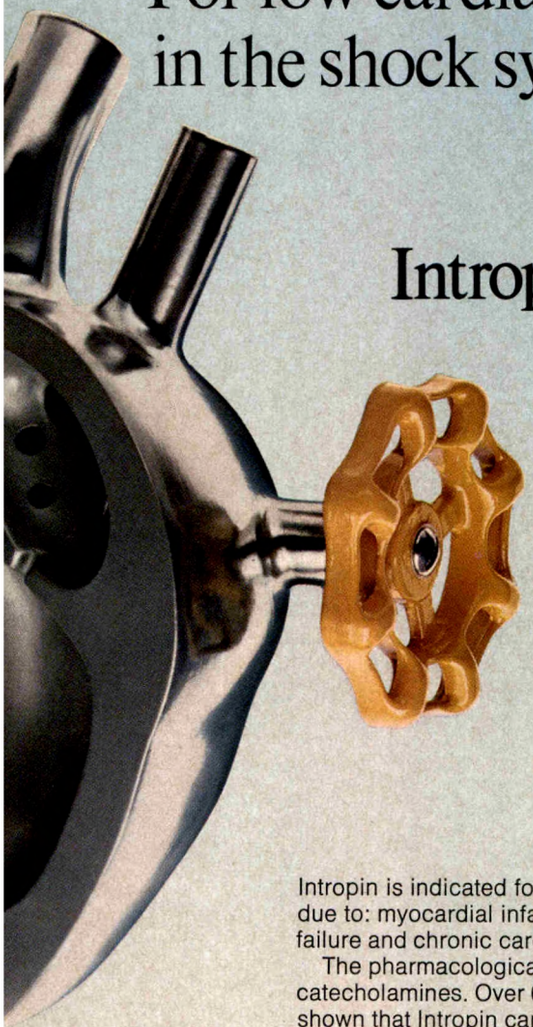
Increased cardiac output

Intropin acts predominantly on the beta receptors of the heart to substantially increase contractility, stroke volume and cardiac output, as confirmed by invasive technique.

Increased blood pressure

Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of Intropin. Prognosis is better in patients whose blood pressure and urine flow have not undergone profound deterioration. Therefore, it is suggested that the physician administer Intropin as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

For low cardiac output and hypoperfusion in the shock syndrome.



Intropin usually will not turn on:

A substantial increase in tachyarrhythmias

One investigator reported less than a 3% incidence of tachyarrhythmias in clinical trials of 270 patients. The tachyarrhythmias which occurred were easily managed.

Excessive myocardial oxygen consumption

Intropin produces less increase in myocardial oxygen consumption than isoproterenol. During administration of Intropin, the myocardial oxygen supply/demand ratio has usually remained stable. Intropin appears to meet additional myocardial oxygen requirements by increasing coronary flow.

Increased total peripheral resistance

Administration of Intropin, at low and intermediate dosages, generally does not increase total peripheral vascular resistance. Blood flow to peripheral vascular beds may decrease while mesenteric flow increases.

Intropin is indicated for the correction of hemodynamic imbalances in the shock syndrome due to: myocardial infarction, trauma, endotoxic septicemia, open heart surgery, renal failure and chronic cardiac decompensation as in congestive failure.

The pharmacological actions of Intropin appear to differ significantly from other catecholamines. Over 6 years of clinical trials at more than 30 teaching hospitals have shown that Intropin can increase cardiac output, vital organ perfusion and renal flow with a low incidence of undesirable effects.

Patients most likely to respond adequately to Intropin are those in whom urine flow, myocardial function and blood pressure have not undergone profound deterioration. Multiclinic trials indicate that the shorter the time interval between onset of signs and symptoms and initiation of therapy with volume correction and Intropin, the better the prognosis. Survival rates are considerably improved when Intropin therapy is initiated within 4 hours of onset of symptoms.

As with all potent drugs, Intropin must be administered under close medical supervision. It is administered only by I.V. drip after dilution in a suitable I.V. solution.

Serious undesirable effects seldom occur

In multiclinic studies, adverse reactions necessitated discontinuation of Intropin therapy in only 11 (2%) of 526 patients.

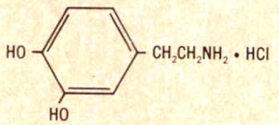
Before prescribing, see complete product information on the following page.

ARNAR-STONE LABORATORIES, INC.

INTROPIN® (dopamine HCl)

5 ml. AMPUL / FOR I.V. INJECTION

DESCRIPTION: INTROPIN (dopamine HCl) is 3,4-dihydroxyphenethylamine hydrochloride, a naturally-occurring biochemical catecholamine precursor of norepinephrine. The chemical structure is:



$C_8H_{11}NO_2 \cdot HCl$ Mol. Wt. 189.65

Dopamine hydrochloride is a white, odorless crystalline powder, freely soluble in water and soluble in alcohol. It is sensitive to light, alkalis, iron salts and oxidizing agents.

Each milliliter of sterile, pyrogen-free INTROPIN Injection contains 40 mg. of dopamine hydrochloride (equivalent to 32.96 mg. of dopamine base) in Water for Injection, USP, containing 1% sodium bisulfite as a preservative.

ACTIONS: INTROPIN exerts an inotropic effect on the myocardium resulting in an increased cardiac output. INTROPIN produces less increase in myocardial oxygen consumption than isoproterenol and its use is usually not associated with a tachyarrhythmia. Clinical studies indicate that INTROPIN usually increases systolic and pulse pressure with either no effect or a slight increase in diastolic pressure. Total peripheral resistance at low and intermediate therapeutic doses is usually unchanged. Blood flow to peripheral vascular beds may decrease while mesenteric flow increases. INTROPIN has also been reported to dilate the renal vasculature presumptively by activation of a "dopaminergic" receptor. This action is accompanied by increases in glomerular filtration rate, renal blood flow, and sodium excretion. An increase in urinary output produced by dopamine is usually not associated with a decrease in osmolality of the urine.

INDICATIONS: INTROPIN is indicated for the correction of hemodynamic imbalances present in the shock syndrome due to myocardial infarctions, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation as in congestive failure.

Where appropriate, restoration of blood volume with a suitable plasma expander or whole blood should be instituted or completed prior to administration of INTROPIN.

Patients most likely to respond adequately to INTROPIN are those in whom physiological parameters, such as urine flow, myocardial function, and blood pressure, have not undergone profound deterioration. Multiclinic trials indicate that the shorter the time interval between onset of signs and symptoms and initiation of therapy with volume correction and INTROPIN, the better the prognosis.

Poor Perfusion of Vital Organs—Urine flow appears to be one of the better diagnostic signs by which adequacy of vital organ perfusion can be monitored. Nevertheless, the physician should also observe the patient for signs of reversal of confusion or comatose condition. Loss of pallor, increase in toe temperature, and/or adequacy of nail bed capillary filling may also be used as indices of adequate dosage. Clinical studies have shown that when INTROPIN is administered before urine flow has diminished to levels approximately 0.3ml./minute, prognosis is more favorable. Nevertheless, in a number of oliguric or anuric patients, administration of INTROPIN has resulted in an increase in urine flow which in some cases reached normal levels. INTROPIN may also increase urine flow in patients whose output is within normal limits and thus may be of value in reducing the degree of pre-existing fluid accumulation. It should be noted that at doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage. Concurrent administration of INTROPIN and diuretic agents may produce an additive or potentiating effect.

Low Cardiac Output—Increased cardiac output is related to INTROPIN's direct inotropic effect on the myocardium. Increased cardiac output at low or moderate doses appears to be related to a favorable prognosis. Increase in cardiac output has been associated with either static or decreased systemic vascular resistance (SVR). Static or decreased SVR associated with low or moderate increments in cardiac output is believed to be a reflection of differential effects on specific vascular beds with increased resistance in peripheral beds (e.g. femoral) and concomitant decreases in mesenteric and renal vascular beds. Redistribution of blood flow parallels these changes so that an increase in cardiac output is accompanied by an increase in mesenteric and renal blood flow. In many instances the renal fraction of the total cardiac output has been found to increase. Increase in cardiac output produced by INTROPIN is not associated with substantial decreases in systemic vascular resistance as may occur with isoproterenol.

Hypotension—Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of INTROPIN, which have little effect on SVR. At high therapeutic doses, INTROPIN's alpha adrenergic activity becomes more prominent and thus may correct hypotension due to diminished SVR. As in the case of other circulatory decompensation states, prognosis is better in patients whose blood pressure and urine flow have not undergone profound deterioration. Therefore, it is suggested that the physician administer INTROPIN as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

CONTRAINDICATIONS: INTROPIN should not be used in patients with pheochromocytoma.

WARNINGS: INTROPIN should not be administered in the presence of uncorrected tachyarrhythmias or ventricular fibrillation.

Do NOT add INTROPIN to any alkaline diluent solution, since the drug is inactivated in alkaline solution.

Patients who have been treated with monamine oxidase (MAO) inhibitors prior to the administration of INTROPIN will require substantially reduced dosage. Dopamine is metabolized by MAO, and inhibition of this enzyme prolongs and potentiates the effect of INTROPIN. The starting dose in such patients should be reduced to at least one-tenth (1/10) of the usual dose.

Usage in Pregnancy—Animal studies have revealed no evidence of teratogenic effects from INTROPIN. In one study, administration of INTROPIN to pregnant rats resulted in a decreased survival rate of the newborn and a potential for cataract formation in the survivors. The drug may be used in pregnant women when, in the judgment of the physician, the expected benefits outweigh the potential risk to the fetus.

Usage in Children—The safety and efficacy of this drug in children has not been established. INTROPIN has been used in a limited number of pediatric patients, but such use has been inadequate to fully define proper dosage and limitations for use. Further studies are in progress.

PRECAUTIONS: Prior to treatment with INTROPIN, hypovolemia should be fully corrected, if possible, with either whole blood or plasma as indicated.

If a disproportionate rise in the diastolic pressure (i.e. a marked decrease in the pulse pressure) is observed in patients receiving INTROPIN, the infusion rate should be decreased and the patient observed carefully for further evidence of predominant vasoconstrictor activity, unless such an effect is desired.

Although in clinical trials inadvertent subcutaneous infiltration did not produce any evidence of necrosis, the usual precautions should be taken to avoid extravasation.

Cyclopropane or halogenated hydrocarbon anesthetics increase cardiac autonomic irritability and therefore may sensitize the myocardium to the action of certain intravenously administered catecholamines. This interaction appears to be related both to pressor activity and to beta adrenergic stimulating properties of these catecholamines. Therefore, as with certain other catecholamines, and because of the theoretical arrhythmogenic potential, INTROPIN should be used with EXTREME CAUTION in patients inhaling cyclopropane or halogenated hydrocarbon anesthetics.

Close monitoring of the following indices—urine flow, cardiac output and blood pressure—during INTROPIN infusion is necessary as in the case of any adrenergic agent.

ADVERSE REACTIONS: The most frequent adverse reactions observed in clinical evaluation of INTROPIN included ectopic beats, nausea, vomiting, tachycardia, anginal pain, palpitation, dyspnea, headache, hypotension, and vasoconstriction. Other adverse reactions which have been reported infrequently were aberrant conduction, bradycardia, piloerection, widened QRS complex, azotemia, and elevated blood pressure.

DOSAGE AND ADMINISTRATION:

WARNING: This is a potent drug: It must be diluted before administration to patient.

Suggested Dilution—Transfer contents of one ampul (5 ml. containing 200 mg. INTROPIN) by aseptic technique to either a 250 ml. or 500 ml. bottle of one of the following sterile intravenous solutions:

1) Sodium Chloride Injection, USP
2) Dextrose 5% Injection, USP
3) Dextrose (5%) and Sodium Chloride (0.9%) Injection, USP
4) 5% Dextrose in 0.45% Sodium Chloride Solution
5) Dextrose (5%) in Lactated Ringer's Solution
6) Sodium Lactate (1/6 Molar) Injection, USP
7) Lactated Ringer's Injection, USP

These dilutions will yield a final concentration for administration as follows:
250 ml. dilution contains 800 mcg./ml. of INTROPIN
500 ml. dilution contains 400 mcg./ml. of INTROPIN

INTROPIN has been found to be stable for a minimum of 24 hours after dilution in the sterile intravenous solutions listed above. However, as with all intravenous admixtures, dilution should be made just prior to administration.

Do **NOT** add INTROPIN Injection to 5% Sodium Bicarbonate or other alkaline intravenous solutions, since the drug is inactivated in alkaline solution.

Rate of Administration—INTROPIN, after dilution, is administered intravenously through a suitable intravenous catheter or needle. An i.v. drip chamber or other suitable metering device is essential for controlling the rate of flow in drops/minute. Each patient must be individually titrated to the desired hemodynamic and/or renal response with INTROPIN. In titrating to the desired increase in systolic blood pressure, the optimum dosage rate for renal response may be exceeded, thus necessitating a reduction in rate after the hemodynamic condition is stabilized.

Administration at rates greater than 50 mcg./kg./min. have safely been used in advanced circulatory decompensation states. If unnecessary fluid expansion is of concern, adjustment of drug concentration may be preferred over increasing the flow rate of a less concentrated dilution.

Suggested Regimen:

1. When appropriate, increase blood volume with whole blood or plasma until central venous pressure is 10 to 15 cm H_2O or pulmonary wedge pressure is 14-18 mm Hg.

2. Begin administration of diluted solution at doses of 2-5 mcg./kg./minute INTROPIN in patients who are likely to respond to modest increments of heart force and renal perfusion.

In more seriously ill patients begin administration of diluted solution at doses of 5 mcg./kg./minute INTROPIN and increase gradually using 5 to 10 mcg./kg./minute increments up to 20 to 50 mcg./kg./minute as needed. If doses of INTROPIN in excess of 50 mcg./kg./minute are required, it is suggested that urine output be checked frequently. Should urine flow begin to decrease in the absence of hypotension, reduction of INTROPIN dosage should be considered. Multiclinic trials have shown that more than 50% of the patients were satisfactorily maintained on doses of INTROPIN less than 20 mcg./kg./minute. In patients who do not respond to these doses with adequate arterial pressures or urine flow, additional increments of INTROPIN may be employed in an effort to produce an appropriate arterial pressure and central perfusion.

3. Treatment of all patients requires constant evaluation of therapy in terms of the blood volume, augmentation of myocardial contractility, and distribution of peripheral perfusion. Dosage of INTROPIN should be adjusted according to the patient's response, with particular attention to diminution of established urine flow rate, increasing tachycardia or development of new dysrhythmias as indices for decreasing or temporarily suspending the dosage.

4. As with all potent intravenously administered drugs, care should be taken to control the rate of administration so as to avoid inadvertent administration of a bolus of drug.

OVERDOSAGE: In case of accidental overdosage, as evidenced by excessive blood pressure elevation, reduce rate of administration or temporarily discontinue INTROPIN until patient's condition stabilizes. Since INTROPIN's duration of action is quite short, no additional remedial measures are usually necessary. If these measures fail to stabilize the patient's condition, use of the short-acting alpha adrenergic blocking agent, phentolamine, should be considered.

HOW SUPPLIED: 5 ml. ampuls containing 40 mg. dopamine HCl per milliliter.

ARNAR-STONE LABORATORIES, INC.
A Subsidiary of American Hospital Supply Corporation
Mount Prospect, Illinois 60056

Extend
Your
Reach...
Cardio-Dynamics

The Dyna-Gram® Way

of Holter Electrocardiography extends the reach of your practice by providing you with sophisticated equipment, an expert staff and a complete ECG report that frees you to devote your time to diagnosis and treatment . . .

Equipment that is reliable and provides uninterrupted ambulatory, office-quality ECGs for up to 24 hours.

A team of professionals behind you devoted exclusively to the processing of Holter recordings with attention to accuracy and detail that is rarely equalled in office or hospital.

The recording is summarized in a report that provides a complete, standardized and documented digest of your patient's ECG.

All of this is the promise of Holter recording.

Cardio-Dynamics delivers the promise!

No other nitroglycerin tablet offers you all these advantages:

New level of stability*

without sacrifice of disintegration time
without sacrifice of bioavailability

New level of tablet elegance

Minimal crumbling or powdering; controlled nitroglycerin volatility; yet disintegrates in vitro as quickly as other nitroglycerin tablets tested; minimum deterioration with time or exposure

New level of convenience

Color-coded tablets as well as labels for easier identification; lessens patient confusion; eases patient conversion (strength or brand).

Please send patient-starter samples of NITROPRN™ (nitroglycerin, USP) sublingual tablets.

Dr. _____

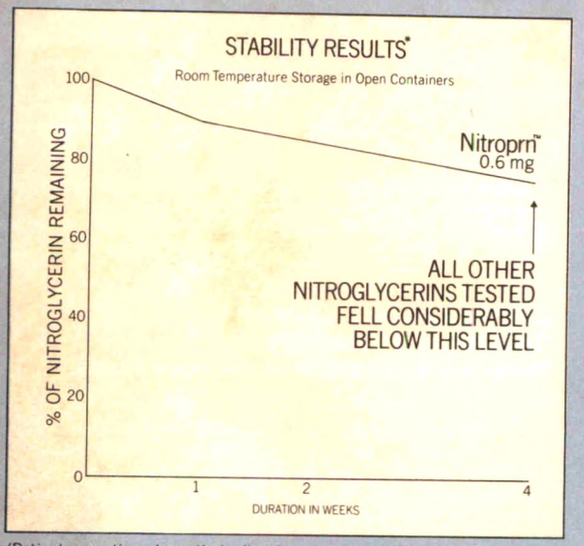
Street _____

City _____ State _____ Zip _____

Authorized Signature _____

The most stable nitroglycerin tablet yet

ALL NITROGLYCERINS START OUT POTENT. HOWEVER, DELIBERATELY DEMANDING TEST CONDITIONS SHOWED NITROPRN RETAINED POTENCY LONGER:



(Patients sometimes leave their nitroglycerin exposed. The open-dish method, a most demanding stability test, shows that Nitroprn retains its potency even under extreme exposure, thus protecting even careless patients.)

After 1 week, NITROPRN could deliver **90%** nitroglycerin; after 4 weeks, it could still deliver **76%** nitroglycerin potency. Yet NITROPRN in vitro disintegration time is either superior or equal to that of other brands of nitroglycerin tablets tested. This consistent level of stability insures potency from tablet to tablet, and assures the angina patient the protection he needs from attack to attack.

Yet NITROPRN costs only pennies more than other nitroglycerins.

NITROPRN™

New Saunders books in/on circulation.

(The word's getting around.)

SELZER: Principles of Clinical Cardiology

Re-establishing management of cardiac patients in the realm of the clinician is Dr. Selzer's aim, and this practical book shows how an analytic problem-solving approach can be tailored to the needs of individual patients. Basic insights into diagnosis, treatment and cardiac disturbances are followed by detailed discussions of diseases affecting the heart and circulation. All physicians who deal even occasionally with heart disease will benefit from this eminently readable book.

By **Arthur Selzer,** MD, Chief of Cardiology and Director of Cardiopulmonary Laboratories, Presbyterian Hospital of Pacific Medical Center, S.F. 735 pp. Illustd. About $20.00. Just Ready. **Order #8060-7.**

GUYTON, TAYLOR & GRANGER: Circulatory Physiology II: Dynamics and Control of the Body Fluids

This second volume covers the dynamics of edema formation in the peripheral tissues and lungs, and describes the relationship of the kidneys, hormonal system and nervous reflexes to body fluid control. Of special interest is new material on the physical bases of pressure transmission through the tissues, and on basic regulatory mechanisms for body fluid control and distribution.

By **Arthur C. Guyton,** MD, Prof. and Chairman; **Aubrey E. Taylor,** PhD, Prof.; and **Harris J. Granger,** PhD, Assoc. Prof.; all of the Dept. of Physiology and Biophysics, Univ. of Mississippi Medical Center. About 400 pp. Illustd. About $20.00. Just Ready. **Order #4361-2.**

Vol. I: Cardiac Output and Its Regulation, 2nd ed., by Arthur C. Guyton, Carl E. Jones & Thomas G. Coleman. 556 pp. 214 figs. $20.00. April 1973. **Order #4360-4.**

HUTCHINSON & ACHESON: Strokes Natural History, Pathology and Surgical Treatment

This neurological view of cerebral ischaemia relates physiological and pathological aspects of cerebral circulation to the natural history of stroke. Effects of hypertension are examined at length; and abnormal electrocardiograms, heart size and elevated serum cholesterol levels are keyed to prognosis. Both medical and surgical approaches to treatment are recommended.

By **E. C. Hutchinson,** MD, Consultant Neurologist, North Staffordshire Hospital Centre, Stoke-on-Trent, Staffs; and **E. J. Acheson,** MD, Research Fellow, Dept. of Medicine, The Royal Infirmary, Manchester. Published by Saunders Ltd., London. 283 pp. Illustd. $23.00 March. **Order #4870-3.**

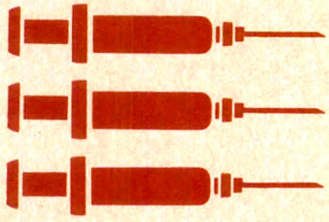
I.V. Administration Guidelines for Premature Ventricular Contractions and Tachycardia

1. Preparation of drug: Dilute before I.V. use.
2. Usual dosage range: 200-1000 mg.
3. Infusion rate: Not to exceed 25-50 mg. per minute. Total I.V. dose not to exceed 1000 mg.
4. Precautionary measures:
   a. Keep patient in supine position.
   b. Monitor electrocardiographically and discontinue if myocardial toxicity is evidenced.
   c. Measure blood pressure almost continuously and temporarily discontinue infusion if blood pressure falls more than 15 mm. Hg.

When therapeutic blood levels are required quickly, I.V. Injections

100 mg. every 5 minutes until arrhythmia suppressed (up to a maximum dose of 1 gram).



For ventricular arrhythmias

SQUIBB® 'The Priceless Ingredient of every product is the honor and integrity of its maker.'™

A74

by a variety of routes

I.V. Infusion

2-6 mg. per minute[1].
(42.8 μg./min./kg.)[2]

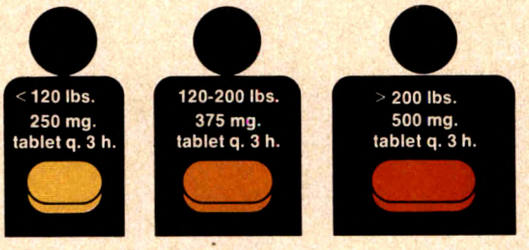
1. Wyman MG, Hammersmith L: Am J Cardiol 33:661-667, 1974
2. Bigger JT, Jr., Giardina EV: MCV Quart 9 (1): 65-76, 1973

Terminate I.V. infusion *4 hours before* oral regimen begun.

Oral Administration Guidelines to Provide 50 mg./kg./day* for Ventricular Arrhythmias

Ventricular Tachycardia
(give priming dose of 1 g. if patient has not received prior infusion)

Premature Ventricular Contractions



*This dosage schedule is for use as a guide for treating the average patient, but all patients must be considered on an individual basis.

Pronestyl®
(Procainamide Hydrochloride)
through the entire therapeutic course

See next page for brief summary.

PRONESTYL® TABLETS
(Procainamide Hydrochloride Tablets)

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate considerations of alternative anti-arrhythmic therapy.

Pronestyl Tablets (Procainamide Hydrochloride Tablets) are veneer-coated tablets providing 250 mg., 375 mg., and 500 mg. procainamide hydrochloride.

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; bear in mind cross sensitivity to procaine and related drugs. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of second degree and third degree A-V block unless an electrical pacemaker is operative.

Administration: Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous if myocardial damage exists.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with severe organic heart disease and ventricular tachycardia that complete heart block, which may be difficult to diagnose, may be present. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related to continued procainamide therapy (see boxed Warning). Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see Precautions). Reactions consisting of fever and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever or any symptoms of upper respiratory tract infection. If any of these symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions and for full prescribing information.

How Supplied: Pronestyl Tablets (Procainamide Hydrochloride Tablets) providing 250 mg., 375 mg., and 500 mg. are available in bottles of 100.

PRONESTYL® INJECTION
(Procainamide Hydrochloride Injection U.S.P.)

Description: Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) is a sterile aqueous solution providing 100 mg. or 500 mg. procainamide hydrochloride per ml. The 100 mg./ml. potency contains 0.9% (w/v) benzyl alcohol and 0.09% sodium bisulfite as preservatives. The 500 mg./ml. potency contains 0.1% methylparaben and not more than 0.2% sodium bisulfite as preservatives.

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; cross sensitivity to procaine and related drugs must be borne in mind. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage, procainamide may produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Because procainamide is a peripheral vasodilator, I.V. administration may produce transient but at times severe hypotension particularly in conscious patients. I.M. injection is less likely to cause serious falls in blood pressure. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

A syndrome resembling lupus erythematosus has been reported. Reactions consisting of fever and chills including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in SGOT following single doses of the drug have been reported. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred; therefore, routine blood counts are advisable during maintenance therapy. If soreness of mouth, throat or gums, unexplained fever or any symptoms of upper respiratory tract infection should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Administration: Oral administration is preferred. When parenteral therapy is necessary, intramuscular administration is the method of choice. *Intravenous use should be limited to extreme emergencies,* **the drug should be administered as a dilute infusion,** and the patient should be monitored electrocardiographically. The intravenous dose should not exceed 1 gram. Administer at a rate not exceeding 25 to 50 mg. per minute.

Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions.

How Supplied: Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) is available in 10 ml. vials providing 100 mg./ml. and in 2 ml. vials providing 500 mg./ml. © 1974 E. R. SQUIBB & SONS, INC. 444-009

From slippers to shoes

chewable 10 mg

Cardilate®

(erythrityl tetranitrate)

increases exercise tolerance for your angina patient

Rx: chewable tablets 10 mg tid or qid (prn)

An effect appears in approximately 5 minutes —total duration of effect up to 4 hours.

For use in the prophylaxis and long-term treatment of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris.

Precautions: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in administering the drug to patients with a history of recent cerebral hemorrhage, because of the vasodilation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

Side Effects: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

WAX: WHAT IT DID FOR THE HONEYCOMB IT NOW DOES FOR POTASSIUM CHLORIDE.

WARREN-TEED® ANNOUNCES

NEW KAON-CL TABS™

(potassium chloride)

CONTROLLED RELEASE TABLETS

– Potassium chloride imbedded in a wax matrix to provide controlled release, thus minimizing possible high local concentration of potassium ion near the bowel wall. The newest idea in potassium chloride supplements is as old as the beehive. Wax... provides an effective vehicle to imbed KCl crystals for a controlled rate of release

New Kaon-CL Tabs™
(potassium chloride)

prolong the release of KCl to minimize the likelihood of producing high localized concentrations of potassium within the G.I. tract...

- protect your patient from the risk of hypokalemia or digitalis intoxication due to potassium depletion that diet alone cannot correct...
- promote adherence to medication schedule by relieving the patient of the inconvenience of liquids...

Three-way convenience for your patients on KCl Supplements...

- because there's no palatability problem
- because there's no dilution problem
- because tablets are physically easier to carry—and to take—than liquids... an especially welcome advantage away from home—encouraging adherence to the prescribed regimen

The controlled release KCl Tablet that protects your patients on diuretics or digitalis

- against hypokalemia due to potassium depletion that cannot be adequately replaced by diet alone
- against the inconvenience of—and often confusion over—dilution of liquid supplements
- from taste-fatigue associated with liquids

Dosage: Prophylactic: 20 mEq. daily (1 tab T.I.D.)
Therapeutic: 40-100 mEq. daily
See following page for brief summary.

WARREN-TEED
PHARMACEUTICALS INCORPORATED
SUBSIDIARY OF ROHM AND HAAS COMPANY
COLUMBUS, OHIO 43215

Warren-Teed®
KAON-CL TABS™
(Potassium Chloride)
CONTROLLED RELEASE TABLETS

Description: Kaon-CL Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg. potassium chloride (equivalent to 6.67 mEq. potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: Kaon-CL Tabs is indicated for the treatment of potassium depletion in patients with hypokalemia and metabolic alkalosis, and for the treatment of digitalis intoxication. During therapy serum potassium levels should be monitored and the dosage titrated to achieve the desired clinical and laboratory effects. Kaon-CL Tabs is also indicated for the prevention of potassium depletion when the dietary intake of potassium is inadequate for this purpose. The prophylactic administration of potassium ion may be indicated in patients receiving digitalis and diuretics for the treatment of congestive heart failure, hepatic cirrhosis with ascites, patients with hypertension on long-term diuretic therapy, hyperaldosteronism states with normal renal function, the nephrotic syndrome, and certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

Warnings: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-CL Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric coated potassium chloride tablets (40-50 per 100,000 patient-years), a few cases associated with wax-matrix tablets have been reported. These data are from foreign marketing experience. Kaon-CL Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia, in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Dosage and Administration: Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq. per day for the prevention of hypokalemia to 40-100 mEq. per day or more for the treatment of potassium depletion.

One Kaon-CL Tabs three times daily provides 20 mEq. of potassium chloride. Two Kaon-CL Tabs three times daily provides 40 mEq. of potassium chloride.

Caution: Federal law prohibits dispensing without prescription.

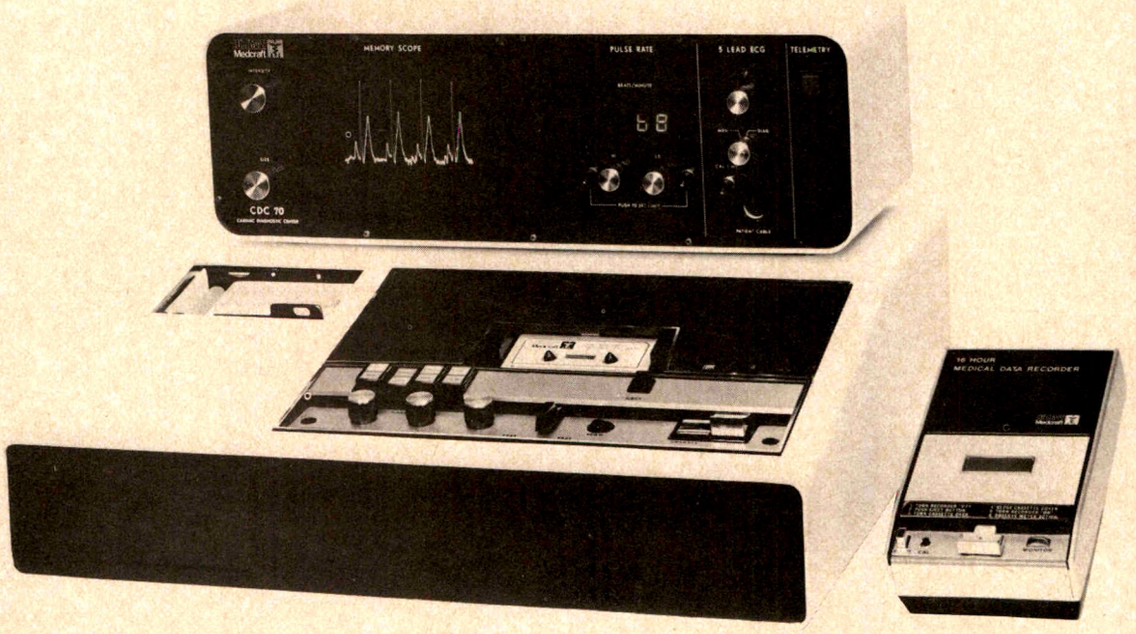
CDC 70 TRADEMARK

One Instrument=A Complete System



Holter Monitoring/Scanning-Stress Testing-Resting ECG

The Medcraft CDC 70 is the most versatile cardiac diagnostic instrument available. It performs all basic ECG diagnostic procedures, including Holter monitoring/scanning and stress testing functions required in your office, clinic and hospital. Innovative design and solid state circuitry give you the most economical, flexible system for monitoring and diagnosing cardiac abnormalities.

As a Holter Monitor/Scanner the CDC 70 is clinically proven to be useful in the detection of intermittent arrhythmic and ischemic heart conditions, evaluations of pacemaker functions, identification of ectopic beats and therapeutic and investigative drug studies. Maximal and sub-maximal stress testing, post coronary and post surgical physical rehabilitation programs provide additional application for total system utilization.

Versatility of the CDC 70 System is further demonstrated by its capability to run a full 12-lead resting ECG in addition to such specialized applications as a telemetry monitor, a bedside patient monitor and universal compatibility to interface with existing computer technology.

The Medcraft CDC 70 can be purchased or leased with convenient terms and is covered by a one year warranty on materials and workmanship. Sales and service are available from a nationwide network fo factory trained representatives.

Interested in an on-site demonstration or detailed information?

Please call direct or write .....

A REMINDER: Now is the time to take advantage of our free Medcraft Holter Recorder with the purchase or lease of a CDC 70 System before July 31, 1975.

Since most people use just one cine film why is Ilford making three?

Simple. To give you the chance to choose the one that gives you films that look exactly right to *your* eyes.

We've found that a lot of you aren't really happy with the film you're using. Maybe you just don't know there's something better. Some of you seem to think the grainy pictures you're getting are the fault of your screen. Chances are, it's the fault of the film.

You're dealing with the world's most important subject: the heart. If you can improve those films, isn't it worth a little time and thought on your part?

The three new Ilford films for cineradiography are: Ilford Cinegram F—A film with exceptionally fine grain emulsion that produces the ultimate in image detail, gradation and resolution. Its image recording capability exceeds that of any currently available image intensifying system. Ilford Cinegram C—A film designed to give higher contrast and a brilliant image while maintaining exceptionally fine grain. And Ilford Cinegram S—A film with an emulsion formulated to produce excellent detail, contrast and resolution on systems that require a high speed film.

All Ilford Cinegram films are made to be used and processed on the equipment you're now using. For more details, talk to your Ilford Man or write: Cine Services Department, Ilford Inc., 70 West Century Road, Paramus, New Jersey 07652. A Ciba-Geigy Co.

Ask your Ilford Man about his new heart films.

IN ANGINA*: **ACTS WITH SUBLINGUAL SPEED**

CHEWABLE SORBITRATE® 5MG.
ISOSORBIDE DINITRATE

As with sublingual ISDN:
acts in 2 minutes for therapeutic use...
acts up to 2 hours for prophylaxis.

In addition:
chewing action helps distribute nitrate over a larger mucosal area.

SUMMARY OF
PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: Sublingual and chewable dosage forms of SORBITRATE are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

Laragh's HYPERTENSION MANUAL

Edited by John H. Laragh, M.D. of the College of Physicians and Surgeons Columbia-Presbyterian in New York

A classic treatise for understanding, diagnosing and treating hypertensio

The most definitive work on the subject to date.

970 pages, 150 illustrations
Price: $37.00

The complete table of contents speaks for itself and is all the promotion that is needed.

Dr. Laragh's Hypertension Manual will undoubtedly become the standard reference work in Hypertension. Use the attached form to place your order. This is the first in a series of Yorke Medical Books—from the publishers of The American Journal of Cardiology, The American Journal of Medicine, The American Journal of Surgery, and Cutis.

Yorke Medical Books AJC-7

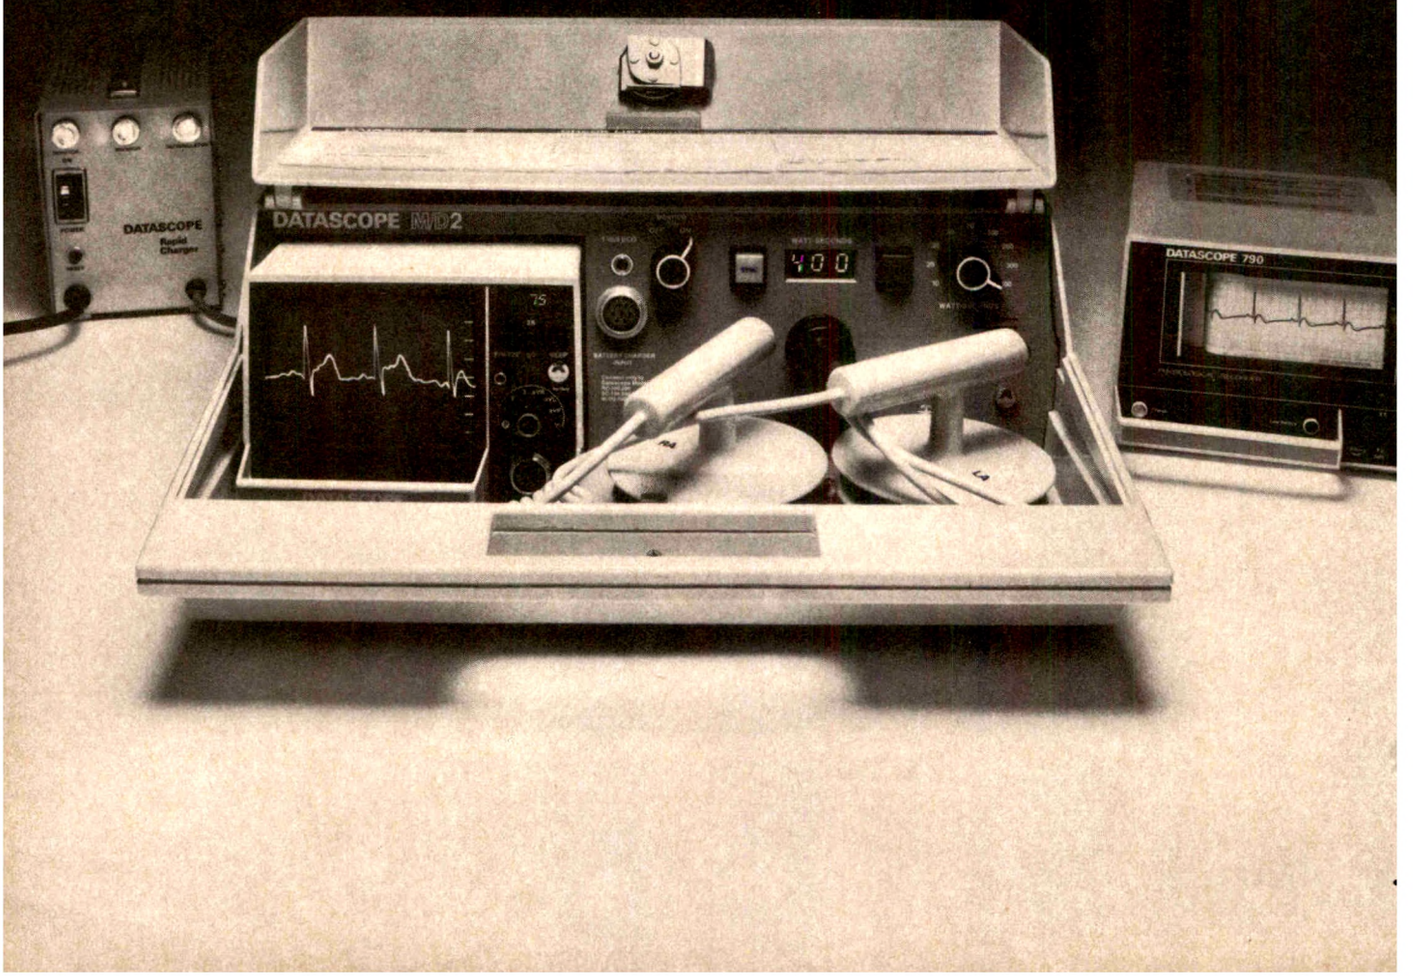
THE DATASCOPE M/D2 SYSTEM. THE FIRST RESCUE SYSTEM AS FLEXIBLE AS THE PEOPLE WHO USE IT.



If there's one thing you can be sure of in cardiac rescue, it's that you can't be sure of anything.

Every situation, either in the hospital or in the field, presents new problems, and requires new solutions.

At Datascope, we've been in emergency medicine since its inception.

Our equipment has faced just about everything. And from that experience we've put together a system that's prepared to face anything: the M/D2 System.

The M/D2 System is built on one very simple principle. *Every instrument in the system must be independent and not compromised by any other instrument.*

In keeping with this philosophy, our monitor, our defibrillator and our strip-chart recorder each have a separate battery source. One unit never puts a drain on another.

But to see its flexibility, let's take our system apart, instrument by instrument.

OUR MONITOR.

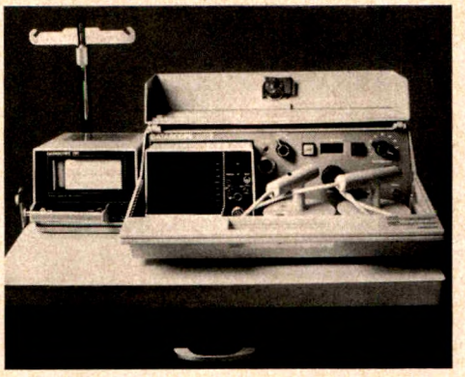
The monitor in the M/D2 System nests inside the defibrillator. You can carry the monitor and defibrillator, use it, and store it as one unit.

But the monitor pulls out* of the M/D2 case and works as a separate unit as well. So it can be placed right on a patient's stretcher in the field. Or put in the most advantageous viewing position at the bedside.

U.S. PATENT 3,865,101

In addition to being so flexible, our monitor outperforms any monitor in emergency medicine.

It has a 5-inch scope with a 8 x 11 cm. viewing area.



It has a memory which provides a bright, non-fade display that's remarkably clear even in strong sunlight.

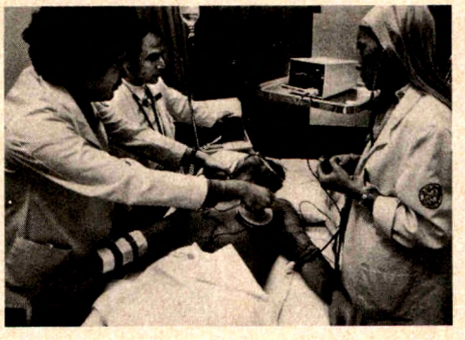
It has a freeze button which lets you stop the ECG for closer study.

It's the only emergency monitor with a digital heart rate readout. And because the readout is an LED display, you can even read it in the dark.

OUR DEFIBRILLATOR.

Like our monitor, our defibrillator has its own battery-pack.

It's the only defibrillator made that gives you a *digital* energy meter. Which displays both stored energy and the results of delivered energy tests.



The defibrillator is exceptionally safe. A warning tone sounds when the selected energy level is reached.

Energy cannot be delivered unless the push-button switch on each paddle is actuated simultaneously.

The energy within the defibrillator is automatically discharged when the unit is turned off.

For paramedic use, the M/D2 is available completely shielded against RF interference across the entire communications band.

OUR RECORDER.

Our recorder is flexible as well. It's carried separately and powered separately. (For good reason. A recorder powered by a common battery puts an enormous drain on the other instruments in the system.)

Our recorder weights only 11 pounds. And when you're using our monitor outside the M/D2 case, our recorder fits right into the space the monitor vacated. Which allows even easier transport

OUR RAPID CHARGER.

Although the M/D2 comes with a standard battery recharger, we offer the first rapid recharging unit as part of our system. Our Rapid Charger allows you to defibrillate with just 60 seconds of recharge. And in just 10 minutes it will recharge the defibrillator to at least 60% of total capacity.

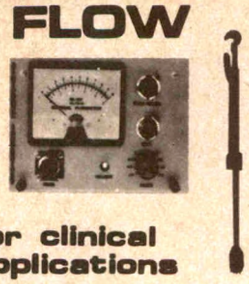
THE SYSTEM. IT'S MORE THAN ANY OF ITS PARTS.

Three independent units. Three independent battery-packs And a Rapid Charger. They work together, or apart. They give you more ability to react than any single unit ever could.

For more information on the M/D2 System, write: Datascope Corp., 580 Winters Avenue, Paramus, N.J. 07652.

THE DATASCOPE M/D2

BLOOD FLOW



for clinical applications

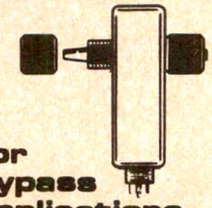
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

Physiological Adaptation to the Environment

F. J. Vernberg, Editor

Admirably fulfills the need for a definitive review of recently acquired information on the mechanisms of physiological adaptation as they relate to molecular, organismic, and ecosystem levels of biological organization. This carefully edited treatise is based on the several sessions of the symposium on adaptive behavior held before standing-room-only audiences at the AIBS meetings at the University of Massachusetts in June of 1973. Many of the 40 participants would not normally have contact with each other, and the sections of the symposium were planned by representative of 16 societies and research stations.

This volume, which should provide many useful insights and guides to future research, is comprised of six sections. Section I deals with the general nature of physiological adaptation. Sections II-IV cover organisms in desert, polar-alpine, and aquatic habitats. The fifth section focuses on the adaptive nature of biological time measurements, and the volume concludes with papers on the positive and negative aspects of modelling and on the interaction of multiple factors on plants and animals.

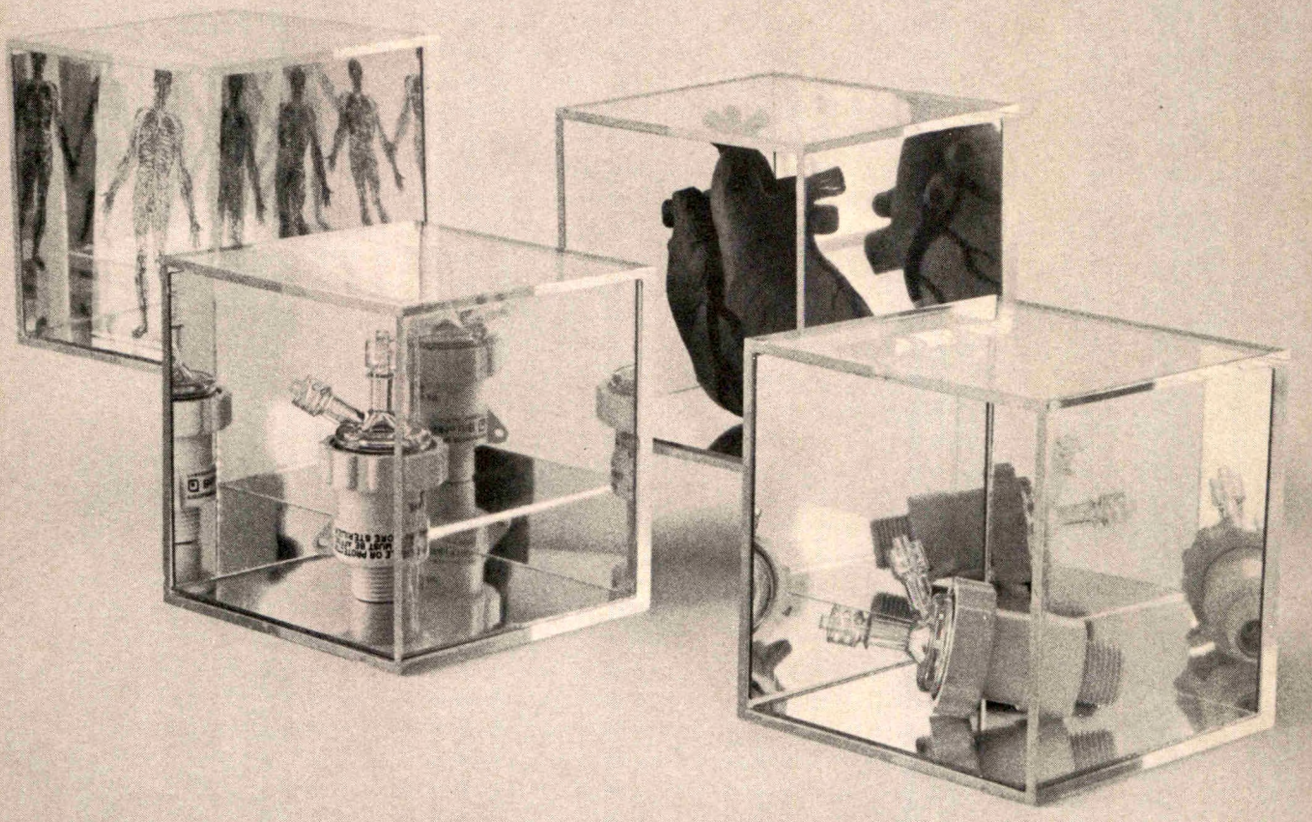
Bell & Howell's Physiological Pressure Transducer... The Cornerstone of Reliability



The building blocks of reliability — dependability, accuracy and performance — are inherent features of Bell & Howell's Model 4-327I Physiological Pressure Transducer.

Modular construction permits interchangeability of components, reducing the costs for replacement parts.

Three levels of isolation prevent the accidental introduction of electrical current.

Additionally, all units are electrically standardized.

The Model 4-327I can also be used in any position and is not damaged by use with defibrillation or electrocautery equipment.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 2 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

In hypertension—
Once you have found him...

TABLETS, 25 mg and 50 mg

HydroDIURIL®

(HYDROCHLOROTHIAZIDE | MSD)

a basic therapeutic approach to hypertension

The importance of early diagnosis in hypertension, so that appropriate treatment can be initiated promptly, has been well established.

Authorities in cardiovascular medicine have come more and more to favor the thiazides as initial drug therapy in early essential hypertension—for several important reasons.

initial medication that is often effective when used alone

The thiazides are well-established baseline therapy. Their effectiveness in lowering blood pressure has been thoroughly documented, and this effectiveness fits the needs of most patients with mild hypertension. Many hypertensives can be maintained for years on thiazide therapy.

suitable when used with other agents

Equally important is the usefulness of the thiazides in combination with other antihypertensive agents, when they are indicated. This retention of the thiazide in the regimen provides a useful baseline upon which the physician may build a therapeutic program. Since thiazides may add to or potentiate the action of other antihypertensive drugs, careful observation for changes in blood pressure must be made.

HydroDIURIL
(HYDROCHLOROTHIAZIDE, MSD)
often an excellent choice

HydroDIURIL is highly effective antihypertensive therapy, initially and over the long term—the results it has helped achieve over many years with many patients make it especially worth your consideration in the early treatment of hypertension.

Contraindications include anuria and hypersensitivity to hydrochlorothiazide or other sulfonamide-derived drugs. Use with caution in patients with severe renal disease, impaired hepatic function, or progressive liver disease.

For a brief summary of prescribing information, please see following page.

MSD
MERCK SHARP & DOHME

Once you have found him...

HydroDIURIL®

(HYDROCHLOROTHIAZIDE | MSD)

in the management of hypertension

Contraindications: Anuria; hypersensitivity to this or other sulfonamide-derived drugs; routine use in an otherwise healthy pregnant woman with or without mild edema.

Warnings: Use with caution in severe renal disease since thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs; potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Use in pregnancy: Thiazides cross placental barrier and appear in cord blood; in pregnancy or in women of childbearing potential, weigh anticipated benefit against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions that have occurred in adults.

Nursing mothers: Thiazides appear in breast milk; if use of drug is deemed essential, patient should stop nursing.

Precautions: Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Warning signs, irrespective of cause, are dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroid or ACTH therapy, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or frank gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid gland with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: *Gastrointestinal System*—Anorexia; gastric irritation; nausea; vomiting; cramping; diarrhea; constipation; jaundice (intrahepatic cholestatic jaundice); pancreatitis; sialadenitis.

Central Nervous System—Dizziness; vertigo; paresthesias; headache; xanthopsia.

Hematologic—Leukopenia; agranulocytosis; thrombocytopenia; aplastic anemia.

Cardiovascular—Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Hypersensitivity—Purpura; photosensitivity; rash; urticaria; necrotizing angiitis (vasculitis) (cutaneous vasculitis); fever; respiratory distress including pneumonitis; anaphylactic reactions.

Other—Hyperglycemia; glycosuria; hyperuricemia; muscle spasm; weakness; restlessness; transient blurred vision.

Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: When used with other antihypertensive drugs, careful observations for changes in blood pressure must be made, especially during initial therapy. Dosage of other antihypertensive agents must be reduced by at least 50 percent as soon as this drug is added to the regimen. As blood pressure falls under the potentiating effect of this agent, further reduction in dosage, or even discontinuation, of other antihypertensive drugs may be necessary.

How Supplied: Tablets containing 25 mg hydrochlorothiazide each in bottles of 100 and 1000 and single-unit packages of 100; Tablets containing 50 mg hydrochlorothiazide each in bottles of 100, 1000, and 5000 and single-unit packages of 100; Tablets containing 100 mg hydrochlorothiazide each in bottles of 100.

addendum

MSD
MERCK SHARP & DOHME

"Required Reading" For Your Hypertensive Patients

Because of the importance of patient motivation, Merck Sharp & Dohme offers "High Blood Pressure," a concise, pocket-sized booklet that defines the patient's own role in the management of hypertension. This booklet is available for you to give to your patients. It is designed to reinforce your explanation of hypertension and it emphasizes the importance of patient understanding in adhering to the regimen you prescribe.

Please ask your Merck Sharp & Dohme Professional Representative or write Professional Service Department, West Point, Pa. 19486 for a supply of this booklet.

Our new Cardiac Output Computer offers a lot more than meets the eye.

Digital display of cardiac output directly in liters per minute. That's the first feature physicians look for in our Model 9510 Cardiac Output Computer.

But in the ICU/CCU environment, where measurements of cardiac output via thermodilution are becoming increasingly important in the proper assessment of the critically ill, computer **versatility and accuracy** are major considerations.

In this respect, our new Model 9510 fills the need precisely. In the critically ill patient, clinical parameters can change rapidly. Accordingly, all instrument controls are front-panel mounted and can be easily adjusted in response to the subtle and changing conditions of the patient.

Both patient temperature **and** injectate temperature are dynamic variables. The ability to rapidly update and fine tune these variables to within 1/10°C., and the selection of various volumes of cold or room temperature injectate, facilitates precise and accurate clinical analysis.

Too, the Model 9510 was designed specifically for use with SWAN-GANZ® Flow-Directed Thermodilution Catheters. Their multilumen design allows assessment of right and left heart filling pressures, in addition to cardiac output.

Other major features include simplicity of operation; ±2.4%, ±3.0% reproducibility with iced and room temperature injectate respectively (mean deviation of sequential measurements in controlled clinical studies); automatic integration of the dilution curve; provision for catheter circuitry checkout prior to insertion; and a portable, self-contained, battery-operated module, with total electrical isolation for patient safety.

For detailed specifications, clinical literature describing the thermodilution cardiac output technique, or a product demonstration, please write Edwards Laboratories, 17221 Red Hill Avenue, P.O. Box 11150, Santa Ana, California 92711, 714/557-8910, Cable: EDSLAB, Telex: 68:5567.

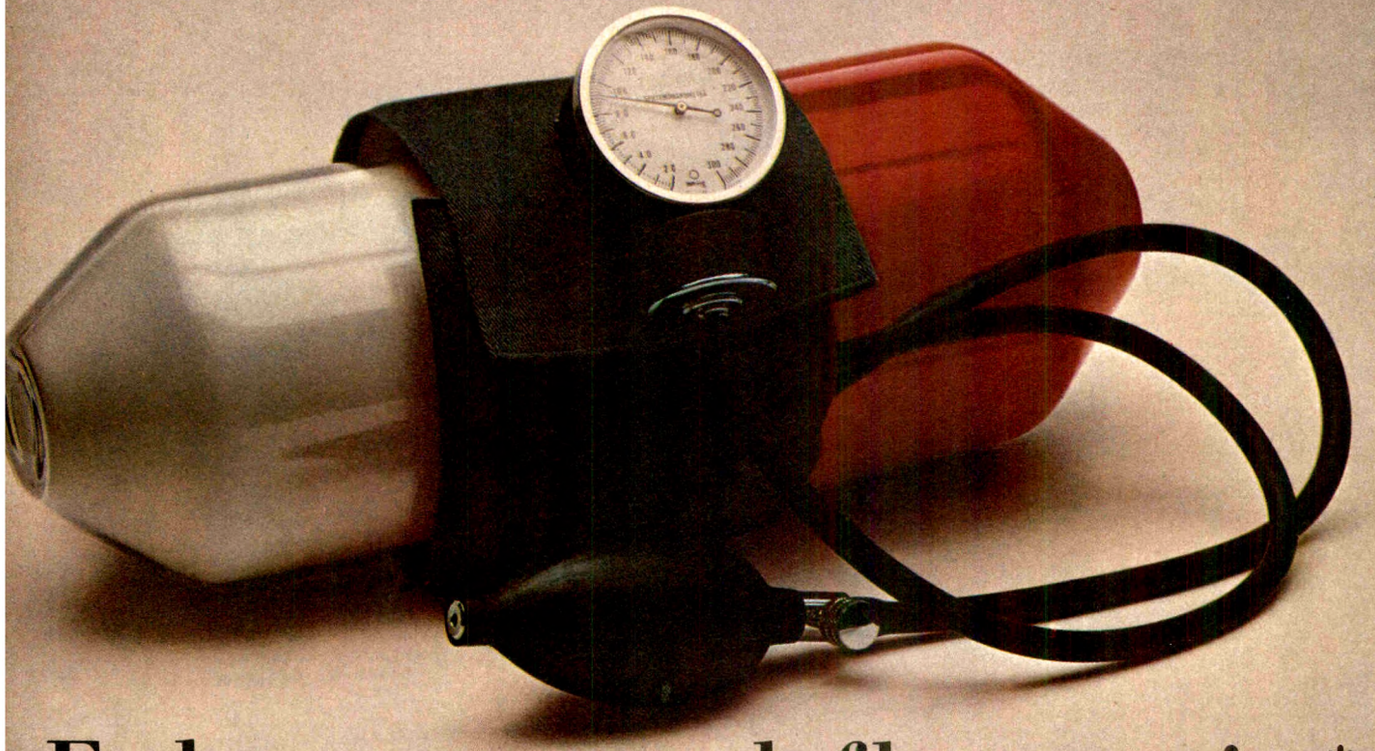
EDWARDS LABORATORIES®

Division of American Hospital Supply Corporation

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

makes sense



For long-term control of hypertension*

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

* **WARNING**
This fixed combination drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

* **Indications:** *Edema:* That associated with congestive heart failure, cirrhosis of the liver, the nephrotic syndrome; steroid-induced and idiopathic edema; edema resistant to other diuretic therapy. *Mild to moderate hypertension:* Usefulness of the triamterene component is limited to its potassium-sparing effect.

Contraindications: Pre-existing elevated serum potassium. Hypersensitivity to either component. Continued use in progressive renal or hepatic dysfunction or developing hyperkalemia.

Warnings: Do not use dietary potassium supplements or potassium salts unless hypokalemia develops or dietary potassium intake is markedly impaired. Enteric-coated potassium salts may cause small bowel stenosis with or without ulceration. Hyperkalemia (>5.4 mEq/L) has been reported in 4% of patients under 60 years, in 12% of patients over 60 years, and in less than 8% of patients overall. Rarely, cases have been associated with cardiac irregularities. Accordingly, **check serum potassium during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetics). If hyperkalemia develops, substitute a thiazide alone. If spironolactone is used concomitantly with 'Dyazide', check serum potassium frequently**—both can cause potassium retention and sometimes hyperkalemia. Two deaths have been reported in patients on such combined therapy (in one, recommended dosage was exceeded; in the other, serum electrolytes were not properly monitored). Observe patients on 'Dyazide' regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving Dyrenium (triamterene, SK&F). Rarely, leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with the thiazides. Watch for signs of impending coma in acutely ill cirrhotics. Thiazides are reported to cross the placental barrier and appear in breast milk. This may result in fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and possibly other adverse reactions that have occurred in the adult. When used during pregnancy or in women who might bear children, weigh potential benefits against possible hazards to fetus.

Precautions: Do periodic serum electrolyte and BUN determinations. Do periodic hematologic studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in postsympathectomy patients. The following may occur: hyperuricemia and gout, reversible nitrogen retention, decreasing alkali reserve with possible metabolic acidosis, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), digitalis intoxication (in hypokalemia). Use cautiously in surgical patients. Concomitant use with antihypertensive agents may result in an additive hypotensive effect. 'Dyazide' interferes with fluorescent measurement of quinidine.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis; rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting (may indicate electrolyte imbalance), diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone.

Supplied: Bottles of 100 capsules; in Single Unit Packages of 100 (intended for institutional use only).

SK&F Co., Carolina, P.R. 00630
Subsidiary of SmithKline Corporation

'DYAZIDE'

Just once or twice daily for maintenance. Hydrochlorothiazide to help keep blood pressure down and triamterene to help keep potassium levels up.

Long before
facing the
"ultimate" test
of stability...

Nitrostat has shown proof of stability

There are a lot of ways to say "stable" when you're dealing with nitroglycerin. Some more meaningful than others.

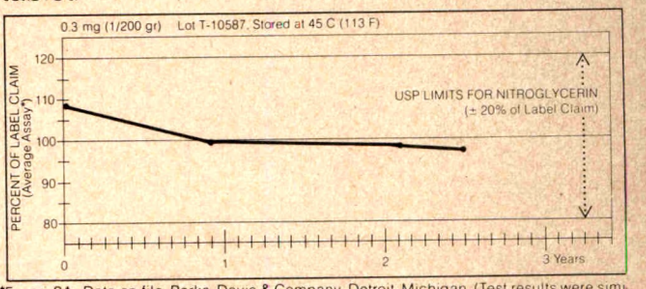
That's why the testing of Nitrostat *includes* tests to simulate, as closely as possible, the actual conditions of use.

For example, we test for **wickability** – a Parke-Davis test (the time in seconds required for water to wet the tablet completely by capillary action under controlled conditions) – to simulate under-the-tongue conditions.

Heat-stable? Yes. Up to 45 C (113 F) (considerably higher than your patient's pocket temperature). See graph.

What's more, the crucial question of maintenance of content uniformity of nitroglycerin is answered by Nitrostat as proved by assay.

Potency? The average assay still shows almost 100% of label claim more than 30 months after manufacture: less chance of your patient taking a superpotent or, more important, a subpotent tablet.



*Fusari SA: Data on file, Parke, Davis & Company, Detroit, Michigan. (Test results were similar for the 0.4-mg and the 0.6-mg strengths.)

Disintegration? We test it using the USP test in 800 ml of water – all tablets usually disintegrate within 30 seconds (USP limit – two minutes).

Dissolution? Using NF Method II, we show greater than 90% dissolution in 30 seconds.

Now, each factor taken by itself may not be decisive. But taken together, they add up to a good reason to specify Nitrostat.

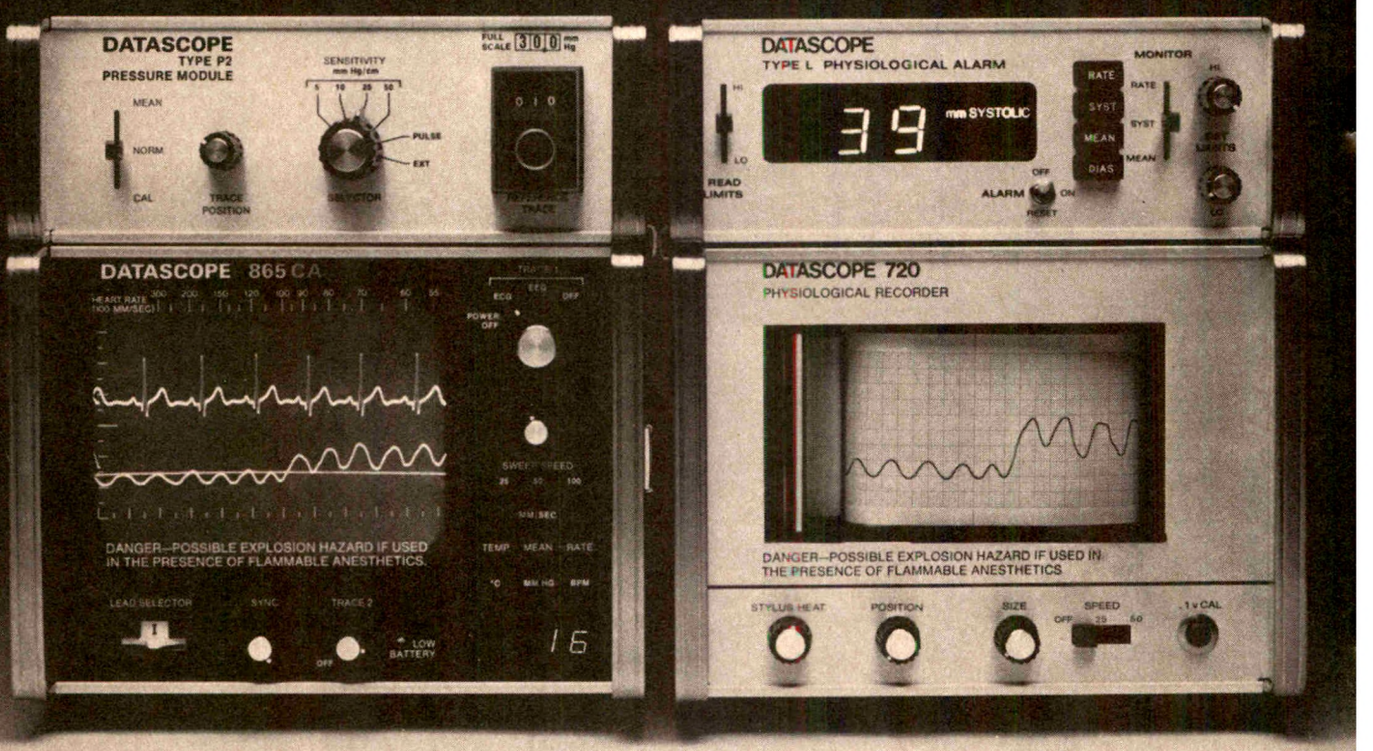
WEDGE PRESSURE MONITORING. UNCOMPLICATED.



The Swan-Ganz® Catheter simplified monitoring. It took you out of the cath lab and into ICU/CCU.

The Datascope Wedge Pressure Group can simplify your job at the bedside even more.

First, we've simplified the job of passing the catheter. Ours is the only monitor made that has an electronic cursor, a unique movable reference trace. It makes reading the pressure changes much easier, much faster, much more accurate.

And once the catheter has been passed, we've simplified the job of monitoring. In fact, we've taken it to the point where the nursing staff can handle it without any assistance.

If you've gotten used to big, bulky monitoring equipment, our wedge pressure group will come as a pleasant surprise. It's extremely light, and compact. It easily fits at bedside.

And it's portable. You can move it where you need it, when you need it.

So you don't have to have a unit for every bed.

Which not only makes life simpler for the people who use it, but also for the people who buy it.

For more information on the Datascope Wedge Pressure Group, write: Datascope Corp., 580 Winters Ave., Paramus, N.J. 07652.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

CONTENTS

CLINICAL STUDIES

131 Left Main Coronary Arterial Obstruction: Long-Term Follow-Up of 141 Nonsurgical Cases

JUAN S. LIM, WILLIAM L. PROUDFIT AND F. MASON SONES, Jr.

In 141 patients with obstructive left main coronary artery disease followed up 5 to 10 years from the date of coronary arteriography, left ventricular hypertrophy, conduction delay in the electrocardiogram and multiple vessel involvement were most common in those dying in the 1st year after diagnosis. Severe angina pectoris, congestive heart failure and decreased left ventricular contractility increased the 5 year mortality rate.

136 Left Main Coronary Artery Disease. Risks of Angiography, Importance of Coexisting Disease of Other Coronary Arteries and Effects of Revascularization

HENRY DeMOTS, LAWRENCE I. BONCHEK, JOSEF RÖSCH, RICHARD P. ANDERSON, ALBERT STARR and SHAHBUDIN H. RAHIMTOOLA

This clinical and angiographic analysis of 58 patients with left main coronary artery disease studied between September 1967 and June 1974 shows that coronary arteriography by the Judkins technique had a low risk. Presence of the disease could not be reliably predicted before arteriography. Coexisting disease in other major coronary arteries constituted an important determinant of the poor prognosis of such patients and precluded surgery in 13 percent. Surgical therapy relieved symptoms more effectively than nonsurgical therapy.

142 Variant Angina Pectoris: Clinical and Anatomic Spectrum and Results of Coronary Bypass Surgery

SAMUEL J. SHUBROOKS, Jr., JOHN M. BETE, ADOLPH M. HUTTER, Jr., PETER C. BLOCK, MORTIMER J. BUCKLEY, WILLARD M. DAGGETT and ELDRED D. MUNDTH

Experience with 20 patients suffering from the variant angina syndrome indicates that all such patients should be studied by coronary angiography. Seventeen patients had significant proximal stenosis of one or more coronary arteries with good distal vessels. Bypass surgery in 15 patients resulted in one noncardiac postoperative death, one myocardial infarction during surgery and long-term relief of pain in all 14 survivors. The three patients without significant coronary artery disease could not be distinguished clinically from those with severe obstructive disease.

148 Oxygen Delivery, Anoxic Metabolism and Hemoglobin Oxygen Affinity (P_{50}) in Patients with Acute Myocardial Infarction and Shock

PROTASIO L. da LUZ, JOSE M. CAVANILLES, SYBIL MICHAELS, MAX HARRY WEIL and HERBERT SHUBIN

A compensatory increase in P_{50} observed in patients with reduced oxygen delivery after acute myocardial infarction supplies an estimated 18 percent increase in oxygen availability. This increase in P_{50} and oxygen availability, independent of changes in cardiac output, is contingent on the presence of other factors, including peripheral shunting and cellular capacity to take up oxygen at a given time.

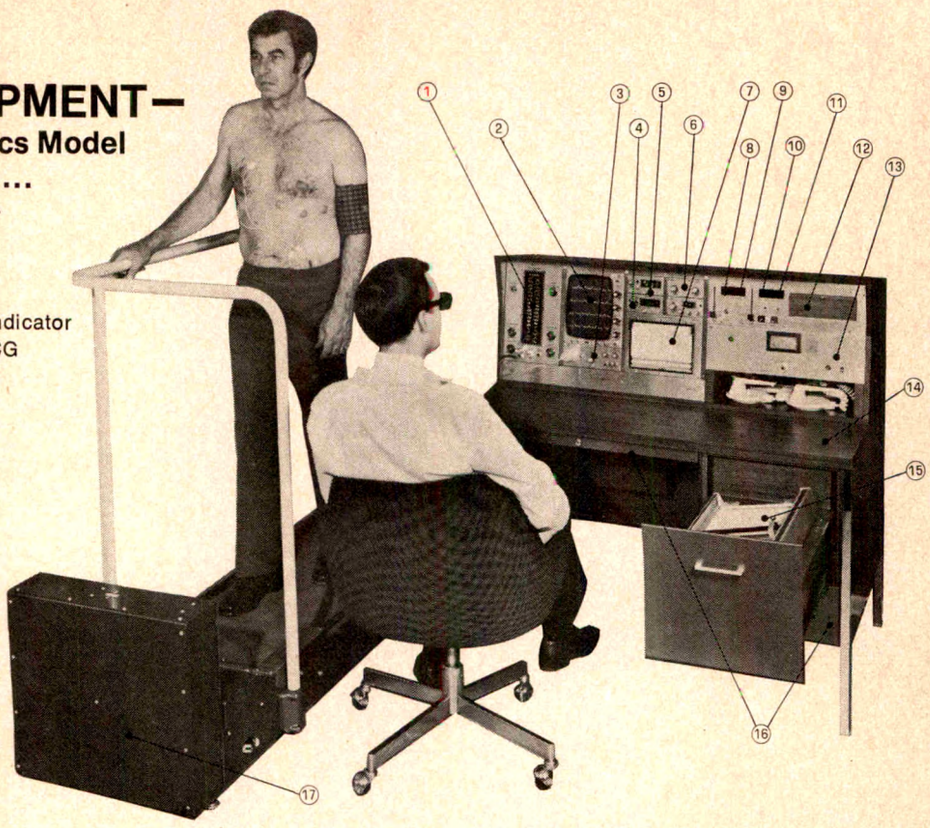
TWO GOOD REASONS WHY AVIONICS IS THE LEADER IN EXERCISE STRESS TESTING!

1. BETTER EQUIPMENT— introducing the new Avionics Model 3600 ExerStress™ Console...

1. Automatic Blood Pressure Monitor
2. Four-Channel Memory Scope
3. Standard 12-lead Capability
4. Accurate Heart Rate Meter
5. ST-Segment Computer With PVC Indicator
6. Automatic Timer For Activating ECG Write-out
7. Three-Channel ECG Writer
8. Digital Display of Treadmill Speed
9. Digital Display of Treadmill Grade
10. Digital Elapsed Time Clock
11. Digital Display of Stage of Test
12. Automatic Programmer For Controlling Treadmill
13. DC Defibrillator
14. Work Area
15. XY Charter of ST-Segment, Heart Rate, and Time
16. Storage Areas
17. Treadmills: Finest Quality Available



2. BETTER SERVICE— full service and maintenance contracts available...

Compare the quality and performance of our system with all others. We'll bring the entire system, including the treadmill, to your hospital, clinic, or office and conduct an actual stress test under your control. You can prove the superior performance and diagnostic quality of our system to your own satisfaction.

Ask any competitor to bring and demonstrate his complete system to you, including treadmill exercising. If he refuses, that should tell you something! If you want the best, we've got it and we're ready to bring it to you.

For action, just use the coupon below.

CONTENTS

155 Measurement of S-T Segment Elevation in Acute Myocardial Infarction in Man. Comparison of a Precordial Mapping Technique and the Frank Vector System

TOSHIO AKIYAMA, MORRISON HODGES, THEODORE L. BIDDLE, BARBARA ZAWROTNY and CATHERINE VANGELLOW

Estimation of the magnitude and direction of the S-T vector derived from the X, Y and Z leads of the Frank vector system serves as a simple alternative to standard precordial S-T segment mapping and allows for continuous monitoring of S-T segment elevations in all patients with acute myocardial infarction, whether the infarction involves the inferior or anterior wall of the left ventricle.

163 Reappearance of Anterior QRS Forces After Coronary Bypass Surgery. An Electrovectorcardiographic Study

HOWARD J. ZEFT, H. DAVID FRIEDBERG, JAMES F. KING, JACK C. MANLEY, JOHN H. HUSTON and W. DUDLEY JOHNSON

Electrocardiographic and vectorcardiographic studies in six patients with typical patterns of transmural anterior wall myocardial infarction with Q waves in the right precordial leads showed regeneration of R waves in these leads and loss of the pattern of definite infarction within 10 days after direct coronary arterial bypass surgery. These studies demonstrate the reversibility of the electrical patterns of myocardial infarction in some patients upon reestablishment of perfusion to ischemic areas.

169 Significant Sex Differences in the Correlation of Electrocardiographic Exercise Testing and Coronary Arteriograms

MICHAEL H. SKETCH, SYED M. MOHIUDDIN, JOSEPH D. LYNCH, ALLEN E. ZENCKA and VINCENT RUNCO

A positive multistage stress test is useful in men but not in women in predicting significant coronary artery disease prior to arteriography. On the other hand, a negative stress test is useful in ruling out such disease in women but not in men. There is no clear explanation for this sex difference and for the high incidence rate (67 percent) of false positive stress tests in women.

174 Comparison of Angiographic and Postmortem Findings in Patients with Coronary Artery Disease

JARED N. SCHWARTZ, YIHONG KONG, DONALD B. HACKEL and ALAN G. BARTEL

Premortem cineangiographic studies of coronary artery stenosis in 25 patients were in agreement with autopsy findings in 79 percent of the segments examined, overestimated it in 6 percent and underestimated it in 15 percent. This confirms the reliability of coronary arteriography in evaluating the severity of coronary artery disease. Common causes of error, particularly of underestimation, included circumferential stenosis, eccentric lesions, obstruction of view by artificial valves and poor opacification because of severe proximal stenosis.

EXPERIMENTAL STUDIES

179 Effect of Practolol on Left Ventricular Dimensions During Coronary Occlusion

JON LEKVEN

Practolol, a relatively cardiospecific beta blocking agent, given to dogs during acute coronary arterial occlusion, reduced myocardial dilatation and increased systolic shortening in ischemic areas. In nonischemic control regions it caused further dilatation and diminished shortening. Practolol thus improved function in ischemic ventricular regions and restored ventricular stroke volume, presumably as a result of improved myocardial oxygen balance.

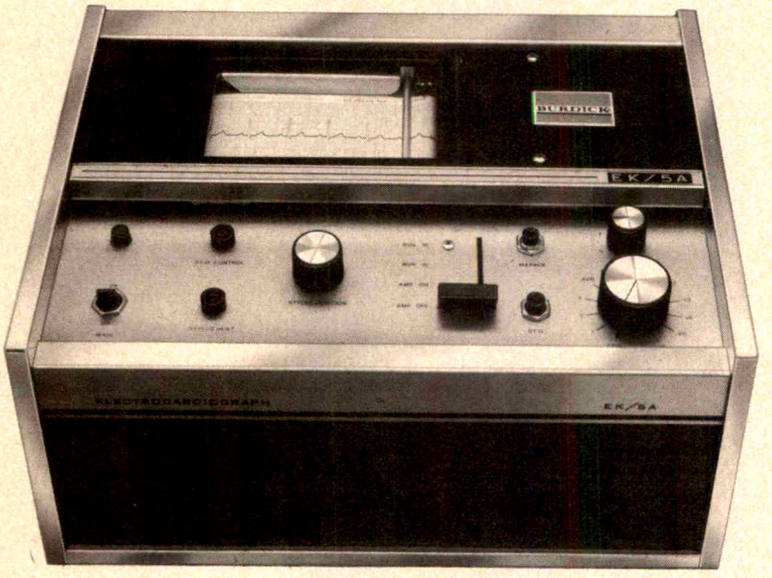
These free supplies will



help you sell this EK-5A.

A special promotion. Now through October 31st, when you sell a new Burdick EK-5A electrocardiograph, Burdick will give your customer enough supplies—Lectro-pads, paper, and mounts—for 100 ECGs.

Tell your prospects that if their ECG charge is 15 or 20 dollars, 100 ECGs are more than enough to cover the purchase of their new Burdick EK-5A electrocardiograph.

And remind them that the EK-5A is an instant-on solid-state electrocardiograph with a coveted reputation for accuracy, definition, and dependability. It exceeds the minimum American Heart Association frequency-response recommendations and is Data-Phone-compatible.

Have your customers take advantage of this pay-for-itself opportunity before the October 31st deadline. For more information, call (608) 868-7631. Or write to The Burdick Corporation, Milton, Wisconsin 53563.

BURDICK®

185 Effect of Graded Reductions in Regional Coronary Perfusion on Regional and Total Cardiac Function

H. L. WYATT, JAMES S. FORRESTER, JOHN V. TYBERG, STEVEN GOLDNER, SAMUEL E. LOGAN, WILLIAM W. PARMLEY and H. J. C. SWAN

This study of graded reduction in regional coronary perfusion and in arterial oxygen concentration in 14 open heart dogs demonstrates that myocardial function depends upon a critical level of coronary perfusion pressure and flow. Regional function dropped sharply when coronary perfusion pressure and flow were reduced to 50 to 65 mm Hg and 25 to 55 ml/min per 100 g, respectively. Changing arterial oxygen concentration affected ventricular performance only at the low range of coronary perfusion pressure (±22 mm Hg).

METHODS

193 Diastolic Compliance of the Left Ventricle in Man

WILLIAM H. GAASCH, MIGUEL A. QUINONES, EFRAIN WAISSER, HANS G. THIEL and JAMES K. ALEXANDER

Pressure-volume data over a range of operating pressures are necessary for assessing left ventricular compliance. The product of end-diastolic stress and left ventricular linear compliance derived from volume compliance and normalized for left ventricular wall thickness provides a useful index of myocardial strain (muscle fiber stretch). This index may be related to systolic performance and allows comparison of length-performance relations in ventricles with normal and abnormal compliance.

REPORTS ON THERAPY

202 Hemodynamic Effect of Dobutamine in Patients with Severe Heart Failure

NASIM AKHTAR, ESTEBAN MIKULIC, JAY N. COHN and M. HAFEEZ CHAUDHRY

Dobutamine, a derivative of dopamine, demonstrated potent inotropic, but limited chronotropic and peripheral vascular, effects in 15 patients with severe congestive heart failure. Cardiac output was significantly increased with no or only slight change in arterial pressure and heart rate. These results justify further therapeutic trial in the short-term management of low output heart failure, particularly in older patients with ischemic heart disease.

206 Effects of Isosorbide Dinitrate on the Response to Atrial Pacing in Coronary Heart Disease

ROBERT J. STEELE, GARY W. BURGGRAF and JOHN O. PARKER

The sublingual administration of 5 mg of isosorbide dinitrate to 20 patients with angiographically proved coronary artery disease provided a significant protective effect against pacing-induced myocardial ischemia at 10 and 65 minutes after its administration. This was demonstrated by prevention of or decrease in severity of angina and S-T segment depression, an increase in lactate extraction, and a significant decrease in left ventricular end-diastolic pressure after isosorbide dinitrate administration.

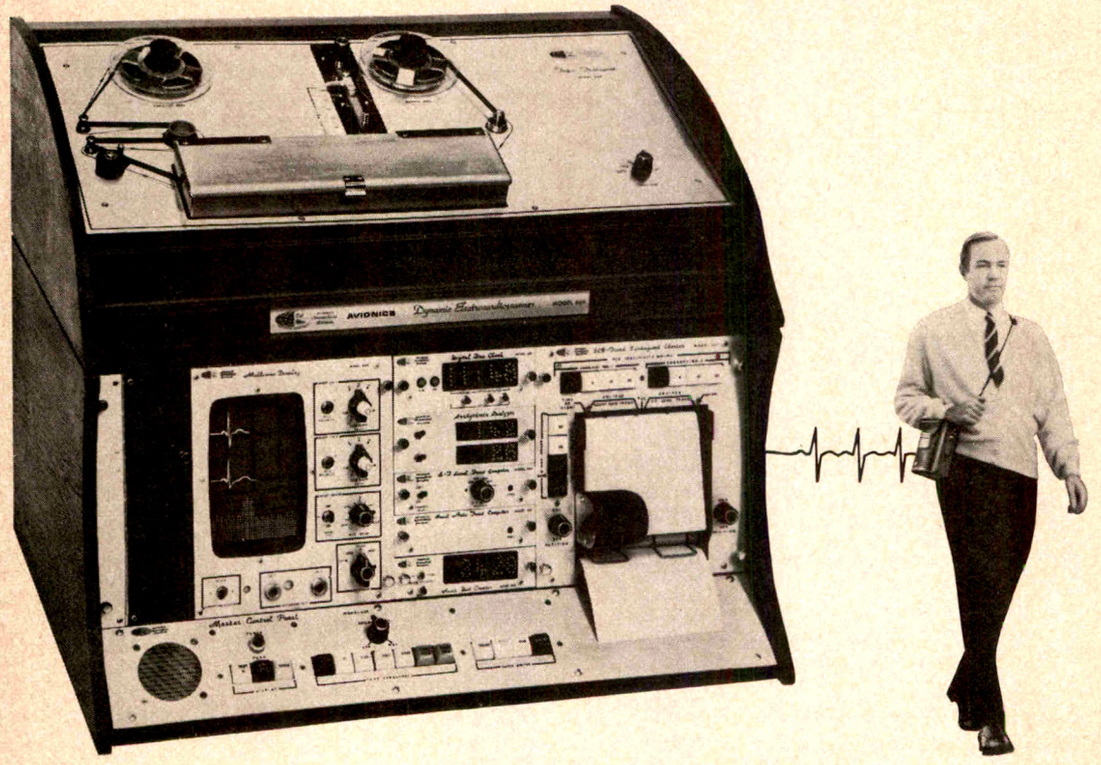
THE NEW 660 A DRAMATIC LEAP FORWARD IN DYNAMIC ELECTROCARDIOGRAPHY!



Model 660 Features:

- **2-channel playback of Holter recordings**
- **2-channel paper writer**
- **120:1 playback ratio (24-hour recording scanned in 12 minutes)**
- **Trend recording of S-T segment and heart rate**
- **Digital display and chart recording of ventricular and supraventricular ectopic beats**
- **Total heart beat counter**
- **Digital display clock**
- **Automatic time print-out on ECG write-out**
- **Adjustable delay loop for tape deck**
- **Solid state, modular design**

Now available to every physician . . . an advanced ECG system for post MI follow-up, pacemaker evaluation, evaluation of drug administration, and detecting the causes of such fleeting symptoms as phantom chest pains and dizziness.

Model 425 Holter Monitor
Provides a 2-channel, 24-hour ECG recording of ambulatory patients.

Model 660 Electrocardioscanner®
Performs a 12-minute scan of the 24-hour, 2-channel tape recording and provides standard ECG documentation of abnormalities and quantification of arrhythmia and ischemic data.

☐ Please send me the literature. I would like to know more about Holter monitoring and the Avionics Dynamic Electrocardiographic Systems.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

CONTENTS

214 Alterations in Myocardial Hydrogen Ion Concentration After Temporary Coronary Occlusion: A Sign of Irreversible Cell Damage

ARNO KRUG

The hydrogen ion (H^+) concentration increased (pH <6.0) in a transmural extension in the left ventricle of cats after ligation of the left anterior descending coronary artery and diminished (pH 7.4) in the border zone between the acid-reacting area and the normal muscle. The persistence of the elevated H^+ concentration in the subendocardial region despite release of the coronary occlusion proves lack of reestablishment of blood flow (no reflow phenomenon) in the involved myocardium after temporary coronary occlusion. This indicates persistent ischemia in involved myocardium despite release of the temporary coronary occlusion. An alkaline reaction of the myocardium is an early indicator of irreversible muscle cell damage.

218 Mitochondrial Function, Oxygen Extraction, Epicardial S-T Segment Changes and Tritiated Digoxin Distribution After Reperfusion of Ischemic Myocardium

JAMES J. KANE, MARVIN L. MURPHY, JOE K. BISSETT, NEIL deSOYZA, JAMES E. DOHERTY and KARL D. STRAUB

Reperfusion for 2 hours failed to improve the indexes of myocardial viability or prevent necrosis after 60 minutes or more of myocardial ischemia in pigs. These results call for caution and critical evaluation of early surgical revascularization as treatment for acute myocardial ischemia or infarction in man.

225 Experimental Coronary Arterial Occlusion and Release. Effects on Enzymes, Electrocardiograms, Myocardial Contractility and Reactive Hyperemia

MARVIN RICHARD BLUMENTHAL, HSUEH-HWA WANG and LETTY MEI PANG LIU

In dogs whose left anterior descending coronary artery was experimentally occluded for 1 to 3 hours and then released, coronary venous and serum enzymes increased within 10 to 20 minutes and significant Q waves appeared within 15 to 30 minutes after release of the occlusion. Thus, clinically, the delayed appearance of serum enzyme elevation and Q waves is attributed largely to a lack of circulation in the infarcted area rather than to prolonged survival time. Viability of myocardium was suggested by S-T elevation after reclamping and by residual contractility and reactive hyperemia.

234 Alterations in Energy Metabolism and Ultrastructure Upon Reperfusion of the Ischemic Myocardium After Coronary Occlusion

GYAN P. SHARMA, KENNETH G. VARLEY, SUNG W. KIM, JAROSLAW BARWINSKY, MORLEY COHEN and NARANJAN S. DHALLA

In 48 dogs changes in myocardial function, metabolism and ultrastructure brought about by 30 minutes, and possibly 60 minutes, of myocardial ischemia were reversible after 60 minutes of reperfusion. Ninety minutes of ischemia caused severe irreversible myocardial damage, as indicated by levels of creatine phosphokinase, glutamic oxaloacetic transaminase and lactic dehydrogenase in the coronary sinus blood and changes in the mitochondria and sarcoplasmic reticulum.

244 Contractile and Biochemical Effects of Coronary Reperfusion After Extended Periods of Coronary Occlusion

PRITPAL S. PURI

With coronary occlusion of 1 to 3 hours' duration, myocardial contractility failed to return in the immediate postperfusion period, but delayed recovery was recorded after 2 weeks of reperfusion. High energy phosphate content of the reperfused myocardium showed a similar pattern of recovery. The extent of recovery varies inversely with the duration of occlusion.

ACCEPTED CONCEPTS IN ANGINA THERAPY*

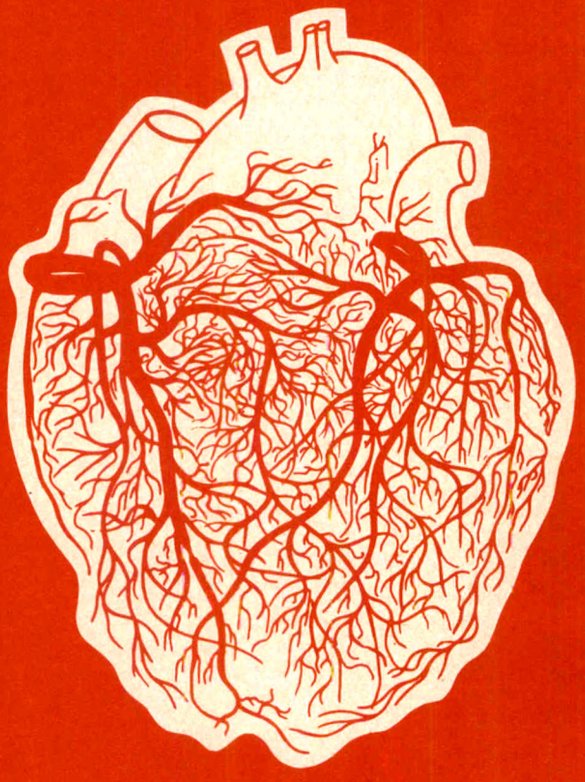
- Nitrates are the first line of defense against angina pectoris
- The therapeutic goal of oral nitrate therapy is an angina-free patient

When higher dosage is necessary in the prophylaxis of angina

prescribe

ISORDIL®
(isosorbide dinitrate)
20 mg.

Scored, oral tablets



Fewer tablets for patients on 80 mg. or more per day (up to a maximum of 120 mg./day)

- **To provide prophylaxis against anginal attacks often caused by unavoidable everyday stress.**
- **To reduce the frequency and severity of angina pectoris attacks. (Not intended to abort the acute episode.)**

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

CONTENTS

252 **Maximal Revascularization (Reperfusion) in Intact Conscious Dogs After 2 to 5 Hours of Coronary Occlusion**

VIRENDRA S. MATHUR, GENE A. GUINN and WALTER H. BURRIS, III

Reperfusion in 56 intact conscious dogs following 2 and 5 hours of left anterior descending coronary occlusion not only did not fail to prevent deterioration and death, but also hastened the development of arrhythmias and myocardial injury. Infarct size can be reduced by reperfusion if performed after 2 hours but not after 5 hours, of occlusion. More studies using other species are indicated before any large scale surgical revascularization is attempted in the early stage of myocardial infarction in man.

CASE REPORTS

262 **Successful Partial Excision of an Intramural Fibroma of the Left Ventricle**

GEORGE J. REUL, Jr., JIMMY F. HOWELL, PEDRO A. RUBIO and PAUL K. PETERSON

Simulating mitral stenosis and insufficiency for years, a massive intramural fibroma of the posterior wall of the left ventricle and most of the interventricular septum was partially excised with good results in a 31 year old man with syncopal episodes and chest pain of 4 years' duration. A left ventricular angiogram demonstrated the calcified lesion preoperatively.

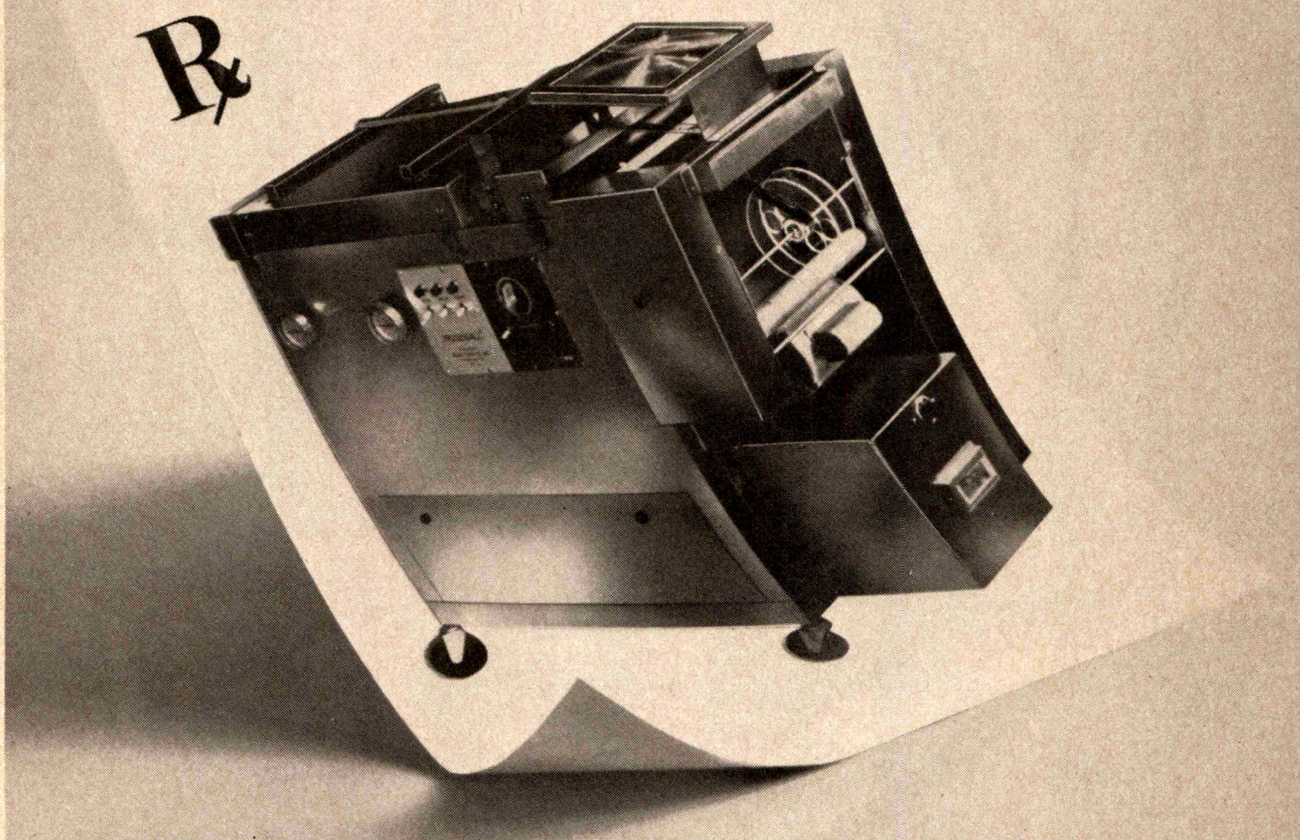
PROCESSALL

A Processor for Diagnostic Cine-Fluorography



The Processall yields fine grain, high acutance, superior resolution and full detail permitting an accurate diagnosis. Artifacts do not occur. Rapid, repeatable, excellent results are secured with ease. Speed is variable permitting pre-selection of desired density and contrast.

The Processall is self-threading and daylight operated. It is designed for ease of operation and maximum reliability with minimal maintenance required. Photosensitive films and papers in roll form may be processed dry-to-dry with a minimum of operator training.

The drying temperature is variable to suit the emulsion being processed.

All models are compact, portable, and fit almost anywhere.

Most major medical centers and hospitals are using the Processall to fulfill their processing requirements.

The Mark 16/35 Processor for faster production (develops one 200 foot case every eight minutes) is also available.

For more information, contact us or your Oscar Fisher Company dealer.

Schering

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action **Hyperstat®** I.V.
Brand of DIAZOXIDE
INJECTION
20 ml ampule
contains 300 mg

"The injection of the [diazoxide] bolus in 10 to 15 seconds results in a prompt blood pressure fall in a high percentage of cases. A maximal blood pressure response usually occurs within 5 to 10 minutes."*

☐ **Rapid reduction to normotensive levels**

Induces rapid reduction of blood pressure generally within 5 minutes... often in 1 or 2 minutes to the lowest level achieved. Blood pressure response facilitated by appropriate diuretic therapy.

☐ **Prolonged activity**

A single injection of HYPERSTAT I.V. generally maintains blood pressure below pretreatment levels for periods up to 12 hours.

☐ **Protective action—helps avert target organ damage**

Cardiac output increases as diastolic pressure is reduced. Coronary and cerebral blood flow maintained. Increased renal blood flow after transient decrease.

☐ **Uncomplicated procedure**

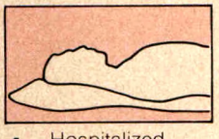
Simple I.V. "push" in a peripheral vein in 30 seconds or less. Close monitoring at frequent intervals is necessary until blood pressure is stabilized (generally 15-30 minutes). Thereafter, hourly measurement should be taken during the balance of effect.

☐ **Stable...convenient...no preparation**

HYPERSTAT I.V. Injection supplied in a 20 ml. ampule containing a stable solution of diazoxide 300 mg. ...ready to use.

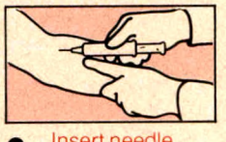
*Marvin Moser, M.D., Assistant Professor of Clinical Medicine, Albert Einstein College of Medicine, and Chief of Cardiology, White Plains Hospital, White Plains, N.Y., in Diazoxide—an effective vasodilator in accelerated hypertension. *Am Heart J* 87(6): 791-795, June 1974.

Administration guidelines



1. Hospitalized patient should be recumbent.

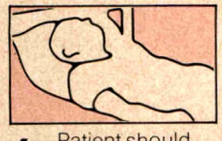
2. Fill dry syringe with appropriate dose of HYPERSTAT I.V. Injection (20 ml. ampule contains 300 mg. diazoxide).



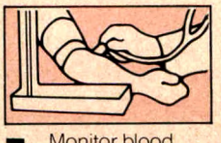
3. Insert needle only into a peripheral vein.

4. Inject entire dose I.V. in 30 seconds or less.

5. Remove needle carefully—avoid extravasation.

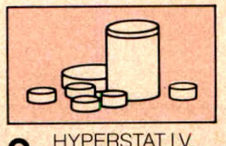


6. Patient should remain recumbent for at least half an hour after injection.



7. Monitor blood pressure closely until stabilized—usually 15-30 minutes.

8. If patient is to be ambulatory, blood pressure should be measured in standing position before surveillance is ended.



9. HYPERSTAT I.V. Injection should be continued until a regimen of oral antihypertensive medication becomes effective—generally within a few days.

Before prescribing HYPERSTAT I.V. Injection, please consult complete product information on next page.

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action **Hyperstat®** I.V.

Brand of DIAZOXIDE

INJECTION
20 ml ampule
contains 300 mg

FOR INTRAVENOUS USE IN HOSPITALIZED PATIENTS ONLY

Description HYPERSTAT I.V. Injection is a rapidly acting antihypertensive agent. Each ampule (20 ml.) contains 300 mg. diazoxide, a nondiuretic benzothiadiazine derivative, in a clear, colorless, aqueous solution; the pH is adjusted to approximately 11.6 with sodium hydroxide. Diazoxide is 7-chloro-3-methyl-2H 1, 2, 4-benzothiadiazine 1, 1-dioxide.

Actions HYPERSTAT I.V. Injection produces a prompt reduction in blood pressure by relaxing smooth muscle in the peripheral arterioles. Cardiac output is increased as blood pressure is reduced by diazoxide; coronary and cerebral blood flow are maintained. Renal blood flow is increased after an initial decrease. Diazoxide has no known direct action on the central nervous system.

Patients refractory to other antihypertensive agents usually remain responsive to diazoxide.

Diazoxide is extensively bound to serum protein (>90%). The plasma half-life is 28 ±8.3 hours; however, the duration of its antihypertensive effect is variable, generally lasting less than 12 hours. Although an antihypertensive response has been obtained with slow intravenous injection, in general, a greater antihypertensive effect is obtained with rapid intravenous administration.

Indications HYPERSTAT I.V. Injection is indicated for the emergency reduction of blood pressure in malignant hypertension in hospitalized patients, when prompt and urgent decrease of diastolic pressure is required. Treatment with orally effective antihypertensive agents should be instituted as soon as the hypertensive emergency is controlled.

HYPERSTAT (diazoxide) I.V. Injection is ineffective against hypertension due to pheochromocytoma.

Contraindications HYPERSTAT I.V. Injection should not be used in the treatment of compensatory hypertension, such as that associated with aortic coarctation or arteriovenous shunt.

The drug should not be used in patients hypersensitive to diazoxide or other thiazides, unless the potential benefits outweigh the possible risks.

Warnings **Usage in Pregnancy:** The safety of HYPERSTAT I.V. Injection in pregnancy has not yet been established.

Information is not available concerning the passage of HYPERSTAT in breast milk. However, it is known that diazoxide crosses the placental barrier and appears in cord blood. Like other thiazides, the drug may produce fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, and possibly other adverse reactions that have occurred in adults.

Usage in Children: The safety of HYPERSTAT I.V. Injection in children has not yet been established.

Hypotension may occasionally result from the administration of HYPERSTAT I.V. If hypotension severe enough to require therapy occurs, it will usually respond to the administration of sympathomimetic agents, such as norepinephrine.

Hyperglycemia occurs in the majority of patients, but usually requires treatment only in patients with diabetes mellitus; it will respond to the usual management, including insulin. Therefore, blood glucose levels should be monitored especially in patients with diabetes or in those requiring multiple injections of diazoxide. Hyperglycemia and hyperosmolar coma associated with transient cataracts developed in one infant receiving repeated daily doses of oral diazoxide. The disturbed carbohydrate metabolism was successfully treated with insulin. Cataracts have been observed in a few animals receiving repeated daily doses of intravenous or oral diazoxide.

Since diazoxide causes sodium retention, repeated injections may precipitate edema and congestive heart failure. This retention responds characteristically to diuretic agents if adequate renal function exists. It should be noted that concurrently administered thiazides may potentiate the antihypertensive, hyperglycemic, and hyperuricemic actions of diazoxide (See Drug Interactions).

Since increased volume of extracellular fluid may be a cause of treatment failure in nonresponsive patients, it may be advisable to reduce this increased volume by means of a diuretic agent.

Although no evidence of excessive anticoagulant effects has been reported, patients, especially those who are hypoalbuminemic and receive HYPERSTAT I.V. Injection and coumarin or its derivatives, may require reduction in dosage of the anticoagulant (See Drug Interactions).

Precautions HYPERSTAT (diazoxide) I.V. Injection is a potent antihypertensive agent requiring close monitoring of the patient's blood pressure at frequent intervals. Its administration may occasionally cause hypotension requiring treatment with sympathomimetic drugs. Therefore, adequate facilities to treat such untoward reactions should be available when HYPERSTAT I.V. Injection is used.

HYPERSTAT I.V. Injection should be administered only into a peripheral vein. Because the alkalinity of the solution is irritating to tissue, extravascular injection or leakage should be avoided; subcutaneous administration has produced inflammation and pain without subsequent necrosis. If leakage into subcutaneous tissue occurs, the area should be treated conservatively.

Maximal antihypertensive effects occur after rapid administration (within 30 seconds) into the vein; a slower injection may fail to reduce blood pressure or produce a very brief response.

As with any potent antihypertensive agent, HYPERSTAT I.V. Injection should be used with care in patients who have impaired cerebral or cardiac circulation, that is, patients in whom abrupt and brief reductions in blood pressure might be detrimental.

Special attention is required for patients with diabetes mellitus and those in whom retention of salt and water may present serious problems (See Warnings). Nondiabetic patients may have a transient, reversible, and clinically insignificant increase in blood glucose following HYPERSTAT I.V. Injection.

Since peritoneal dialysis or hemodialysis can reduce levels of diazoxide in the blood, patients undergoing dialysis may require more than one injection.

Adverse Reactions

Frequent and serious adverse reactions: Sodium and water retention after repeated injections, especially important in patients with impaired cardiac reserve; hyperglycemia frequently requiring treatment in diabetic patients, especially after repeated injections.

Infrequent but serious adverse reactions: Hypotension to shock levels; myocardial and/or cerebral ischemia, usually transient but possibly leading to thrombosis and manifested by angina, atrial and ventricular arrhythmias, and marked electrocardiographic changes; unconsciousness, convulsions, paralysis, or confusion; persistent retention of nitrogenous wastes after repeated injections; sensitivity reactions, such as rash, leukopenia, and fever. Rarely, acute pancreatitis has been reported.

Other adverse reactions: Nausea, vomiting, and/or abdominal discomfort; vasodilative phenomena, such as flushing, generalized or localized sensations of warmth, headache (sometimes throbbing), and sweating; orthostatic hypotension, lightheadedness, and weakness of short duration; supraventricular tachycardia and palpitation; transient hyperglycemia in nondiabetic patients; transient retention of nitrogenous wastes; nonanginal "tightness in the chest"; warmth or pain along the injected vein; cellulitis without sloughing and/or phlebitis at the site of extravasation; anorexia and alteration of taste; ileus; bradycardia; back pain; chest discomfort; dyspnea, choking sensation; apprehension or anxiety, malaise, and blurred vision occurred on single occasions; parotid swelling, salivation, lacrimation; ringing in the ears; diarrhea and constipation; increased nocturia; euphoria.

Drug Interactions Since diazoxide is highly bound to serum protein, it may displace other substances or drugs which are also bound to protein, such as bilirubin or coumarin and its derivatives. These potential interactions must be considered when administering HYPERSTAT I.V. Injection. The concomitant administration of diazoxide with thiazides or other commonly used potent diuretics may potentiate the hyperglycemic, hyperuricemic, and antihypertensive effects of diazoxide.

Overdosage Overdosage of HYPERSTAT I.V. Injection may cause an undesirable hypotension. Usually, this can be controlled with sympathomimetic agents, such as norepinephrine; failure of the blood pressure to rise in response to such an agent suggests that the hypotension may have been caused by something other than diazoxide. Excessive hyperglycemia resulting from overdosage will respond to conventional therapy of hyperglycemia.

Diazoxide may be removed from the blood by peritoneal dialysis or hemodialysis.

Animal Pharmacology and Toxicology In studies involving a number of species, including the rat, cat, dog, and monkey, diazoxide has been shown to exert significant antihypertensive actions through its direct effect on peripheral arterioles, which neither impairs cardiac function nor seriously diminishes perfusion of kidneys. In addition, in each species tested, including the rat, dog, and monkey, diazoxide elicits hyperglycemia, increased serum-free fatty acids and decreased plasma insulin levels by a mechanism thought to involve both suppression of insulin release and enhanced catecholamine action.

Although the data are not conclusive, reproduction and teratology studies in several species of animals indicate that diazoxide, when administered during the critical period of embryo formation, may interfere with normal fetal development, possibly through altered glucose metabolism. Parturition was occasionally prolonged in animals treated at term.

Dosage and Administration HYPERSTAT I.V. Injection is administered undiluted and rapidly by intravenous injection. It should only be given into a peripheral vein. Do not administer it intramuscularly, subcutaneously, or into body cavities. Avoid extravasation of the drug into subcutaneous tissues.

The response to HYPERSTAT I.V. Injection varies from patient to patient. Generally, blood pressure decreases within five minutes, often within one to two minutes, to the lowest level achieved. The blood pressure increases relatively rapidly in the next ten to 30 minutes, and then more slowly over the following two to 12 hours, nearly reaching but rarely exceeding the pretreatment level. The response to successive injections is frequently better than that to the initial injection.

Treatment of hypertensive emergencies with HYPERSTAT I.V. Injection should be limited to a few days and a regimen of oral antihypertensive medications should be instituted as soon as possible.

With the patient recumbent, the contents of one 20 ml. ampule containing 300 mg. of HYPERSTAT I.V. Injection are administered intravenously in 30 seconds or less. Slow intravenous injection may fail to reduce the blood pressure or may produce an exceedingly short response.

Specific dosage is required in children or in unusually large or small patients. This dosage may be calculated on the basis of 5 mg./kg. body weight (0.3 ml./kg.) (See Warnings).

A second administration of HYPERSTAT (diazoxide) I.V. Injection may be required for a satisfactory reduction in blood pressure, if the first injection fails to give an adequate response within 30 minutes.

Repeated administration of HYPERSTAT I.V. Injection at intervals of four to 24 hours usually will maintain the blood pressure below pretreatment levels until a regimen of oral antihypertensive medication becomes effective. The interval between injections may be adjusted by the duration of the response to each injection. It is usually unnecessary to continue treatment with HYPERSTAT I.V. Injection for more than four to five days.

Following the use of HYPERSTAT I.V. Injection, the blood pressure should be monitored closely until it has stabilized. Thereafter, measurements taken hourly during the balance of the effect will indicate any unusual response. A further decrease in blood pressure at 30 minutes or more after injection should be investigated for causes other than the action of HYPERSTAT I.V. Injection. It is preferable that the patient remain recumbent for half an hour after injection. In ambulatory patients, the blood pressure should be measured with the patient standing before surveillance is ended.

Since repeated administration of HYPERSTAT I.V. Injection can lead to sodium and water retention, administration of a diuretic may be necessary both for maximal blood pressure reduction and to avoid congestive failure.

How Supplied HYPERSTAT I.V. Injection is supplied in a 20 ml. ampule containing diazoxide 300 mg. in a clear, colorless aqueous solution; box of one ampule.

Protect from light and freezing.

Store away from heat.

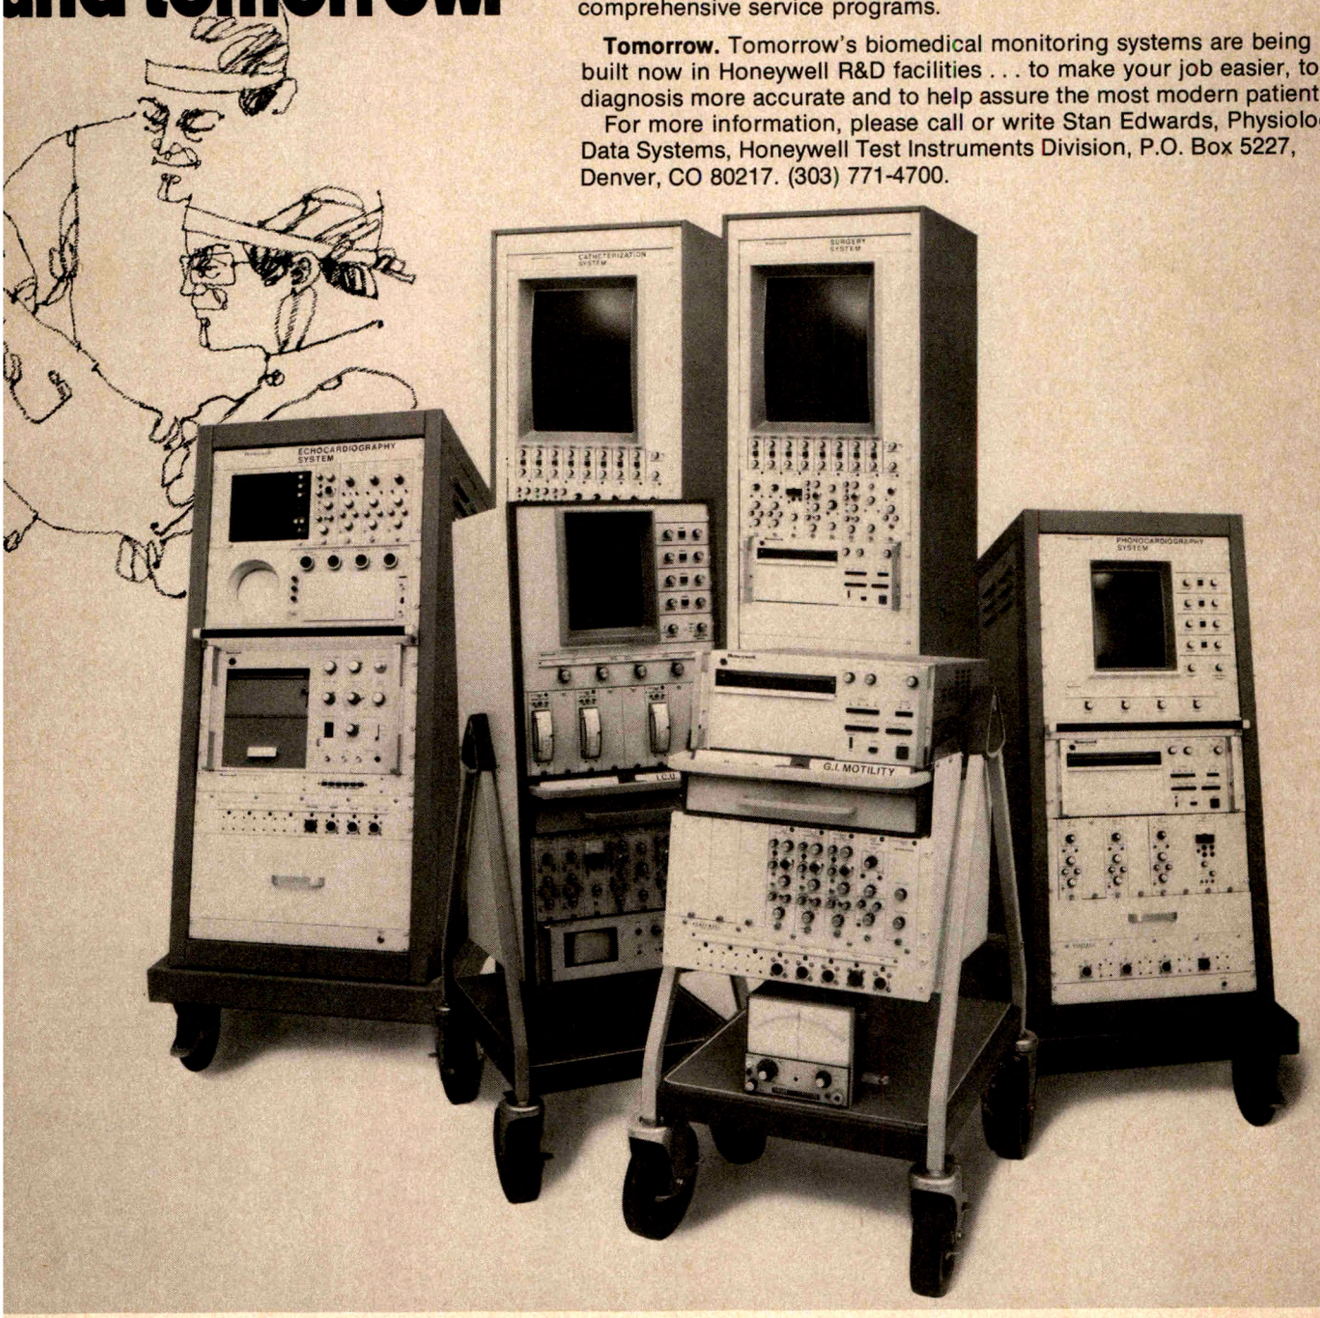
Our patient care commitment... yesterday, today and tomorrow.

Yesterday. The Honeywell patient care commitment began more than 15 years ago. We recognized that physiological data systems must consist of more than just good hardware, that our commitment to you and better patient care must be total.

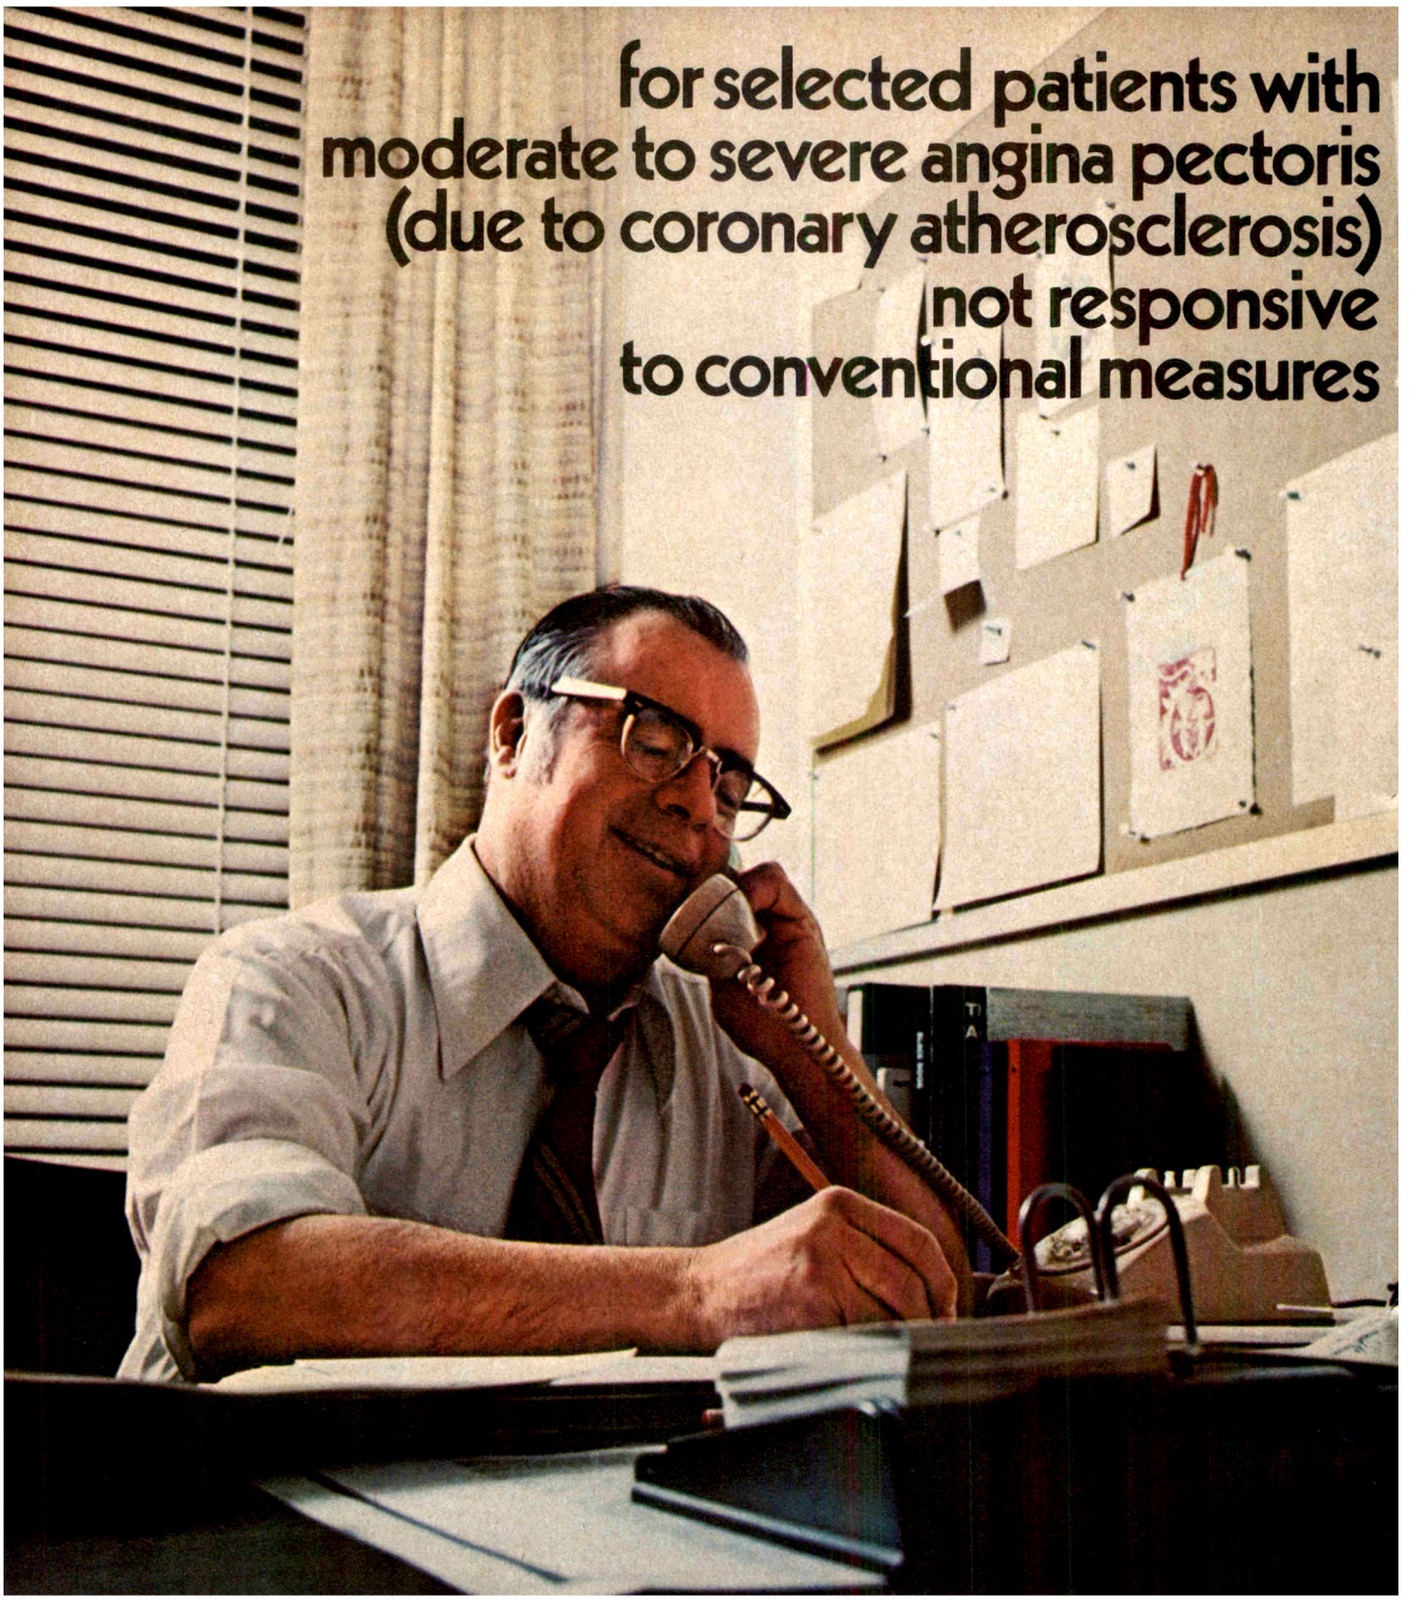
Today. Honeywell products for health care can be found in cardiovascular diagnostic, surgical monitoring facilities, hospital data centers and clinical laboratories all over the world.
Our commitment includes six different physiological data systems: phonocardiography, echocardiography, catherization, surgery, surgical intensive care and a G.I. motility system. Each medical-engineered and supported by Honeywell application specialists. Our commitment includes professional training for your people and a choice of several comprehensive service programs.

Tomorrow. Tomorrow's biomedical monitoring systems are being built now in Honeywell R&D facilities . . . to make your job easier, to make diagnosis more accurate and to help assure the most modern patient care.

For more information, please call or write Stan Edwards, Physiological Data Systems, Honeywell Test Instruments Division, P.O. Box 5227, Denver, CO 80217. (303) 771-4700.



Honeywell



for selected patients with
moderate to severe angina pectoris
(due to coronary atherosclerosis)
not responsive
to conventional measures

Inderal® often enables more activity with less pain

can permit a more normal life

INDERAL (propranolol hydrochloride) often improves exercise tolerance, and thus enables the responsive patient to do more with less pain. When the diagnosis of angina pectoris has been carefully established, and after failure of an adequate trial of such conventional measures as weight control, cessation of smoking, rest, avoidance of precipitating factors, and sublingual nitroglycerin, INDERAL may be added to the regimen of selected patients with moderate to severe angina pectoris. Patients selected to receive INDERAL must not have existing heart failure or bronchial asthma; and all contraindications, warnings, and precautions should be carefully observed (see "Guidelines for using INDERAL" on following page).

INDERAL should not be continued unless there is reduced pain or increased work capacity.

decreases myocardial oxygen demand

When physical effort or other precipitating factors cause excessive catecholamine stimulation of the heart, the demand for oxygen may exceed capacity for delivery of oxygen in a coronary circulation compromised by atherosclerosis. The result—anginal pain.

Thus, in responsive patients, the net effect of INDERAL is to reduce cardiac work (rate × force of contraction) so that oxygen demand can be met more adequately by a reduction of sympathetically induced increases in heart rate, systolic blood pressure and velocity of contraction.

On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to the decreased oxygen requirement.

to reduce pain

Reduction in anginal pain, as indicated either by fewer anginal attacks, more pain-free days, or lowered consumption of nitroglycerin tablets, has been clearly demonstrated in 29 clinical studies.[1-29] One other study reported that propranolol was not effective.[30] The results showed that approximately three-quarters of the patients had less pain and used less nitroglycerin when taking INDERAL than on placebo.

and increase work capacity

In 14 of 17 controlled clinical trials, INDERAL was shown to increase work capacity.[2,8,10,12,13,15,16,18,22,23,25,27,28,31]

In one of these investigations, an eight week double-blind crossover study,[8] the effects of propranolol hydrochloride were evaluated in 19 (18 male, 1 female) patients with rigorously documented angina pectoris of at least six months' duration with a minimum of five episodes per week, and a positive Master 2-step test. "The number of episodes of pain was reduced, nitroglycerin consumption was decreased, and exercise tolerance was increased."

Inderal®

Brand of

propranolol hydrochloride

Ayerst®

Tablets 10 mg., 40 mg. and 80 mg.

(See last two pages of advertisement for prescribing information.)

Guidelines for using Inderal®
(propranolol hydrochloride)

selection of patients

INDERAL is indicated for selected patients with moderate to severe angina pectoris who have failed to respond to an adequate trial of conventional measures, including weight control, cessation of smoking, rest, avoidance of precipitating factors, and sublingual nitroglycerin. INDERAL should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL has a widespread pharmacologic action and therefore a potential for adverse effect. The diagnosis of angina should therefore be more carefully established before instituting INDERAL than may be warranted before beginning conventional therapy. Due consideration must be given to the contraindications and warnings associated with beta-adrenergic blockade.

adequate and individualized dosage

Dosage must be individualized. Starting with 10-20 mg. three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. The value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See WARNINGS.)

role of congestive heart failure

Inhibition with beta-blockade carries the potential hazard of depressing myocardial contractility and precipitating cardiac failure in patients either with or without a history of cardiac failure. INDERAL is contraindicated in patients with congestive heart failure and heart block unless the failure is secondary to a tachyarrhythmia treatable with INDERAL. (See WARNINGS.)

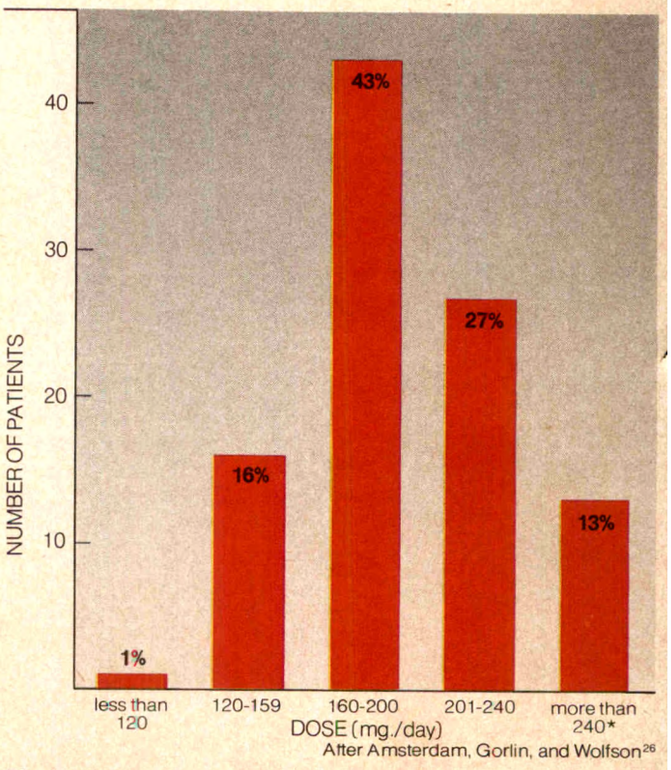
At the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely. If cardiac failure continues, propranolol should be withdrawn, keeping in mind the need to avoid *abrupt* withdrawal unless required by overriding clinical considerations.

avoid abrupt withdrawal of Inderal

There have been reports of exacerbation of angina and of myocardial infarction occurring in angina pectoris patients following *abrupt* discontinuation of INDERAL therapy. The patient should be cautioned against interruption or cessation of therapy without his physician's advice. When discontinuance of chronically administered INDERAL is planned, the dosage should be gradually reduced over a period of weeks and the patient should continue to be carefully monitored.

most patients need about 160mg. a day

DURATION OF THERAPY 29.4 ± 16.5 MONTHS (MEAN ± S.D.).
NUMBER OF PATIENTS: 89



After Amsterdam, Gorlin, and Wolfson[26]

Effective dosage range in 89 patients with angina pectoris who benefited from INDERAL. The largest group reacted well to between 160 and 200 mg. of INDERAL per day.

**The value and safety of daily doses of more than 320 mg. have not been established. See DOSAGE AND ADMINISTRATION and OVERDOSAGE OR EXAGGERATED RESPONSE.*

for selected patients* with moderate to severe angina pectoris where conventional measures have failed

BRIEF SUMMARY

(For full prescribing information, see package circular.)

Inderal®

Brand of propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support or vital functional balances.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias. Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyrotoxicosis, exercise).

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: *Angina Pectoris due to Coronary Atherosclerosis*

The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL is indicated in selected patients

(Prescribing information continued on following page.)

*See SELECTION OF PATIENTS on opposite page.

with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipitating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH CORONARY ARTERY DISEASE AND/OR ANGINA PECTORIS, when discontinuance of chronically administered INDERAL is planned, the dosage should be gradually reduced over a period of several weeks and the patient should continue to be carefully monitored. There have been reports of exacerbation of angina and myocardial infarction occurring following *abrupt* discontinuation of INDERAL therapy.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura.

Central Nervous System: lightheadedness, mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, non-thrombocytopenic purpura, thrombocytopenic purpura.

Miscellaneous: reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION: The oral route of administration is preferred.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg. three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. The value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See WARNINGS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL

(propranolol hydrochloride)

TABLETS

No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each tablet contains 80 mg. of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

Inderal®

One of the most powerful weapons in man's fight against cholesterol.

A low saturated fat/low cholesterol diet can be effective, easy to maintain and delicious with the help of Fleischmann's® Margarine and Egg Beaters,™ Fleischmann's cholesterol-free egg substitute.

Of all leading margarines, only Fleischmann's is made from 100% corn oil. And clinical tests show corn oil is unsurpassed in lowering serum cholesterol levels. Fleischmann's Margarine brings that corn oil goodness and delicious taste to your patients' diets. And Egg Beaters, Fleischmann's cholesterol-free egg substitute, lets patients enjoy the taste and nutrition of eggs, but no cholesterol. Yes, Fleischmann's helps a butter-and-egg man enjoy a delicious, sensible diet that's low in cholesterol and saturated fat. We even have free recipe booklets to give patients lots of ideas on sensible eating. To receive your sample copy of "Dietary Control of Cholesterol" and "Cooking with Egg Beaters," write to Fleischmann's, P.O. Box 1538, Elm City, North Carolina 27898. Allow 4-6 weeks for delivery. Offer good only in U.S.A. while supply lasts. Address must include zip code. Void where prohibited.

Fleischmann's makes sensible eating delicious.

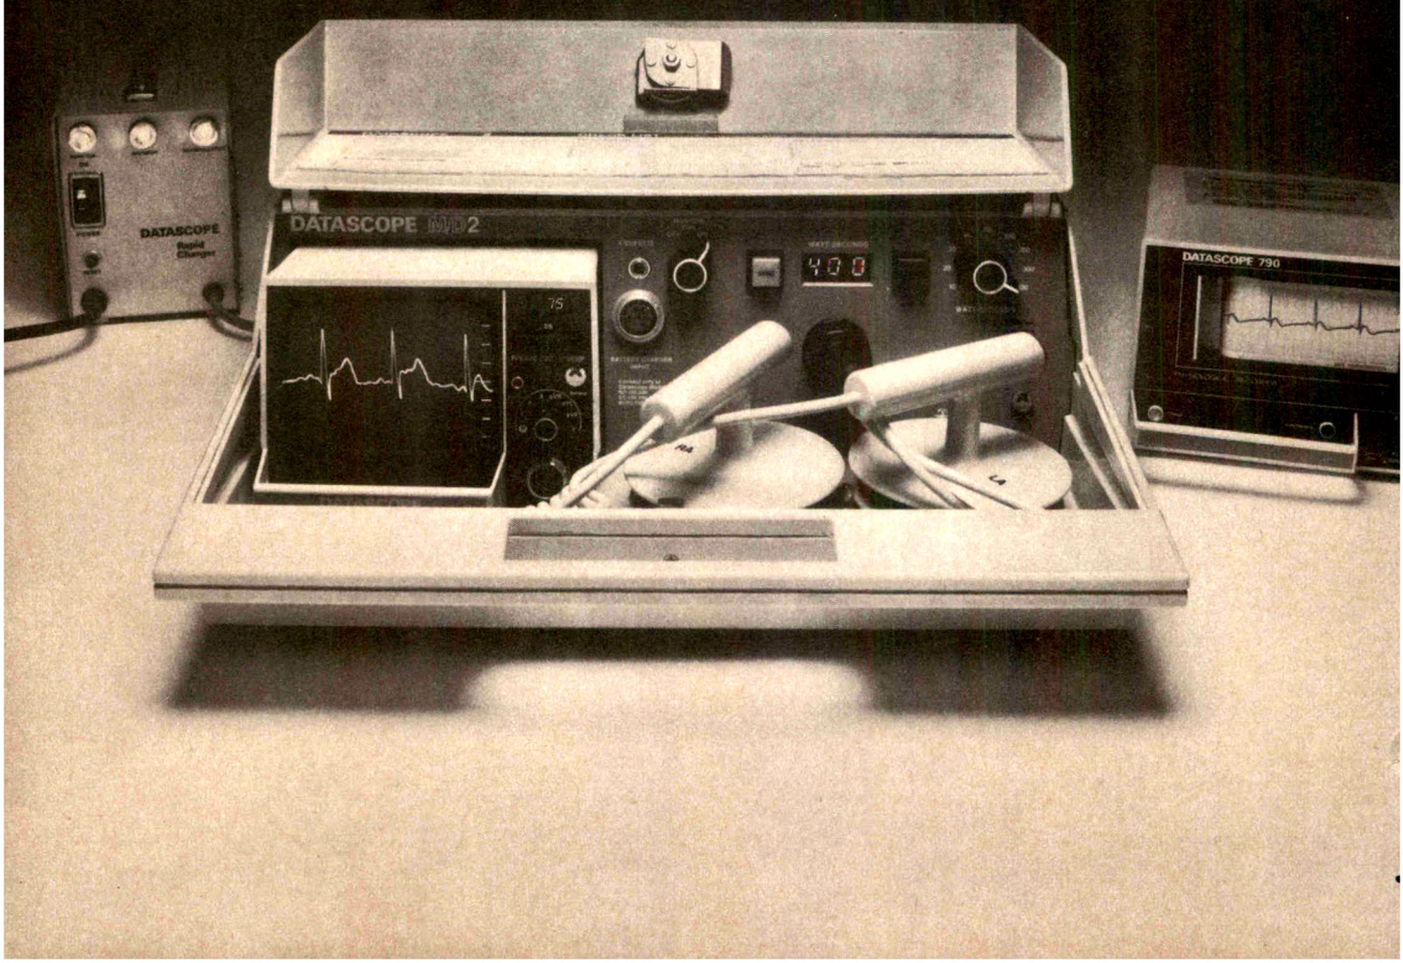
THE DATASCOPE M/D2 SYSTEM. THE FIRST RESCUE SYSTEM AS FLEXIBLE AS THE PEOPLE WHO USE IT.



If there's one thing you can be sure of in cardiac rescue, it's that you can't be sure of anything.

Every situation, either in the hospital or in the field, presents new problems, and requires new solutions.

At Datascope, we've been in emergency medicine since its inception.

Our equipment has faced just about everything. And from that experience we've put together a system that's prepared to face anything: the M/D2 System.

The M/D2 System is built on one very simple principle. *Every instrument in the system must be independent and not compromised by any other instrument.*

In keeping with this philosophy, our monitor, our defibrillator and our strip-chart recorder each have a separate battery source. One unit never puts a drain on another.

But to see its flexibility, let's take our system apart, instrument by instrument.

OUR MONITOR.

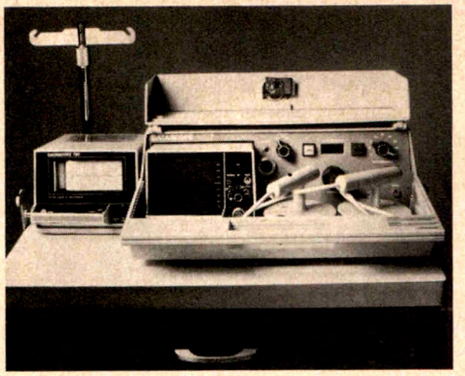
The monitor in the M/D2 System nests inside the defibrillator. You can carry the monitor and defibrillator, use it, and store it as one unit.

But the monitor pulls out* of the M/D2 case and works as a separate unit as well. So it can be placed right on a patient's stretcher in the field. Or put in the most advantageous viewing position at the bedside.

U.S. PATENT 3,865,101

In addition to being so flexible, our monitor outperforms any monitor in emergency medicine.

It has a 5-inch scope with a 8 x 11 cm. viewing area.



It has a memory which provides a bright, non-fade display that's remarkably clear even in strong sunlight.

It has a freeze button which lets you stop the ECG for closer study.

It's the only emergency monitor with a digital heart rate readout. And because the readout is an LED display, you can even read it in the dark.

OUR DEFIBRILLATOR.

Like our monitor, our defibrillator has its own battery-pack.

It's the only defibrillator made that gives you a *digital* energy meter. Which displays both stored energy and the results of delivered energy tests.

The defibrillator is exceptionally safe. A warning tone sounds when the selected energy level is reached.

Energy cannot be delivered unless the push-button switch on each paddle is actuated simultaneously.

The energy within the defibrillator is automatically discharged when the unit is turned off.

For paramedic use, the M/D2 is available completely shielded against RF interference across the entire communications band.

OUR RECORDER.

Our recorder is flexible as well. It's carried separately and powered separately. (For good reason. A recorder powered by a common battery puts an enormous drain on the other instruments in the system.)

Our recorder weights only 11 pounds. And when you're using our monitor outside the M/D2 case, our recorder fits right into the space the monitor vacated. Which allows even easier transport.

OUR RAPID CHARGER.

Although the M/D2 comes with a standard battery recharger, we offer the first rapid recharging unit as part of our system. Our Rapid Charger allows you to defibrillate with just 60 seconds of recharge. And in just 10 minutes it will recharge the defibrillator to at least 60% of total capacity.

THE SYSTEM. IT'S MORE THAN ANY OF ITS PARTS.

Three independent units. Three independent battery-packs. And a Rapid Charger. They work together, or apart. They give you more ability to react than any single unit ever could.

For more information on the M/D2 System, write: Datascope Corp., 580 Winters Avenue, Paramus, N.J. 07652.

THE DATASCOPE M/D2

The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Give enough, long enough—The recommended dosage: 50 mg t.i.d. at least one hour before meals for several weeks or longer.

Persantine® Tablets of 25 mg
dipyridamole

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

Boehringer Ingelheim

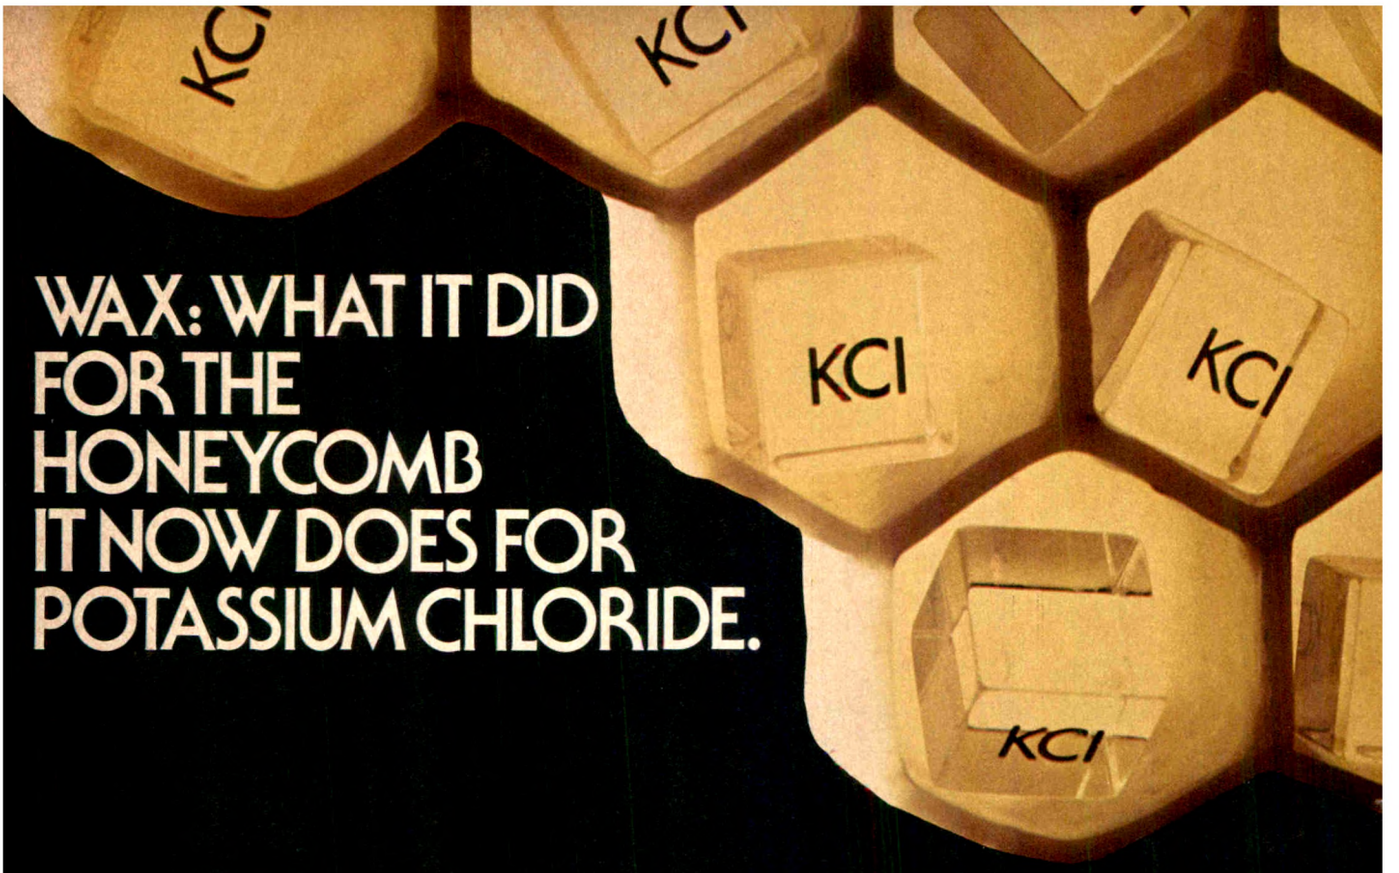
One of a series of paintings of the heart in the style of well-known artists.

The Heart . . . in the style of Vincent van Gogh (1853-1890)

He created paintings and drawings of uncommon luminosity and dynamism. His works, marked by profound emotions and a stirring power of expression, had a decisive influence on all of modern painting.



WAX: WHAT IT DID FOR THE HONEYCOMB IT NOW DOES FOR POTASSIUM CHLORIDE.

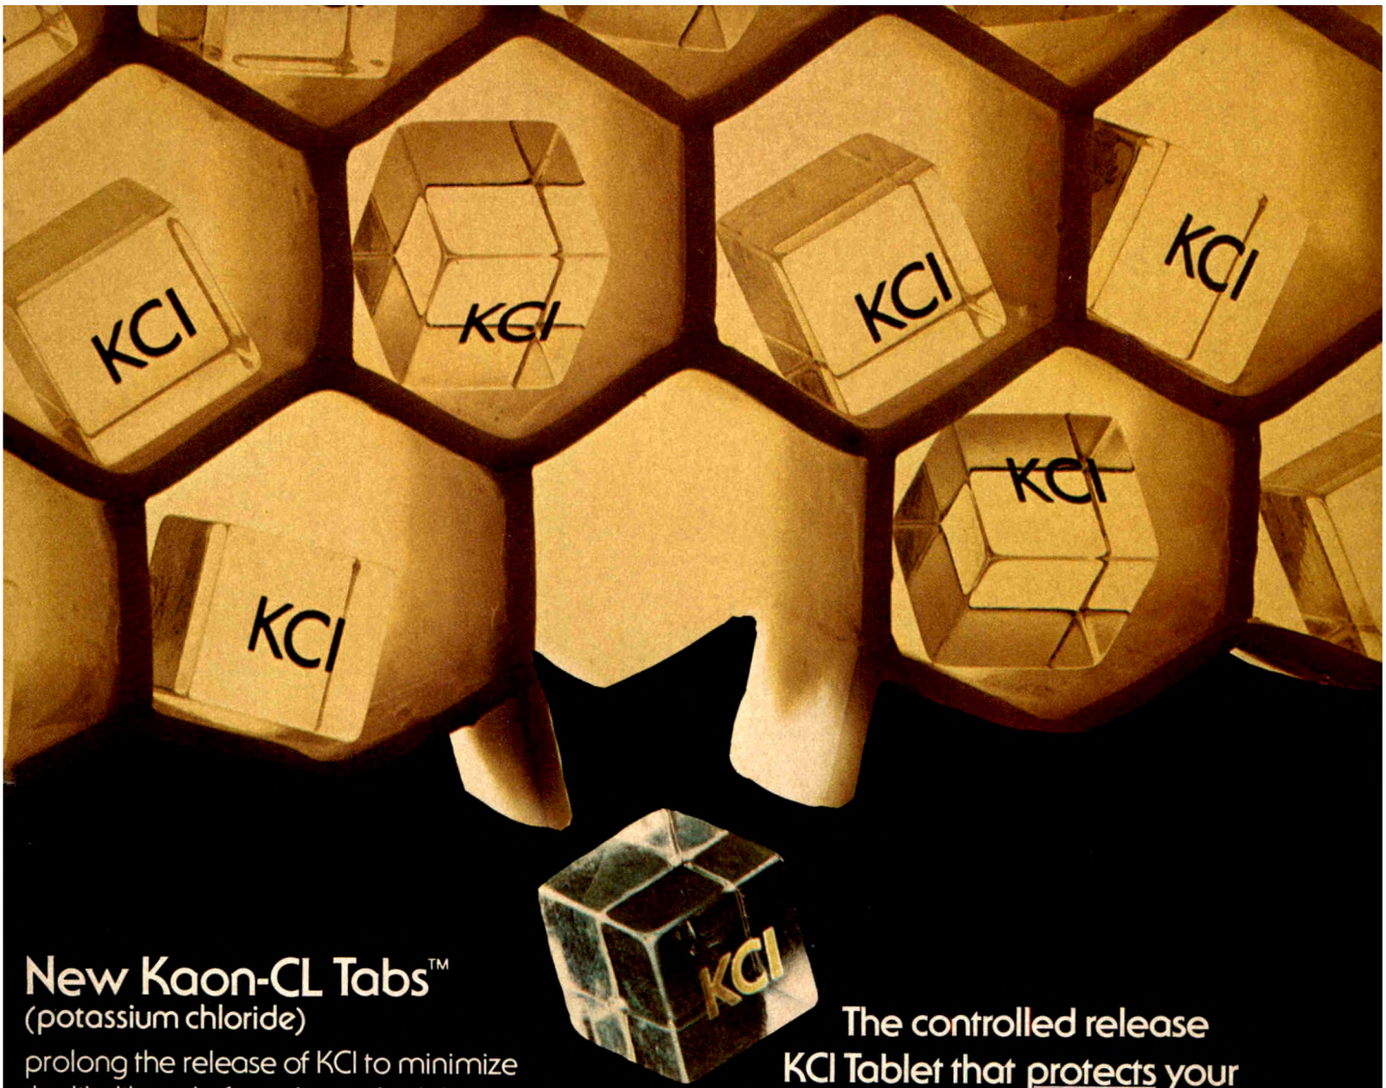
WARREN-TEED® ANNOUNCES

NEW KAON-CL TABS™

(potassium chloride)

CONTROLLED RELEASE TABLETS

– Potassium chloride imbedded in a wax matrix to provide controlled release, thus minimizing possible high local concentration of potassium ion near the bowel wall. The newest idea in potassium chloride supplements is as old as the beehive. Wax... provides an effective vehicle to imbed KCl



New Kaon-CL Tabs™
(potassium chloride)

prolong the release of KCl to minimize the likelihood of producing high localized concentrations of potassium within the G.I. tract...

- protect your patient from the risk of hypokalemia or digitalis intoxication due to potassium depletion that diet alone cannot correct...
- promote adherence to medication schedule by relieving the patient of the inconvenience of liquids...

Three-way convenience for your patients on KCl Supplements...

- because there's no palatability problem
- because there's no dilution problem
- because tablets are physically easier to carry—and to take—than liquids... an especially welcome advantage away from home—encouraging adherence to the prescribed regimen

The controlled release KCl Tablet that protects your patients on diuretics or digitalis

- against hypokalemia due to potassium depletion that cannot be adequately replaced by diet alone
- against the inconvenience of—and often confusion over—dilution of liquid supplements
- from taste-fatigue associated with liquids

Dosage: Prophylactic: 20 mEq. daily (1 tab T.I.D.)
Therapeutic: 40-100 mEq. daily
See following page for brief summary.

WARREN-TEED
PHARMACEUTICALS INCORPORATED
SUBSIDIARY OF ROHM AND HAAS COMPANY

Warren-Teed®
KAON-CL TABS™
(Potassium Chloride)
CONTROLLED RELEASE TABLETS

Description: Kaon-CL Tabs is a sugar coated (not enteric-coated) tablet containing 500 mg. potassium chloride (equivalent to 6.67 mEq. potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: Kaon-CL Tabs is indicated for the treatment of potassium depletion in patients with hypokalemia and metabolic alkalosis, and for the treatment of digitalis intoxication. During therapy serum potassium levels should be monitored and the dosage titrated to achieve the desired clinical and laboratory effects. Kaon-CL Tabs is also indicated for the prevention of potassium depletion when the dietary intake of potassium is inadequate for this purpose. The prophylactic administration of potassium ion may be indicated in patients receiving digitalis and diuretics for the treatment of congestive heart failure, hepatic cirrhosis with ascites, patients with hypertension on long-term diuretic therapy, hyperaldosteronism states with normal renal function, the nephrotic syndrome, and certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

Warnings: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon-CL Tabs (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric coated potassium chloride tablets (40-50 per 100,000 patient-years), a few cases associated with wax-matrix tablets have been reported. These data are from foreign marketing experience. Kaon-CL Tabs should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia, in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Dosage and Administration: Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq. per day for the prevention of hypokalemia to 40-100 mEq. per day or more for the treatment of potassium depletion.

One Kaon-CL Tabs three times daily provides 20 mEq. of potassium chloride. Two Kaon-CL Tabs three times daily provides 40 mEq. of potassium chloride.

Caution: Federal law prohibits dispensing without prescription.

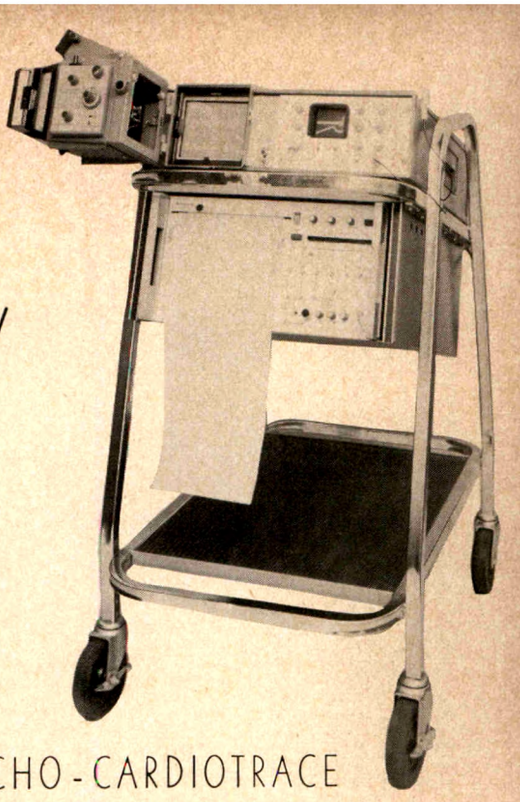
ECHOCARDIOGRAPHY



TAKE A LOOK AT . . .

METRIX ECHO-CARDIOTRACE

. . . PERFORMANCE

- Improved echo-processing makes the ECHO-CARDIOTRACE one of the highest resolution instruments available.
- Posterior as well as anterior TGC (Time Gain Compensation) allows easy visualization of posterior wall details while maintaining other landmark echoes at optimum levels.
- Isolated ECG for maximum patient safety standard on all units.
- Interfaces with Honeywell, E for M, Cambridge and Irex recorders.

. . . CONVENIENCE

- *Simultaneous* A and TM echoes (on two scopes), as well as TCG trace.
- For previewing and convenient visualization the TM display can be used in the storage mode to see the "whole picture" before photographing. Use in non-storage if maximum display resolution is required.
- Optional swing-away camera starts the TM sweep whenever shutter is opened.
- Portable roll-around cart with space for recorder or accessories and large casters for ease of movement.

. . . SUPPORT

- Local service centers (more than 30) offering fast, competent service.
- One year warranty.
- Periodic educational seminars.
- The experience of over a decade of producing high-quality diagnostic ultrasonic instruments.

tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Cardilate®
(erythrityl tetranitrate)

chewable tablets 10 mg.
t.i.d. or q.i.d. (p.r.n.)

CLINICAL STUDIES

Left Main Coronary Arterial Obstruction: Long-Term Follow-Up of 141 Nonsurgical Cases

JUAN S. LIM, MD
WILLIAM L. PROUDFIT, MD
F. MASON SONES, Jr., MD, FACC

Cleveland, Ohio

The prognosis of 141 patients with obstructive left main coronary artery disease was studied. The patients were followed up for 5 to 10 years from the date of coronary arteriography. The 5 year cardiac mortality rate was 51 percent. During the first 3 years after diagnosis, the mortality rate was especially high, 21.9, 34.7 and 43 percent, respectively. Among patients who died in the 1st year after diagnosis, evidence of left ventricular hypertrophy or conduction delay in the electrocardiogram and multiple vessel involvement indicated poor prognosis. Severe angina pectoris, evidence of congestive heart failure and generalized decrease in left ventricular contractility increased the 5 year mortality rate. More than 97 percent of the total patient population had additional lesions elsewhere in the coronary arteries.

The left main coronary artery supplies branches to most of the left ventricle. An obstructive lesion involving this vessel suggests a poor prognosis. Recent studies[1–3] have tended to support the impression that patients with this lesion constitute a high risk group. A long-term progress study of a large population of patients who did not have surgical intervention is not available.

Selection of Patients and Methods

Patients who had coronary arteriography from January 1961 through December 1966 were selected for this study. Those included had at least 50 percent narrowing of the left main coronary artery and had no coronary surgery within 5 years from the date of coronary arteriography. Patients with congenital or rheumatic heart disease were excluded. The objective was to obtain a minimal follow-up period of 5 years for all patients who had not undergone surgery during that time. One hundred forty-one consecutive patients fulfilled the selection criteria; all were successfully followed up for a minimum of 5 years, and 96 percent were followed up for 6 years. These patients constituted 6 percent of the subjects with obstructive disease by coronary arteriography.

All patient data were coded before follow-up information was collected. Clinical symptoms were classified according to previously established criteria.[4] A diagnosis of hypertension was made if at the time of admission for coronary arteriography the systolic blood pressure was 150 mm Hg or more, or

1 vessel involvement (left main coronary)	50 (2)	0	0	0
2 vessel involvement	50 (10)	62 (8)	0 (2)	33 (3)
3 vessel involvement	25 (12)	38 (13)	50 (2)	83 (6)
4 vessel involvement	50 (22)	48 (25)	33 (3)	90 (11)

*Data expressed as percent with total number of cases in each category in parentheses. Twenty-two patients without a left ventriculogram were not included in the calculations.

the diastolic pressure was 100 mm Hg or more. The obstruction in the coronary arteries was classified as 50 to less than 75 percent narrowing of lumen diameter, 75 to less than 90 percent narrowing, 90 percent narrowing to almost total obstruction and total obstruction. The presence of demonstrable collateral formation from either a right to left or left to right direction was noted. Follow-up data were obtained by questionnaires and telephone interviews. The principal sources of information were attending physicians, the patients, their relatives and former employers.

The 5 year mortality rate for various categories was calculated by the direct method. The survival curve was constructed by actuarial method[5] and analysis of data was performed manually.

tients died in the follow-up period and 43 survived. The patients with longer follow-up periods had arteriography performed at earlier dates.

Clinical features: The clinical data on those who died within 5 years and on those who survived were compared. The ages ranged from 26 to 63 years (mean 53 years) in 7 women and from 32 to 72 years (mean 52 years) in 134 men. The ratio of slightly greater than 19 men to 1 woman is higher than the ratio of 8.2 men to each woman in a previous progress study[3] of unselected patients. Hypertension was noted in 34 percent of the patients and, although the number of cases was small, there was no apparent difference between the incidence of hypertension in survivors and nonsurvivors. The serum cholesterol value at the time of admission for coronary arteriography was also not significantly different in the two groups.

Mortality and arteriographic findings: The 5 year cardiac mortality rate correlated with the cardiac catheterization findings (Fig. 2). The degree of obstruction of the left main trunk did not appear to affect the 5 year mortality rate. Since more than 97 percent of the patients had multiple arterial involvement, the mortality in patients with lesser degrees of narrowing could be explained on this basis. Because only four patients had isolated left main coronary artery disease, comparison of their data with those of patients who have additional lesions is difficult. Diffuse involvement, as exemplified by four vessel disease, appears to have a high mortality rate. Patients with generalized decreased contractility of the left ventricle have a poor prognosis (75 percent 5 year mortality rate). The presence of a localized abnormality in contractility did not make a significant difference in mortality when data in affected patients were compared with those in patients with a normal left ventriculogram.

When the number of vessels involved and the left ventriculogram were correlated with the 5 year mortality rate, the rate was highest in the category with multiple vessel involvement combined with diffuse decrease in contractility (85 and 90 percent mortality rate in three and four vessel involvement, respectively, Table I). Left ventriculograms were not made in 22 patients whose data were therefore not included in the correlation. Because the value of left ventriculography was not appreciated at the time, it was not routinely performed in our early experience. Intercoronary collateral formation was present in 89 patients (63 percent). Those who died within 5 years tended to have more frequent demonstrable collateral vessels (right to left as well as left to right), but the difference was insignificant (49 to 73 versus 40 to 68).

The 5 year cardiac mortality rate for the whole group of patients was 51 percent (Table II). There were only 5 noncardiac deaths among the 98 deaths in the follow-up period. Thirty-one cardiac deaths, including three at catheterization, occurred in the 1st year after arteriography (43 percent of the 5 year cardiac mortality rate). Of 53 patients with severe left main coronary arterial stenosis (75 percent narrowing to total occlusion), 52.8 percent (28 patients) survived more than 5 years; 2 of these patients subsequently received coronary bypass grafts.

Factors influencing 5 year survival: Various factors were analyzed (Table III) to determine how those who survived more than 5 years differed at the time of catheterization from those who died in less than 5 years. In addition, because of the high mortal-

ity rate during the 1st year, those who died within 1 year were also compared with those who died after the 1st year but within 5 years of arteriography. Evidence of left ventricular hypertrophy or conduction delay in the electrocardiogram and four vessel arterial involvement were the only significant factors in the early mortality data. Comparison of those who died in the 5 year follow-up period with those who survived revealed significant differences in the severity of symptoms (angina pectoris), clear evidence of congestive heart failure on examination or a history strongly suggestive of it in the recent past, normal electrocardiogram or evidence of left ventricular hypertrophy or conduction delay, four vessel involvement and generalized decreased contractility observed in the left ventriculogram.

The survival curves of patients with left main coronary arterial obstruction and those with three vessel disease without involvement of the left main trunk as reported by Bruschke et al.[3] are compared in Figure 3. The curve in patients with left main coronary disease is slightly lower in the first 3 years. The 5 year mortality data are similar in both groups when correction for noncardiac deaths is made for patients with three vessel disease. The survival curves of the two subgroups are significantly lower than that of the unselected population with coronary disease.

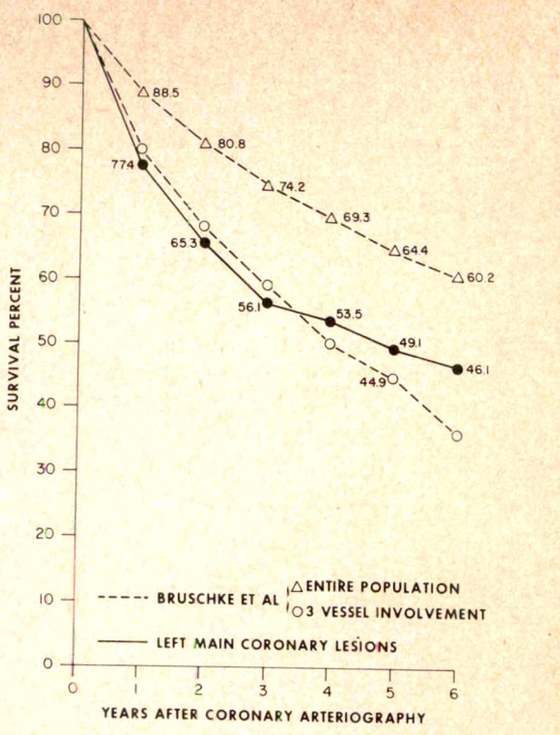

FIGURE 3. Survival curves of patients with left main coronary arterial obstruction and in the series of cases reported by Bruschke et al.[3] Patients with left main coronary arterial lesions were not included in the curve for three vessel involvement.

Discussion

At the time coronary arteriography was performed in these patients, the coronary bypass grafting technique was not available. Consequently, patients with left main coronary arterial obstruction were not treated surgically except for a few attempts at procedures, coronary ostial dilation and direct patch grafting, that had a high surgical mortality rate.[6] The prognosis of this group of patients not operated on could be studied with little bias from surgical selection.

From our study we conclude that the prognosis of patients with left main coronary stenosis is poor, particularly in the first 3 years after diagnosis. Comparison with studies reported by other investigators[1,2] is difficult because of their small series and short period of follow-up. However, the published figure[1] of a 50 percent mortality rate with an average follow-up of 25 months is quite high. Bruschke et al.,[3] from the Cleveland Clinic, reported on 37 patients and their 5 year mortality rate of 56.8 percent is closer to our figure of 51 percent.

The three cardiac catheterization deaths (2.1 percent mortality rate) in this report occurred before 1967, and this figure is relatively high since the overall mortality rate for coronary arteriography in our laboratory was less than 0.1 percent at that time. It probably reflects a combination of insufficient experience with this type of lesion and the lack of an effective surgical procedure to deal with it. Opacification of the left coronary ostium, performed cautiously in the left anterior oblique projection with a small amount of contrast medium, should precede selective left coronary arteriography. When a left main coronary lesion is revealed by this "test dose," left coronary arteriography is carried out expeditiously with the catheter tip positioned at or just inside the left ostium. The number of injections of contrast medium is kept to an adequate minimum, enough to visualize the two main branches of the left coronary artery. The capability of performing immediate revascularization with bypass grafts, when required, must be available.

Among patients with obstructive coronary artery disease the subgroups having left main trunk obstruction or multiple vessel involvement have the worst prognosis. In those with left main trunk obstruction and multiple vessel obstruction, surgery seems particularly indicated. Evidence of left ventricular hypertrophy or conduction delay in the electrocardiogram and of severe diffuse impairment of contractility in the left ventriculogram are additional factors that worsen the prognosis.

Although the arteriographic and left ventriculographic findings have predictive value, a number of patients with severe obstructive disease in the left main coronary artery and a few with a poorly contractile left ventricle or a combination of these lesions survive many years. They are the exceptions, but they illustrate the varied and complicated course of patients with this disease.

Left Main Coronary Artery Disease

Risks of Angiography, Importance of Coexisting Disease of Other Coronary Arteries and Effects of Revascularization

To elucidate the determinants of the poor prognosis of patients with left main coronary artery disease and to assess the efficacy of diagnostic and therapeutic interventions the angiographic features and clinical course of 58 patients with left main coronary artery disease studied between September 1967 and June 1974 were analyzed. Eighty-three coronary arteriograms were obtained in these 58 patients using the Judkins technique; there were no immediate complications although one patient died 3 days after study. Previously cited predictors of left main coronary artery disease such as calcification of the left main coronary artery, unstable or nonexertional angina and marked S-T segment depression with exercise were found in a minority of patients; thus, the presence of the disease could not reliably be predicted before arteriographic study. Coexisting disease was found in either two or three other coronary arteries in 46 of 58 patients; only 2 patients had isolated left main coronary artery disease.

Because the criteria for operability have changed in recent years, operability in each case was reassessed by two investigators using current criteria without knowledge of the treatment actually given or its outcome. The condition of 10 of 58 patients was judged inoperable in retrospect because of severe coexisting distal coronary artery disease (8 patients) or ventricular dysfunction (2 patients). Of 19 patients whose condition was judged operable in retrospect but who were treated without surgery, 9 died, 8 within 18 months; 10 have survived 12 to 83 months. Another 27 patients with a condition judged operable in retrospect had received saphenous vein bypass grafts. In this group, there were four operative and three late deaths. The severity of angina decreased in survivors treated surgically but was unchanged in survivors treated without surgery. The improvement in survival rates of surgically treated patients was not statistically significant.

The data indicate that coronary arteriography can be performed at low risk with the Judkins technique even though preangiographic prediction of left main coronary artery disease is unreliable. Coexisting disease in other major coronary arteries is an important determinant of the poor prognosis of patients with left main coronary artery disease and precludes surgery in 13 percent. Isolated left main coronary artery disease is uncommon. Surgical therapy relieves symptoms more effectively than nonsurgical therapy.

Recent reports have described the clinical presentation, the poor prognosis and the increased risks of coronary arteriography and surgery in patients with left main coronary artery disease.[1–4] This review of 58 patients examines, in particular, the suitability of the Judkins technique[5] for the coronary arteriographic examination of patients with left main coronary artery disease, arteriographic findings relating to the poor prognosis of such patients, reliability of clinical indexes for the preangiographic prediction of the disease and the impact of coronary arterial surgery.

Materials and Methods

A review of the 2,450 coronary arteriograms obtained between September 1967 and June 1974 at the University of Oregon Medical School revealed 58 patients with 50 percent or greater reduction in luminal diameter of the left main coronary artery. A 50 percent reduction of luminal diameter corresponds to a 75 percent reduction of cross-sectional area and produces a significant reduction of blood flow.[6,7] The Judkins technique was used in all studies.[5,8] Twenty-two patients had two angiographic studies each and one patient had four studies. Of these 25 follow-up studies, 6 were performed without intervening surgery at an average interval of 27 months (range 6 to 66 months) and 19 at an average interval of 9 months postoperatively. Two patients with less than 50 percent narrowing on an initial investigation were entered into the study only when 50 percent narrowing of the left main coronary artery was demonstrated in a later investigation.

The degree, type and location of the left main coronary arterial lesion and the severity and location of other coronary artery disease were assessed. Left ventricular cineangiography and pressure were used to evaluate ventricular function. The presence or absence of left main coronary arterial calcification, best identified fluoroscopically, was noted.

Because criteria for operability have changed in recent years, particularly with the advent of saphenous vein bypass grafting, the suitability of each of the 58 patients for saphenous vein bypass grafting was reassessed by two investigators using current criteria. These criteria, which require assessment of the morphologic features of distal vessels, filling patterns, branch disease, runoff capacity and ventricular function, have been described previously.[9] The retrospective determination of operability was made without knowledge of the therapy given or its outcome.

Hospital records, data on outpatient clinic examinations, records of Bureaus of Vital Statistics and interviews with patients, their relatives and referring physicians were used to determine the clinical course of the patients after angiography and surgery. The presence or absence of hypertension, diabetes mellitus, lipid abnormalities or history of prior myocardial infarction was noted. Angina at the time of angiography and at the present time was classified as mild (occurring less than once daily), moderate (occurring several times daily), severe (frequent episodes occurring with mild exertion and at rest in a stable pattern) or unstable (recurrent angina at rest persisting after admission to the hospital with transient ST-T wave electrocardiographic changes).

Electrocardiograms were examined for evidence of transmural infarction, ischemia or nonspecific abnormalities. Stress electrocardiography was performed in 19 patients using supine bicycle exercise with continuous electrocardiographic monitoring.[10]

Survival rates in surgically and nonsurgically treated patients were determined by actuarial method.[11] Standard errors of survival estimates were determined by the Greenwood formula,[12] and the two patient groups were compared using a normal distribution test.[12]

Results

Clinical Features

Angina was severe in 20 patients, unstable in 6, moderate in 24, mild in 5 and absent in 3. The three patients without angina had coronary arteriography in the course of evaluations for valvular or myocardial disease. Although 14 patients gave a history of myocardial infarction, only 7 had evidence for it in their current electrocardiograms. Four additional patients had electrocardiographic evidence of transmural infarction without a clinical history of infarction. Sixteen patients were hypertensive and 6 diabetic; 23 of 40 patients tested had elevations of serum cholesterol and triglyceride levels.

Electrocardiograms were normal in 12 patients and revealed left ventricular hypertrophy in 11, prior myocardial infarction in 12, ischemic ST-T wave changes in 6 and nonspecific abnormalities in 18. Stress electrocardiography was positive in 14 of 19 patients; only 2 of the 19 had S-T segment depression of more than 2 mm.

Of 58 patients, 26 had 50 to 70 percent stenosis and 32 had 71 to 95 percent stenosis of the left main coronary artery. Fifty-six patients had coexisting disease of other major coronary arteries. Twenty-eight had coexisting disease in three other vessels, 18 in two other vessels and 10 in one other vessel. Only two patients had isolated disease of the left main coronary artery. Thirty-six patients had associated disease of the left anterior descending coronary artery, 40 associated disease of the left circumflex coronary artery and 48 associated disease of the right coronary artery. Only six patients had no associated disease of either the left anterior descending or the circumflex coronary artery.

There were no deaths or other major complications during angiography. One patient had ventricular fi

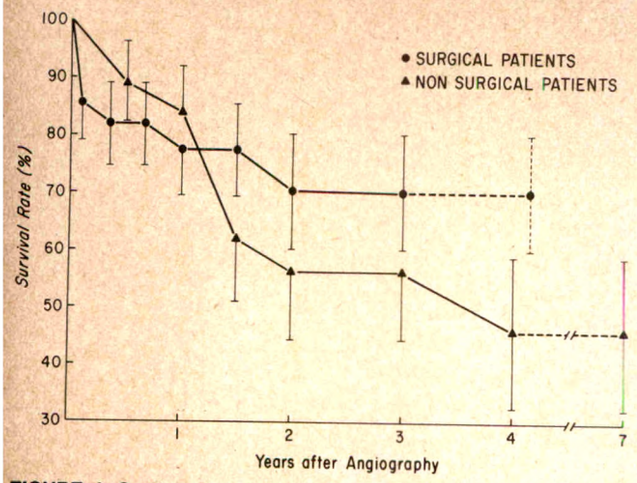

FIGURE 1. Survival curves determined by the actuarial method are shown for the nonsurgically treated patients whose condition was judged operable by current criteria and for patients treated surgically with saphenous vein bypass grafting. The difference in survival rates is not statistically significant. Vertical bars indicate standard error.

brillation 6 hours after angiography and was resuscitated, but died 3 days later of recurrent ventricular arrhythmias. No evidence of myocardial infarction was found at autopsy.

The condition of 10 patients (17 percent) was judged inoperable, in 2 (4 percent) because of ventricular dysfunction (left ventricular end-diastolic pressure greater than 25 mm Hg and ejection fraction less than 0.30) and in 8 (13 percent) because the distal vessels were considered unsuitable for placement of a vein graft.

Follow-Up of Nonsurgically Treated Patients

Surgery was not performed in 26 patients for various reasons, including patient refusal, left ventricular dysfunction and coronary arterial anatomy unsuitable for surgery. One of these patients was lost to follow-up study after 18 months. The frequency of associated disease in these 24 patients is shown in Table I. By current criteria, the condition of seven of these patients was considered inoperable and that of 19 operable. Of the former, five (71 percent) died 3 days to 18 months after angiography (mean survival 6 months). The remaining two are alive after 17 months of observation.

The condition of 19 patients was judged operable by current criteria but they were treated without surgery. Nine of these patients died 1 to 39 months after angiography (average 14 months). One of these nine patients had been accepted for surgery but elected to delay the procedure for a month and died suddenly with ventricular fibrillation. Ten patients are still alive after a period of observation averaging 48 months (range 12 to 83 months). Figure 1 shows the survival curve for these patients. The number of patients at risk and of those surviving at various intervals is shown in Table II. Figure 2 shows the severity of angina of survivors at the time of angiography and currently.

Survivors (no.)	17	16	12	9	8	5	4	

* All patients except one were operated on within 1 month of coronary arteriography.

Follow-up of Surgically Treated Patients

Thirty-two patients were treated surgically. Internal mammary arterial implants were performed in 6 of these 32 patients before 1969; there were three operative deaths and one late death 33 months after the procedure. In one of the six, intractable angina recurred and saphenous vein bypass grafting was performed with symptomatic benefit. Three patients whose condition was judged inoperable by current criteria received internal mammary arterial implants. Two of these patients died in the intraoperative period; the third patient is alive nearly 7 years postoperatively.

Twenty-seven patients, one of whom had previously received an internal mammary arterial implant, were treated with saphenous vein bypass grafting. One of the 27 was reoperated on 24 months later when angina recurred and angiography demonstrated extension of disease. There were four operative deaths (14 percent) in the course of the 28 operations; three late deaths were caused by digitalis intoxication, acute myocardial infarction and congestive heart failure, respectively. The suitability of the patient in the latter case for saphenous vein bypass grafting is questionable retrospectively because his ejection fraction was only 0.29. He had no angina after operation but continued to be severely limited by symptoms of heart failure until the time of death. A total of 40 grafts were performed in the 18 patients who had postoperative angiography. Thirty-two (80 percent) of 40 grafts were patent.

Figure 1 shows the actuarially determined survival estimates, and Table I the extent of coexisting disease in these surgically treated patients. All 20 surviving patients experienced reduction in the severity of angina, and 13 of these survivors are angina-free. The functional state of this group of patients before surgery and at present is shown in Figure 2. The surgically and nonsurgically treated groups were similar with respect to frequency of prior myocardial infarction, incidence of hypertension, diabetes mellitus and lipid abnormalities, severity of left main coronary arterial stenosis, extent of distal vessel involvement and

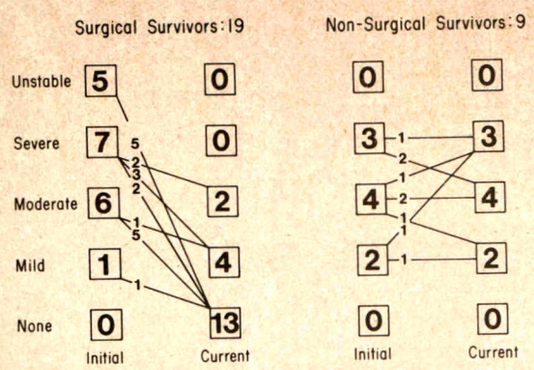

FIGURE 2. Comparison of functional status at time of angiography and currently in 19 surgically treated **(left)** and 9 nonsurgically treated survivors **(right).** Improvement in functional state occurred in each survivor in the surgical group, and more than half of the survivors are asymptomatic. Improvement in the condition of some nonsurgically treated patients was balanced by deterioration in others; however, none of the survivors are asymptomatic. The number of nonsurgically treated patients evaluated is smaller because of the greater mortality in that group.

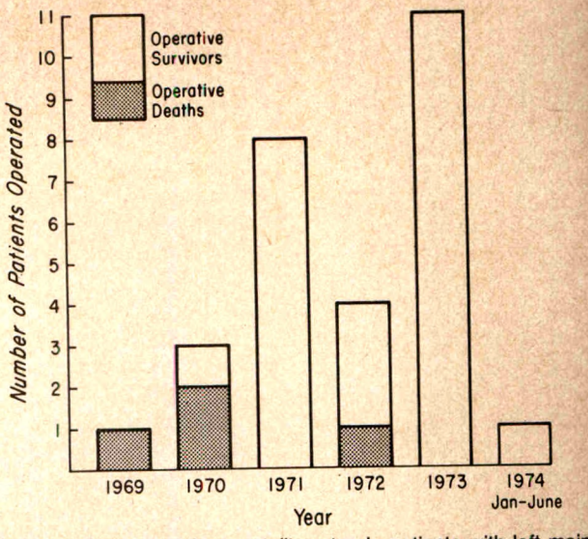

FIGURE 3. Early operative mortality rates in patients with left main coronary artery disease were high. However, since the beginning of 1971, only one patient, a man with unstable angina and diffuse coronary disease, has died at operation.

age. The difference in survival data is not statistically significant.

Discussion

Coronary Arteriography

The potential for sudden death during coronary arteriography in patients with left main coronary artery disease has been demonstrated.[1,2] However, a high mortality rate is not inevitable because similar patients studied with use of the Sones technique exclusively or a combination of the Sones and Judkins techniques have had a low mortality rate.[3,4] It has been suggested that the Judkins technique is inappropriate for use in patients with left main coronary artery disease.[2] Although complication rates may vary from one laboratory to another, this review of a 7 year experience using the Judkins technique exclusively with no deaths during 83 angiographic studies and a single death 3 days after angiography establishes that the technique can be performed at low risk in the presence of left main coronary artery disease. The relation of the single death to coronary angiography is uncertain. Our experience is similar to that of Webster et al.,[13] who reported that no deaths occurred during 29 studies at the Cleveland Clinic but that two patients died 1 and 3 days, respectively, after angiography.

Prediction of Left Main Coronary Artery Disease

The suggestion that special precautions be taken during angiography in patients with left main coronary artery disease presumes that the presence of the lesion can be accurately predicted or suspected. Severe or nocturnal angina, marked S-T segment depression during stress electrocardiography and left main coronary arterial calcification have been suggested as indicators of the lesion.[1,2] Although severe angina was found in 44 percent of our patients and its presence should alert the physician to the possibility of left main coronary artery disease, it is not a sensitive marker since 56 percent of our patients had less than severe angina and three patients had no angina. Conversely, in a group of 55 patients with unstable angina, only 2 had left main coronary artery disease.[14] Only two of our patients had marked S-T segment depression during stress electrocardiography. This finding may reflect our procedure of continuously monitoring the electrocardiogram during exercise and stopping the test as soon as diagnostic abnormalities appear rather than after completion of a predetermined work load.[10] Marked S-T segment depression may be caused by widespread disease in other major coronary arteries as well as by left main coronary artery disease.[15] Calcification of the left main coronary artery was found in 12 (21 percent) of our patients and is a reliable but insensitive marker of the disease. Because left main coronary artery disease may be found in patients with no angina and with normal resting and stress electrocardiograms, all patients undergoing coronary angiography must be approached as patients with left main coronary artery disease. The elements of a proper approach have been reviewed elsewhere.[16,17]

Angiographic Features Relating to Prognosis

The poor prognosis of patients with left main coronary artery disease must be attributed either to an intrinsic characteristic of the lesion such as its proximal location or a propensity to rapid progression of disease or to some factor commonly found in association with it that produces its lethal effect alone or in concert with the lesion.

Hydraulic analysis suggests that the reduction in blood flow caused by stenosis of a major trunk vessel is no greater than the reduction in flow caused by comparable stenoses in each branch vessel.[18] There-

fore, left main coronary artery disease should have an effect on flow to an extent similar to that caused by equal degrees of obstruction in the left anterior descending and circumflex coronary arteries. Analysis of the angiograms of our 25 patients who had two angiographic studies demonstrates that the rate of progression of disease in the left main coronary artery is no greater than that in other major coronary arteries and cannot by itself explain the poor prognosis in this lesion.

A striking feature of patients with left main coronary artery disease was the *extent of coexisting disease* in other major coronary arteries. In eight (13 percent) of our patients coexisting disease was so severe that it precluded surgery and these patients had a very poor prognosis. It has been demonstrated that the prognosis of patients with left main coronary artery disease is similar to that reported in patients with three vessel disease alone.[3] Although progression of disease in the left main coronary artery alone may not be rapid, small changes in the left main coronary artery and one of its branches occurring simultaneously may have a critical effect on flow because critical stenoses in series are additive in their effects on flow.[19] For all these reasons, we believe that the poor prognosis of patients with left main coronary artery disease is largely related to the high frequency of severe coexisting coronary artery disease. The prognosis of isolated left main coronary artery disease found in only two of our patients is unknown because of the small number of cases available for analysis.

Efficacy of Surgical Therapy

An appropriate assessment of the benefits of surgery can be made by comparison of patients treated with and without surgery only after exclusion of those patients who are not surgical candidates. The prognosis of this latter group is unlikely to be altered by surgical therapy and is extremely poor. Inclusion of patients with inoperable conditions in the nonsurgical group does not allow comparison of patients at equal risk. The surgically treated group had a reduced frequency of angina in contrast to the nonsurgically treated patients in whom angina persisted. The effect of surgery on survival, as shown in Figure 1, was not statistically significant but may be greater than indicated because our early experience with saphenous vein bypass grafting, in which there was a high operative mortality rate, is included (Fig. 3). Since the end of 1970, there have been 23 operative survivors among 24 patients with left main coronary artery disease, and the estimated survival rate of these patients 3 years postoperatively is 78 percent rather than the 70 percent shown for the entire group. The improvement in survival data of the patients operated on more recently is largely the result of a reduction in operative mortality but may also reflect a tendency to perform bypass grafting in a greater number of obstructive lesions.

Comparisons of larger groups of surgically[4] and nonsurgically[3] treated patients suggest that saphenous vein bypass grafting prolongs life, but the suitability for surgery of the nonsurgically treated patients is not established[3] and the reported follow-up time of surgical survivors is short.[4] Also, comparison of groups of patients from different institutions may be misleading. Although achievement of low operative mortality rates now appears possible, further follow-up will be required to determine whether the propensity to widespread disease in these patients may offset the effects of successful surgery.

Conclusions

We conclude: (1) All patients undergoing coronary angiography should be considered to have left main coronary arterial stenosis and appropriate precautions should be taken because clinical findings suggested as predictors of left main coronary artery disease were found in less than half of our patients. Uncommonly, left main coronary artery disease may be found even in the angina-free patient. (2) Coronary arteriography can be performed at low risk with either the Sones or Judkins technique in the presence of left main coronary artery disease if careful technique is observed. (3) A major factor in the poor prognosis of patients with left main coronary artery disease is the frequent presence of associated disease in other major coronary arteries. In our group of 58 patients, the condition of 13 percent was inoperable for this reason. Extrapolation from clinical precepts derived from the majority of patients with severe coexisting disease to the occasional patient with isolated left main coronary artery disease may not be warranted. (4) At present, an improved survival rate with surgery cannot be demonstrated. However, the operative risk is low and the majority of patients operated on are free of angina.

Twenty patients are described with the variant angina syndrome (recurrent angina at rest with S-T segment elevations occurring only during pain and no evolution of infarction). In contrast to patients previously reported on, all but one had progressive unstable angina before hospitalization. Angina was frequently associated with arrhythmias, including ventricular fibrillation (2 instances), ventricular tachycardia (4), frequent ventricular premature beats (5), atrioventricular block (4), sinus bradycardia (2), sinoatrial exit block (1) and supraventricular tachycardia (1). Seventeen patients had significant proximal stenosis of one or more coronary arteries with good distal vessels. Bypass surgery in 15 of these patients resulted in one noncardiac postoperative death, one perioperative infarction and relief of pain in all 14 survivors. After a 17 month mean follow-up period (range 4 to 38 months), all survivors are pain-free. Three patients had no significant coronary disease; one of these became asymptomatic with medical therapy, one continues to have angina and one died suddenly. Patients with normal coronary arteries could not be distinguished clinically or by electrocardiogram from those with severe obstructive lesions. This experience suggests that all patients with the variant angina syndrome should be studied by coronary angiography, and that most patients with significant fixed coronary lesions will do well after coronary bypass surgery.

In 1959, Prinzmetal et al.[1] described a form of variant angina pectoris characterized by pain occurring at rest or during ordinary activity rather than with exertion. The electrocardiogram during this variant angina showed S-T segment elevations with prompt return to control levels upon remission of pain. Since there was no evolution of myocardial infarction and since the course was believed to be stable or to improve with time, this type of angina was differentiated from "preinfarctional angina." However, many studies have indicated[2–9] that subsequent infarction in areas in which S-T-segment elevations were observed frequently occurs and that mortality in the follow-up period is significant.

Since Prinzmetal's original description, coronary angiography and coronary artery bypass surgery have come into general use. However, the roles of medical and surgical therapy in this syndrome are controversial, and it has recently been suggested that the latter is not appropriate for the majority of these patients.[10] This paper therefore describes the clinical spectrum, angiographic features and results of medical and surgical therapy in 20 patients admitted to the Massachusetts General Hospital with the variant angina syndrome, 15 of whom had coronary bypass surgery.

TABLE I

Clinical Data on 20 Patients with Variant Angina Pectoris

Case no.	Age (yr) & Sex	Duration of Angina	Duration of Accelerated Angina	Exertional Angina	Pain Relief with NTG	S-T Elevations	Arrhythmias During Pain
			Anterior or Anterolateral S-T Elevations				
1	54M	1 month	1 hour	Yes	Yes	V_1—V_6	VF
2	54M	8 months	1 week	Yes	Yes	I, aVL, V_1—V_4	VT
3	58M	1 year	5 days	No	Yes	V_1—V_5	VPBs
4	64F	1 week	1 week	No	Yes	V_1—V_4, aVL	...
5	58F	1 hour	1 hour	No	No	I, aVL, V_1—V_4	SB, VPBs
6	50F	10 years	3 weeks	Yes	Yes	V monitor	VT
7	53M	3 weeks	2 days	Yes	Yes	V_1—V_6	SAB
8	58M	4 years	1 month	Yes	Yes	aVL, V_2—V_6	...
9	49M	2 days	2 days	Yes	Yes	I, aVL, V_5—V_6	...
10	52F	8 days	8 days	Yes	Yes	I, aVL, V_2—V_6	...
11	56F	1 hour	1 hour	Yes	Partial	V_2—V_6	...
12	59F	12 hours	12 hours	No	Partial	V_1—V_6	VPBs, SVT, AF
			Inferior or Inferoapical S-T Elevations				
13	55M	2 years	Few hours	Yes	Yes	II,III, aVF	2° AVB, VT, VF
14	45F	2 weeks	2 weeks	No	No	II,III, aVF	SB, SA
15	44M	3 years	1 week	Yes	Partial	II,III, aVF	VPBs
16	53F	4 months	...	Yes	Yes	II,III, aVF	SA, SB, 3° AVB
17	39F	18 months	1 month	Yes	Yes	II,III, aVF	VPBs
18*	42F	6 months	1 hour	No	Yes	II,III, aVF	2° AVB
19*	45F	2 weeks	1 hour	No	Yes	II,III, aVF	SB, 2° AVB, VT
20*	58F	4 years	3 weeks	No	Yes	II,III, aVF, V_5—V_6	...

*Patients without significant coronary artery disease.

AF = atrial flutter; AVB = atrioventricular block; NTG = nitroglycerin; SA = sinus arrest; SAB = sinoatrial block; SB = sinus bradycardia; 2° = second degree; SVT = supraventricular tachycardia; 3° = third degree; VF = ventricular fibrillation; VPBs = ventricular premature beats; VT = ventricular tachycardia.

Patient Selection

Twenty patients admitted to the Massachusetts General Hospital from January 1971 to January 1974 fulfilled the criteria for variant angina pectoris: recurrent angina at rest associated with S-T segment elevations, not in the area of an old infarction, with return of the S-T segments to control levels after relief of pain, and without evolution of myocardial infarction by serial electrocardiograms or by cardiac enzymes. These patients were 8 men averaging 53 years of age and 12 women averaging 52 years of age. All patients had selective coronary angiography. Seventeen patients had significant obstructive coronary lesions, that is, greater than 70 percent luminal narrowing. Three patients had no significant coronary artery disease by angiogram.

Results with Comment

History and Physical Examination

The clinical characteristics of these patients are shown in Table I. The total duration of angina ranged from 1 hour to 10 years. All patients had angina at rest, frequently at a predictable time of day. In contrast to the stable course depicted in Prinzmetal's original description,[1] all but one of the patients in this series (Patient 16, who had stable angina over a 4 month period) had progressive, unstable angina for 1 hour to 1 month, leading to hospitalization for increasing frequency and duration of severe pain. Although previous reports have described exertional pain only rarely in variant angina,[4,8,10,11–14] 12 of our patients had angina on exertion as well as during rest; in 7, the pain began with exertion only and progressed to pain during rest. All 12 of these patients had significant obstructive coronary lesions. The three patients with angiographically normal arteries (Patients 18 to 20) had pain only during rest. Pain was completely relieved by nitroglycerin in 15 patients; 2 had no response and 3 had only partial relief.

Physical examination of the cardiovascular system was normal except for the presence of an apical fourth heart sound gallop in 10 patients. All three patients with variant angina and no significant coronary artery disease were female.

Electrocardiographic Findings

Figure 1 shows the course of S-T segment changes during and after pain in Patient 19, who had angiographically normal coronary arteries. Similar S-T elevations during pain occurred inferiorly or inferoapically in 8 patients and anteriorly or anterolaterally in 12 patients (Table I). Concurrent S-T depressions appeared in reciprocal leads in all. The three patients

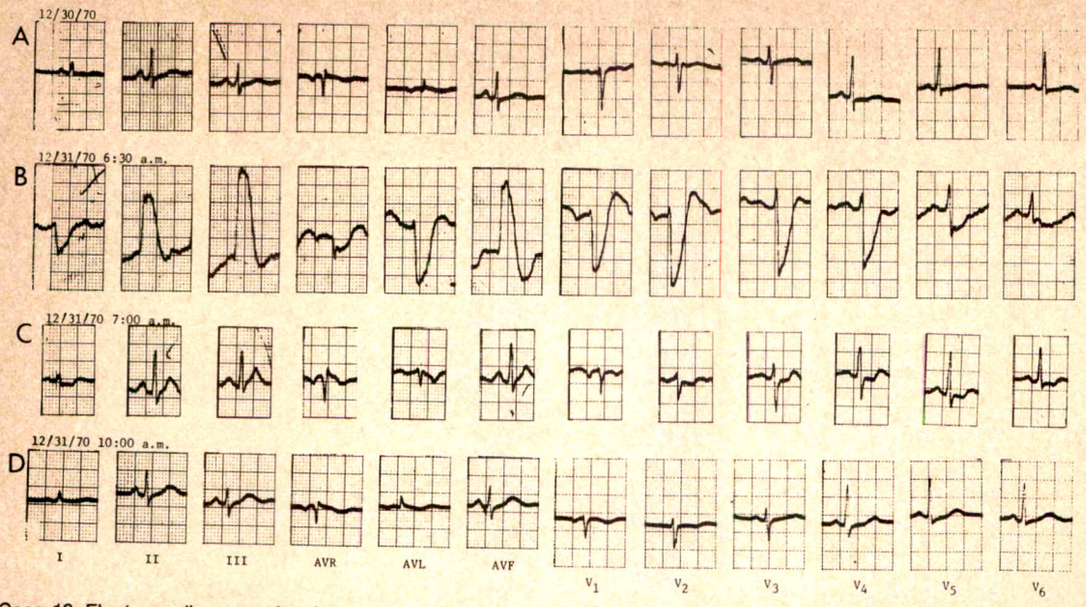

FIGURE 1. Case 19. Electrocardiograms showing representative changes in S-T segments during pain. **A,** in the absence of pain. **B,** during pain, showing marked S-T elevations in the inferior leads with reciprocal depressions anterolaterally. **C,** 30 minutes later, after relief of pain, showing persistent slight anterolateral S-T depressions. **D,** return to normal 3 hours later.

TABLE II

Cardiac Catheterization Data and Course of 20 Patients with Variant Angina Pectoris

Case no.	Location of Significant Coronary Lesions	Left Ventricle	Coronary Vessels Bypassed	Follow-Up Data
		Anterior or Anterolateral S-T Elevations		
1	Proximal LAD	Normal	LAD	No angina, 25 mo.
2	Proximal LAD, LAD diagonal, LCxM	. . .	LAD, LAD diagonal	No angina, 19 mo.
3	Proximal LAD	. . .	LAD	No angina, 22 mo.
4	Proximal LAD	. . .	LAD	No angina, 14 mo.
5	Proximal LAD	Inferoapical aneurysm	LAD	No angina, 22 mo.
6	Proximal LAD, RCA	Normal	LAD	No angina, 38 mo.
7	Proximal LAD; occluded RCA	Inferoapical akinesis; slight anterolateral hypokinesis	LAD, RCA	No angina, 9 mo.
8	Proximal LAD, LCx	Normal	None	No angina, 7 mo.
9	Proximal LAD, LAD diagonal; occluded RCA	Slightly enlarged; inferior akinesis; anterolateral hypokinesis	LAD, RCA	No angina, 6 mo.
10	Proximal LAD; occluded RCA	Anterolateral hypokinesis; apical dyskinesis	LAD	No angina, 4 mo.
11	Proximal LAD, LCxM; occluded RCA	Slight enlargement; inferior akinesis; anterolateral and apical hypokinesis	LAD, LCxM, RCA	Died postop
12	Proximal LAD, LCxM	Apical akinesis; inferior hypokinesis	LAD, LCxM	No angina, 11 mo.
		Inferior or Inferoapical S-T Elevations		
13	LCA ostium, distal RCA	Inferoapical hypokinesis	LAD, RCA	No angina, 20 mo.
14	Proximal LAD, LCx and RCA	Normal	LAD, LCx, RCA	MI with anesthesia preop
15	Proximal LAD, mid RCA	Inferoapical akinesis	LAD, RCA	No angina, 10 mo.
16	Proximal LAD, LAD diagonal, mid RCA	Inferior hypokinesis	LAD, RCA	No angina, 5 mo.
17	Proximal LCx, LCxM	Normal	None	No angina, 5 mo.
18	None	Normal	None	Recurrent angina, 17 mo.
19	None	Normal	None	No angina, 40 mo.
20	None	Normal	None	Died suddenly, 8 mo.

LAD = left anterior descending coronary artery; LCA = left coronary artery; LCx = left circumflex artery; LCxM = left circumflex marginal artery; MI = myocardial infarction; postop = postoperatively; preop = preoperatively; RCA = right coronary artery.

without significant coronary disease angiographically (Patients 18 to 20) had S-T elevations inferiorly, a finding reported in the majority of patients with variant angina and insignificant coronary disease.[2–4,10–13,15–18] Nevertheless, four such patients had anterior S-T elevations.[2,11,18,19] Thus, the location of S-T elevation does not predict presence or absence of fixed obstructive coronary lesions. In the other 17 cases, the location of S-T elevation correctly predicted a cardiac area supplied by a significantly obstructed coronary artery. However, several patients (Cases 6, 7, 9 to 11, 13 to 16) had additional significant coronary disease that was not predicted by the leads showing S-T elevations (Table II).

The electrocardiogram in the absence of pain returned to normal in 6 patients, including the 3 without significant coronary disease, and showed persistent nonspecific S-T segment and T wave abnormalities in the other 14. In no cases did new Q waves develop, nor was there serial evolution of nontransmural infarction. Four patients (Cases 2, 7, 9 and 11) had electrocardiographic evidence of an old inferior wall infarction; all four had S-T elevations in the anterior leads during variant angina.

Serious arrhythmias during episodes of pain were common (Table I). With pain, ventricular fibrillation occurred in two patients and ventricular tachycardia in four, including one patient without significant coronary disease angiographically (Case 19). Five additional patients had frequent ventricular premature beats during pain. Whether ischemia involved the anterior or inferior wall did not appear to affect the incidence of ventricular irritability. Second degree atrioventricular (A-V) block of the Wenckebach type occurred in three patients, including two with angiographically normal coronary arteries. Intermittent complete A-V block occurred in one patient. All four patients with A-V block had evidence of inferior wall ischemia. Marked sinus bradycardia during pain occurred in two patients with inferior and in one patient with anterior ischemia. Sinoatrial (S-A) exit block of the Wenckebach type was seen in one patient with anterior ischemia. One patient had periods of supraventricular tachycardia during pain.

The frequency of arrhythmias in our patients is in accord with data from previous studies in which ventricular irritability,[3,4,7,8,10,15,16,19] atrial fibrillation,[4,9,14] supraventricular tachycardia,[10,11] second and third degree A-V block,[3,4,10–12,16,17,20–22] extreme sinus slowing[18] and S-A block[22] have been reported.

Angiography

Coronary angiographic data are summarized in Table II. Seventeen patients had greater than 70 percent fixed obstruction of a major coronary artery. Five patients had significant disease of one major coronary vessel only (Cases 1, 3 to 5 and 17). Nine patients had significant disease of two major arteries with the left anterior descending artery being involved in all (Cases 2, 6 to 10, 12, 15 and 16). Three patients (Cases 11, 13 and 14) had the equivalent of significant three vessel disease. All patients had adequate distal vessels and none had diffuse inoperable disease. Three patients (Cases 18 to 20) had no angiographically significant coronary disease. The occurrence of multiple vessel obstructive disease is in contrast to Prinzmetal's suggestion that variant angina is associated with severe disease of a single coronary artery only.[1] Indeed, the distribution of coronary lesions in these patients does not appear to differ from that in patients with typical exertional angina, except for the absence of diffuse distal disease.

Left ventricular angiograms were performed for all but three patients and were normal in eight. Four patients with old inferior infarction had evidence of inferior wall akinesis or dyskinesis. Eight patients had evidence of hypokinesis in the left ventricular areas supplied by stenotic vessels (Table II).

Coronary spasm is often postulated to be an etiologic factor in initiation of pain in patients with variant angina. This was not observed in any of our patients; however, none of our patients experienced angina during angiography. Prinzmetal et al.[1] originally proposed that pain was due to "temporarily increased tonus of a single large narrowed coronary artery." More recently, spasm has been demonstrated to occur during coronary angiography of patients with variant angina, either in an essentially normal vessel[16,22] or in the area of a plaque that did not cause significant obstruction in the absence of spasm.[10] Thus, spasm may be an important factor, at least in patients with the syndrome of variant angina and normal coronary arteries. The role of spasm in patients with significant fixed obstructive lesions is not known. Experimental studies of coronary occlusion in dogs have indicated that S-T elevations are indicative of more severe myocardial ischemia than are S-T depressions.[23] Possibly, the combination of spasm and fixed obstruction might result in greater ischemia.

Hospital Course

Medical treatment: After admission to the hospital, despite absolute bed rest, angina associated with S-T elevations continued to occur in all patients but one (Case 6). Four patients (Cases 8, 13, 14 and 19) had no further pain on treatment with long-acting nitrates and propranolol in doses of 80 to 160 mg/day. One patient (Case 17) continued to have angina with propranolol in a dose of 320 mg/day but not when the dose was increased to 560 mg/day. Two patients (Cases 7 and 20) had a marked decrease in frequency and severity of pain with long-acting nitrates alone. The other patients continued to experience angina with propranolol (40 to 320 mg/day) and, in most cases, long-acting nitrates. Because of continued pain at rest in spite of intensive medical therapy, 10 patients underwent intraaortic balloon pumping before angiography. This procedure resulted in cessation of pain in all but two patients, one with continued significant pain (Case 4) and one with persistent mild pain (Case 2).

Bypass surgery: Because of the unstable progressive severity of their angina and the frequently asso-

ciated arrhythmias despite intensive medical therapy in most cases, 15 of the 17 patients with significant coronary lesions underwent coronary arterial bypass grafting. Two patients (Cases 8 and 17) received only medical therapy in spite of anatomic features suitable for bypass grafting. Six patients had single vein grafts, all to the left anterior descending coronary artery. Seven patients had double grafts, to the left anterior descending and right coronary arteries in five, to the left anterior descending artery and its diagonal branch in one and to the left anterior descending and circumflex arteries in one. Two patients had triple grafts to the left anterior descending, left circumflex and right coronary arteries. There was one in-hospital death (due to severe pulmonary infection and renal failure). One patient (Case 14) had an intraoperative myocardial infarction related to failure of a temporary pacemaker to function when complete A-V block occurred during induction of anesthesia. All others tolerated the bypass procedure well.

Follow-Up

All 14 patients surviving bypass surgery are living after an average follow-up period of 17 months (range 4 to 38 months) and all are pain-free (Table II). No patient has had further difficulties with arrhythmias, and no myocardial infarctions have occurred postoperatively. The favorable postoperative course of these patients differs from previously reported experiences. Five of the six patients with bypass surgery described by McAlpin et al.[10] had pain at rest within 4 weeks, associated with occlusion of the graft in three and occlusion of the vessel just distal to the graft in another. Recently, Bodenheimer et al.[12] reported that two of three patients with bypass grafting had continued pain postoperatively, one with a perioperative infarction and one with an occluded graft. Betriu et al.[11] described a patient with bypass grafting who had a postoperative infarction and continued angina with an occluded graft.

The two patients in our series with significant obstructive lesions treated medically are asymptomatic, one (Case 8) 7 months after admission on a regimen of isosorbide dinitrate and propranolol, 160 mg/day, and one (Case 17) 5 months after admission on a regimen of isosorbide dinitrate, quinidine and propranolol, 560 mg/day. Prinzmetal et al.[1] and, more recently, McAlpin et al.[10] suggested that the clinical course in these patients is rather stable and that their symptoms tend to decrease with time. The latter investigators therefore recommended that surgery be reserved only for patients with incapacitating symptoms refractory to medical therapy. In contrast, review of other reported cases indicates a high incidence of infarction and death for patients given medical therapy alone.[2–9] We hope that successful bypass surgery will alter this unfavorable prognosis.

Patients without significant coronary artery disease: Of the three patients in this group, one (Case 19), who had multiple episodes of ventricular tachycardia during pain, has had gradual disappearance of symptoms and is doing well 40 months after admission on therapy with isosorbide dinitrate, propranolol, quinidine and diphenylhydantoin. Another (Case 18), after several months without pain, again experienced frequent anginal episodes relieved by nitroglycerin; long-acting nitrates could not be employed because of severe headaches associated with their use. The third patient (Case 20) died suddenly during an episode of pain 8 months after hospitalization while receiving long-acting nitrates.

Patients having angina pectoris in association with evidence of myocardial ischemia but with normal coronary angiograms have been reported to follow a benign course.[24,25] Whether the occurrence of S-T elevations during pain is associated with a more unfavorable course in such patients with normal coronary arteries is unknown. The association of A-V block or serious ventricular arrhythmias, or both, with pain in two of our three patients without significant coronary disease, and in most of the similar isolated cases previously reported,[3,4,15–17,19] appears to indicate a severe degree of ischemia in these patients, perhaps related to occlusive spasm. Although the condition of two of our patients improved with time after medical therapy, as has that of some other similar patients,[11,12,17,18] one of our patients and four described by others[4,15,18,19] died suddenly during anginal episodes. Surgery does not appear to be indicated for these patients. Dhurandhar et al.[15] described such a patient with documented proximal right coronary arterial spasm only who had bypass grafting to the distal right coronary artery. Ten days postoperatively recurrent variant angina developed, and he died with the graft remaining patent. Recently, Betriu et al.[11] reported on three patients with nonsignificant obstructive lesions who underwent bypass grafting; one died postoperatively, one had recurrence of pain and one had a postoperative infarction with an unknown subsequent course. The demonstration by Oliva et al.,[17] in a patient having the variant angina syndrome with normal coronary arteries in the absence of pain, that the site of spasm during pain varied and at times involved a long segment of the right coronary artery extending as far distally as the posterior descending artery, may explain the ineffectiveness of bypass grafting in these patients.

Conclusions

Our experience suggests that all patients with the variant angina syndrome should be studied by coronary angiography since no clinical or electrocardiographic manifestations could distinguish those patients with angiographically normal coronary arteries from those with severe proximal obstructive lesions. In contrast to findings in most previous reports, all but one of our patients had an unstable and progressive course. Although our patients were inevitably a selected group, since their angina was severe enough to result in hospitalization, the same is true of other series. Patients with severe proximal obstructive lesions can undergo coronary artery bypass surgery with a low risk and excellent postoperative course over a prolonged follow-up period.

Los Angeles, California

Changes in systemic oxygen delivery after acute myocardial infarction were investigated in 21 patients. In seven patients with shock, circulatory failure was characterized by a significant reduction in cardiac index, a decrease in oxygen transport and oxygen consumption and an increase in concentration of blood lactate; a decrease in the affinity of hemoglobin for oxygen (increased P_{50}) was also noted. The P_{50} averaged 28.8 ± 0.87 (standard error of the mean) torr in patients with shock and 26.0 ± 0.45 torr ($P < 0.05$) in patients without circulatory failure. However, there was no significant difference in oxygen extraction from arterial blood between the two groups.

The time course of the changes in P_{50}, cardiac index and oxygen consumption was separately examined in 12 patients. In six patients with shock, P_{50} increased by an average of 4.6 ± 2.05 torr ($P < 0.05$) and this augmentation accounted for an estimated 18 percent increase in oxygen release. Maximal P_{50} values were observed after 24 hours of circulatory failure. In the absence of shock, no consistent changes in P_{50}, cardiac index or oxygen consumption were observed.

These data indicate that a reduction in oxygen delivery after acute myocardial infarction is followed by a compensatory increase in P_{50}. This change in P_{50} accounts for increases in oxygen availability independently of changes in cardiac output.

Circulatory failure after acute myocardial infarction is associated with a critical reduction in the viable mass of left ventricular myocardium.[1] Previous studies have documented that a decrease in cardiac output usually follows an acute infarction.[2,3] The extent to which this reduction in cardiac output is a critical determinant of survival is contingent on a concurrent reduction in oxygen availability.[4–6] Hence, pulmonary gas exchange, circulating hemoglobin and the affinity of the hemoglobin for oxygen constitute important variables in addition to cardiac output.[7]

The affinity of hemoglobin for oxygen is quantitatively assessed by P_{50}, the oxygen tension at which the hemoglobin is 50 percent saturated with oxygen. P_{50} is a major determinant of the position of the oxyhemoglobin equilibrium curve, which in turn influences the arteriovenous oxygen difference [$C(a\text{-}\bar{v}\ DO_2)$]. Increases in P_{50} indicate a rightward shift of the oxyhemoglobin equilibrium curve and therefore a decrease in the affinity of hemoglobin for oxygen. This favors oxygen unloading, thus increasing $C(a\text{-}\bar{v}\ DO_2)$ and oxygen delivery to tissues. Similarly, decreases in P_{50} indicate a leftward shift of the oxyhemoglobin equilibrium curve and therefore increased affinity of hemoglobin for oxygen.[7–9]

*Values obtained at initial hemodynamic study.
†Values obtained within 4 to 6 hours of initial study.
AMI = acute myocardial infarction; Ant = anterior; CHF = prior congestive heart failure; D = diabetes mellitus; H = arterial hypertension; HS = hemodynamic study; Inf = inferior; MAP = mean arterial pressure; UO = urinary output.

Recently, increases in P_{50} have been observed in patients with heart failure and acute myocardial infarction[8,9] and have been interpreted as a compensatory mechanism for increasing oxygen availability when systemic blood flow is reduced. This study was undertaken to quantitate the extent to which these changes in P_{50} compensate for decreases in cardiac output and modify the course of circulatory failure.

Material and Methods

Patients

Twenty-one patients admitted to the coronory care unit of the University of Southern California Center for the Critically Ill between November 1971 and December 1972 were the subjects of this study. There were 12 men and 9 women whose ages ranged from 47 to 85 (median 70) years. All 21 subjects had a diagnosis of acute myocardial infarction based on a typical clinical history, characteristic Q waves and S-T segment changes in the electrocardiogram and significant increases in serum creatine phosphokinase, glutamic oxaloacetic transaminase and lactic dehydrogenase. The clinical features of the 21 patients are summarized in Table I.

Seven patients had acute circulatory failure (shock), characterized by clammy skin, mental obtundation, reduction in intraarterial systolic pressure to less than 90 torr* or a decrease of more than 50 torr in patients who had systemic hypertension, urinary output of less than 30 ml/hour, and lactate concentration of arterial blood in excess of 1.4 millimole/liter. Four of the seven had anterior wall myocardial infarction and three had inferior wall infarction. Clinical signs of shock appeared after an estimated interval of 56 (2 to 216) hours after the onset of chest pain. Only one patient with shock survived.

Among the remaining 14 patients, 9 survived for 15 days or longer and 5 died, respectively, of ventricular arrhythmia, extension of the acute infarction, cerebral death after resuscitation from cardiac arrest, rupture of the left ventricle and progressive congestive heart failure.

* torr = pressure of 1 mm Hg at 0° C and standard gravity.

Methods

Initial hemodynamic studies were performed in 15 patients during the first 24 hours after the estimated time of infarction. In four patients the hemodynamic studies were undertaken after 48 hours (Table I). Informed consent was obtained from all patients. After local anesthesia with 2 percent lidocaine, a Swan-Ganz® catheter[10] was inserted into a basilic vein and advanced to the pulmonary artery; correct position was documented by characteristic pressure curves and chest roentgenograms. The femoral artery was cannulated percutaneously utilizing a thin-walled Teflon® catheter (B-D Longdwel, 18 gauge, internal diameter 1.05 mm, length 20 cm). Pressures were measured with a Statham P23Db transducer, in conjunction with a two channel (model 7702B) or eight channel (model 7878A) Hewlett-Packard medical recorder.

Cardiac output was determined by the dye-dilution technique using indocyanine green. The area under each dye curve was calculated by numerical integration.[11]

Blood was sampled simultaneously from the pulmonary and femoral arteries within 3 minutes after inscription of

$C(a\text{-}\bar{v}DO_2)$ = arteriovenous oxygen difference; CI = cardiac index; CaO_2 = arterial oxygen concentration; ER = O_2 extraction ratio; Hb = hemoglobin concentration; LAC = arterial lactate; NS = not significant; O_2TI = O_2 transport index; *P* = probability; VO_2 = systemic O_2 consumption; SEM = standard error of the mean.

the dye curve. Blood gas analyses were completed within 15 minutes after blood withdrawal. The partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2) and pH were measured at 37° C with the standard electrode technique utilizing a Radiometer system (Radiometer Company, Denmark, model PHA 927). The saturation of hemoglobin with oxygen (SO_2), carboxyhemoglobin saturation and hemoglobin concentration (Hb) were measured with a spectrophotometer (Co-Oximeter, model 182, Instrumentation Laboratories).

Oxygen concentration was calculated by the formula: $Hb \times \%SO_2 \times 1.39 + PO_2 \times 0.0031$. The oxygen transport index was computed as the product of the arterial oxygen concentration and cardiac index.[12] The oxygen consumption index was calculated by cardiac index $\times C(a\text{-}\bar{v}\ DO_2) \times 10$. The percent of oxygen extracted from the arterial blood was calculated from the ratio of $C(a\text{-}\bar{v}\ DO_2)$ and arterial oxygen concentration and expressed as extraction ratio. Lactate was measured by a semiautomated adaptation of the technique of Marbach and Weil.[13]

P_{50}(pH 7.40 and 37° C) was calculated by the formula[14] $P_{50} = 26.6 \times PO_2C/PO_2S$, in which PO_2C represents the measured PO_2 of a venous sample corrected to standard conditions and PO_2S is the PO_2 corresponding to the measured oxygen saturation (corrected for carboxyhemoglobin) on the standard oxyhemoglobin equilibrium curve as obtained with the aid of a computer program.[15] The resultant value for P_{50} was defined as the "calculated" P_{50}. The method by which P_{50} is computed from single measurements of pH, PO_2 and SO_2 of venous blood has recently been validated in this laboratory.[16] The standard deviation of the differences between the "calculated" P_{50} and the "actual" P_{50} for 92 samples of blood with saturations between 20 and 90 percent was ±1.0 torr. In this study the "actual" P_{50} was obtained in three different ways: (1) The PO_2 was plotted against SO_2 and the P_{50} was read from the curve of best visual fit using the points of SO_2 between 20 and 90 percent; (2) by Hill's equation[17]; and (3) as the mean of four to six calculated P_{50} values. There was no significant difference between the P_{50} values obtained in these three ways.

The Student *t* test for unpaired data was used for statistical comparisons between groups of patients and the paired Student *t* test for comparisons of sequential measurements in the same group of patients.

Results

Cardiac output, oxygen availability and anoxic metabolism: The cardiac and oxygen transport indexes were significantly decreased in patients with

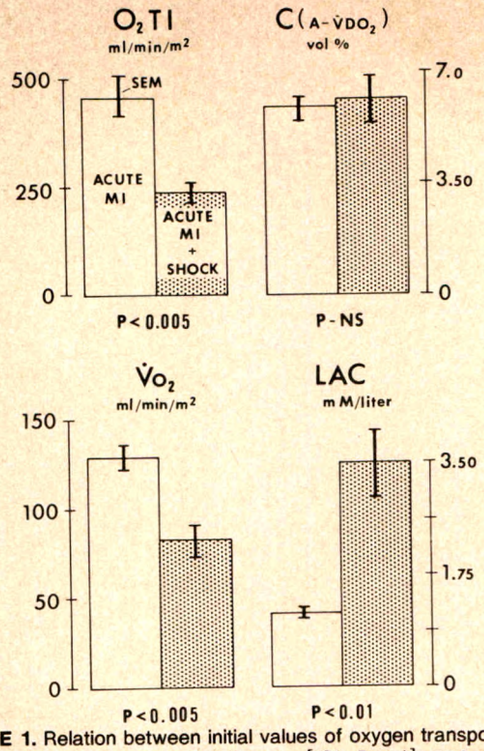

FIGURE 1. Relation between initial values of oxygen transport index (O_2TI), arteriovenous oxygen difference [$(C(A-\bar{v}DO_2)]$, systemic oxygen consumption ($\dot{V}_{O_2}$) and arterial lactate concentration (LAC) in 7 patients with myocardial infarction and 14 patients with infarction complicated by shock. NS = not significant; P = probability; SEM = standard error of the mean.

shock by comparison with values in patients without shock (Table II). However, arterial oxygen concentrations were not significantly different in the two groups of patients. The lower hemoglobin concentrations in patients with shock were in part related to the multiple blood samples removed for laboratory studies. Reductions in the oxygen transport among patients with circulatory failure were therefore related to reductions in cardiac output and, to a lesser extent, to lowering of hemoglobin concentration. Oxygen consumption was significantly reduced in patients with circulatory failure and this was associated with a concurrent increase in blood lactate. The reduction in cardiac output was only partially compensated for by increases in $C(a-\bar{v}\ DO_2)$ and the oxygen extraction ratio (Table II, Fig. 1).

In the absence of shock, the cardiac index was only slightly reduced and the oxygen consumption was within normal limits, confirming previous observations by Valentine et al.[18] Arterial blood lactate was normal in 10 patients, indicating that the oxygen uptake was sufficient for maintenance of aerobic metabolism. The lactate values were slightly increased to levels from 1.4 to 1.9 millimoles/liter in four patients, two of whom were among the five who died.

P_{50} and oxygen extraction: When patients with shock were compared with those without shock, a difference in P_{50} was noted (Table III). P_{50} was significantly higher ($P < 0.05$) and the affinity of hemoglobin for oxygen thereby less among those with shock.

pH_a = arterial pH; $P\bar{v}_{O_2}$ = PO_2 in mixed venous blood; SEM = standard error of the mean; $S\bar{v}_{O_2}$ = oxygen saturation in mixed venous blood; Temp. = temperature.

The in vivo P_{50}, representing P_{50} at the patients' temperature and pH, was not significantly different from the P_{50} at 37° C and pH 7.40. Despite this increase in P_{50}, $C(a-\bar{v}\ DO_2)$ was not significantly higher among the patients in shock, thus suggesting that factors other than the affinity of hemoglobin for oxygen altered oxygen extraction.

Quantification of the effect of P_{50}: The specific effect of a rightward shift of the oxyhemoglobin equilibrium curve on oxygen availability was next examined. We compared the $C(a-\bar{v}\ DO_2)$ calculated on the basis of the oxygen saturation derived from the measured PO_2 according to the Severinghaus equation,[19] which assumes a normal P_{50}, with the $C(a-\bar{v}\ DO_2)$ obtained from the measured oxygen saturation. In 21 normal persons previously studied in our laboratory, the P_{50} averaged 27.0 ± 1.3 (standard deviation) torr. In 9 of the 21 patients in the present series, the P_{50} exceeded 27.0 torr, averaging 28.7 ± 0.42 (standard error of the mean) torr (Table II). The pH averaged 7.40 ± 0.02 units and the temperature 37.5 ± 0.25° C.

* = $P < 0.05$ (a vs. b)

a = initial values; b = values obtained at the time of the highest P_{50}; CI = cardiac index; C(a-$\bar{v}$ DO_2) = arteriovenous oxygen difference; Hb = hemoglobin concentration; LAC = arterial lactate concentration; SEM = standard error of the mean; $\dot{V}O_2$ = oxygen consumption.

In these nine patients, the C(a-$\bar{v}$ DO_2) based on measured saturations exceeded calculated values by 1.07 ± 0.29 volumes percent ($P < 0.01$). Consequently, estimates of oxygen consumption based on measured oxygen saturations and simultaneous determinations of cardiac index were 20.0 ± 8.64 ml/min per m² ($P < 0.05$) greater than those based on calculated values of oxygen saturations. This is equivalent to a 19 percent increase in cardiac index.

P_{50} changes over time and their influence on oxygen availability: In 12 patients, including 6 who were in shock, adequate hemodynamic and metabolic measurements were available after the initial studies (Table IV). These data were used to further assess the extent to which increases in P_{50} might compensate for reductions in cardiac output. Results herein reported refer to maximal increases in P_{50} that were observed at intervals ranging from 4 to 69 hours after the initial measurements. Among the patients with shock, the average P_{50} increased by 4.6 torr ($P < 0.05$), the C(a-$\bar{v}$ DO_2) by 0.96 volume percent, and the oxygen consumption by 15 ml/min per m² ($P < 0.05$); the hemoglobin concentration was reduced in four of the six patients, but the differences were not statistically significant. Since there was no significant change in cardiac index, the increase in oxygen consumption was accounted for by the increased C(a-$\bar{v}$ DO_2). Although the oxygen consumption increased significantly, it still remained in a subnormal range and lactic acidosis persisted during the period of observation as an indication of persistent anaerobic metabolism. In the patients without shock no significant changes in P_{50}, cardiac index, C(a-$\bar{v}$ DO_2), oxygen consumption or lactate were observed.

When increases in P_{50} were observed in the absence of shock, cardiac output was usually decreased. In Patients 9 and 11, substantial increases in P_{50} followed concurrent reductions in cardiac output (Table IV). Once again, increases in P_{50} were related to reductions in systemic blood flow.

Discussion

In this study we confirmed a significant reduction in cardiac index among the patients with circulatory failure and further demonstrated a parallel reduction in oxygen transport and oxygen consumption. Oxygen consumption was calculated from cardiac output and arteriovenous oxygen difference rather than measured directly. In these critically ill patients, measurements that require the patient's cooperation, such as the direct measurement of oxygen consumption, are often not feasible.

Oxygen consumption is a function of both supply and demand. The reduction in oxygen consumption could therefore be due to a decrease in supply or demand, or both. The possibility that a reduction in oxygen demand exceeds the reduction in supply is excluded in patients with shock by the presence of lactic acidosis. This indicates that tissue demands for

oxygen were greater than the supply, resulting in anaerobic metabolism.

A reduction in oxygen supply was indicated by the decrease in cardiac output and oxygen transport. Since the arterial oxygen concentration approximated normal value and the arteriovenous oxygen difference was increased, the reduction in oxygen transport and consumption are both attributable primarily to the reduction in cardiac output.

This interpretation of the basis for the reduction in oxygen consumption is consistent with the findings in patients without shock. In these patients cardiac output was only slightly reduced and the increase in oxygen extraction from arterial blood allowed for an equilibrium between oxygen supply and demand that was reflected by the normal values of both oxygen consumption and arterial lactate.

Compensatory Mechanisms for Reduced Oxygen Supply

The mechanisms by which a patient may compensate for a reduction in cardiac output include redistribution of blood flow and increased tissue extraction of oxygen.[20,21] Redistribution of blood flow probably occurred among patients with shock but was not specifically quantitated in our study. However, the extraction of oxygen was increased, as demonstrated by the arteriovenous oxygen difference, which exceeded 6 volumes percent, and the extraction ratios, which were greater than 30 percent. These findings are in contrast to data from studies on normal subjects in whom Reeves et al.[22] observed values for arteriovenous oxygen difference ranging from 3.5 to 4.5 volumes percent and from Parer et al.,[23] who documented extraction ratios averaging 21 percent.

P_{50} was characteristically increased in patients in whom acute myocardial infarction was followed by circulatory failure; these results parallel those of other investigators. Woodson et al.[24] and Metcalfe et al.[8] related the increase in P_{50} to reductions in cardiac output in patients with chronic heart failure. Shapell et al.[25] documented increases in P_{50} among patients in whom angina pectoris was induced by atrial pacing. Decreases in the affinity of the hemoglobin for oxygen also have been reported in human subjects after ascent to high altitudes.[26] Increases in P_{50} in patients with acute myocardial infarction recently reported by Kostuk et al.[9] were more pronounced among patients whose clinical course was complicated by heart failure. Since P_{50} was significantly increased in the majority of our patients with circulatory failure at the time of the initial measurements, a larger arteriovenous oxygen difference would be anticipated among such patients than in those without shock. However, this was not the case, indicating that factors other than the affinity of the hemoglobin for oxygen are involved in the extraction of oxygen at the tissue level. Among such factors, peripheral arteriovenous shunting, with part of the cardiac output bypassing ischemic areas, or reduced capability of the cells to take up oxygen, or both, might account for the unexpectedly high levels of mixed venous oxygen saturation observed among the patients with shock.

Quantitative Effect of Increased P_{50}

Our data demonstrate that the rightward shift of the oxyhemoglobin equilibrium curve would by itself provide an estimated 18 percent increase in oxygen availability. Whether this shift in the position of the curve will actually increase oxygen release by the same amount is contingent on the presence of additional factors such as peripheral shunting and the capability of the cells to take up oxygen at a given time.

The impact of an increase in P_{50} on the progression of circulatory failure may further depend on the time course of such changes. In the majority of the patients in this series, the highest P_{50} values were noted more than 24 hours after the onset of circulatory failure. Although significant increases in oxygen uptake followed increases in P_{50}, it is not as yet known whether this occurs rapidly enough to affect survival. Nevertheless, increases in P_{50} represent a potentially important compensatory mechanism when critical reductions in systemic flow limit survival after acute myocardial infarction. This mechanism may have added significance since oxygen availability is improved by the enhancement of oxygen release at the capillary level without augmenting the work load of the heart. In patients with acute myocardial infarction an increase in P_{50} also may be beneficial by increasing oxygen release to ischemic areas, thereby potentially reducing the size of the infarction.[27]

Measurement of S-T Segment Elevation in Acute Myocardial Infarction in Man

Comparison of a Precordial Mapping Technique and the Frank Vector System

TOSHIO AKIYAMA, MD

Rochester, New York

Precordial S-T segment mapping has been used to evaluate the extent of ischemic injury in patients with acute myocardial infarction. Because precordial S-T segment mapping is time-consuming and is limited to patients with anterior wall myocardial infarction, we evaluated the possibility of using the magnitude (ST-VM) and direction (ST-VD) of the S-T vector, derived from X, Y and Z leads of the Frank vector system, as a substitute for the precordial S-T segment mapping technique.

Precordial S-T segment mapping and Frank system vectorcardiograms were simultaneously obtained in three groups: (1) nine normal subjects; (2) nine patients with persistent S-T segment elevation 2 to 15 months after acute anterior myocardial infarction; and (3) nine patients with acute anterior myocardial infarction studied on 41 occasions. For both systems the S-T segments were analyzed 20 and 60 msec after completion of inscription of the QRS complex. The sum of the S-T segment elevations for the 35 sites (ΣST) and the number of sites (NST) in which S-T segment elevations exceeded 0.1 mv were computed for the precordial S-T maps. The ST-VM and ST-VD were calculated by standard formulas from X, Y and Z lead tracings of the Frank vector system. Good correlations were observed between: ST-VM and ΣST ($r = +0.818$ and $+0.791$ at 20 and 60 msec, respectively, $P < 0.001$); and ST-VM and NST ($r = +0.773$ and $+0.705$ at 20 and 60 msec, respectively, $P < 0.001$). Furthermore, changes in the location of S-T segment elevations in serial precordial S-T segment maps were reflected by changes in ST-VD. Observations in patients with inferior wall myocardial infarction suggest that ST-VM and ST-VD can be serially followed in such patients. Thus, estimation of the magnitude and direction of the S-T vector is a simple alternative to standard precordial S-T segment mapping that allows for continuous monitoring of S-T segment elevations in all patients with acute myocardial infarction.

The degree and extent of epicardial S-T segment elevation have been used to evaluate myocardial ischemic injury in animal experiments.[1–3] Maroko et al.[2] found a good correlation between epicardial S-T segment elevation and the extent of injury to the underlying myocardium, as determined by depression of myocardial creatine phosphokinase activity.[2]

Recently, precordial S-T segment mapping has been used in man to delineate alterations in myocardial ischemia,[4,5] examine the effects of therapy on the extent of myocardial ischemia[6] and detect exten-

sions of myocardial infarction.[7] However, because the technique requires the recording and measurement of 35 to 72 separate electrocardiographic complexes, it is a laborious and time-consuming process. Furthermore, Maroko et al.[5] have stated that the technique should not be used in patients with inferior wall myocardial infarction.

We[8] have recently demonstrated that it is feasible to record the vectorcardiogram continuously in patients with acute myocardial infarction. In view of the aforementioned limitations of precordial S-T segment mapping, we evaluated the possibility of using the magnitude and direction of the S-T segment vector as a substitute for the precordial S-T segment mapping technique.[8a]

Methods

Patient Groups

We studied 29 patients classified into three groups (Table I). Group I (normal subjects) consisted of nine men who had no history of cardiovascular disease and who had a normal cardiac examination and 12 lead electrocardiogram. Group II (acute myocardial infarction) consisted of 11 patients who had clinical, enzymatic and electrocardiographic evidence of acute myocardial infarction. Nine of the 11 had anterior wall infarction by electrocardiographic criteria and 2 had inferior wall infarction. The latter two are discussed separately; they were not included in the statistical analysis because of the limitations of precordial S-T mapping in inferior wall infarction. Group III consisted of 9 patients who had had an acute myocardial infarction 2 to 15 months previously and who had persistent S-T elevation in the precordial leads of the 12 lead electrocardiogram. Sixty-six studies were performed in the 29 patients (Table I). The small number of women (4 of 29) is due to difficulties in accurate placement of precordial electrodes in these patients.

Data Collection

Precordial S-T segment mapping: A "chest blanket" with 35 holes (2 cm in diameter) was constructed of thin sheet rubber. The 35 holes were placed in a 5 by 7 grid; the 5 horizontal holes were designated by the letters A (top) to E (bottom), and the 7 vertical columns were numbered from 1 (patient's right) to 7 (patient's left). The holes were spaced according to the method of Maroko et al.[5] The chest blanket was taped on the patient's chest with the top right hole (A1) placed in the second intercostal space at the right parasternal line, and the bottom left hole (E7) at or close to the sixth intercostal space in the left midaxillary line. With subjects in the supine position, a pediatric size chest electrode (Welsh electrode, Bowen and Co., Bethesda, Md.) was sequentially applied to the chest wall through the 35 holes, using an electrode paste (Redux Creme, Hewlett-Packard Corp., Palo Alto, Calif.) Several complexes were recorded at each point on a standard electrocardiograph (Cardi-O-Mite, model S-200, Bendix Corp., Rochester, N. Y.) at a paper speed of 25 mm/sec and a standardization of 1 mv/10 mm.

Frank system X, Y and Z lead recording: While the precordial S-T segment map was being recorded, a continuous recording of the X, Y and Z leads was made, using the technique previously described.[8] In this technique, the Frank X, Y and Z leads are continuously monitored and recorded on a strip chart recorder. Eight disposable electrodes are applied to the patient according to the Frank lead system,[9] with five electrodes on the thorax, one electrode on the back of the neck and one electrode on each leg. A special resistor network transforms the information from the leads into the conventional Frank X, Y and Z signals. These signals (corresponding roughly to leads I, aVF and V_1, respectively, of the routine 12 lead electrocardiogram) are routinely displayed at the patient's bedside and at the nursing station. When permanent records are desired (as in this study, for example), the X, Y and Z leads are recorded at a paper speed of 100 mm/sec with a standardization of either 20 or 40 mm/mv on a pressurized ink direct recorder (Brush Mark 880, Gould Corp., Cleveland, Ohio). Representative tracings are shown in Figure 1. We[8] have previously found excellent agreement between vectorcardiographic loops obtained with a standard commercial vectorcardiograph (Hewlett-Packard, model 1507A) and those obtained by plotting our Frank X, Y and Z leads against one another. We routinely use one or more of the Frank system signals instead of the usual single lead system to monitor the rhythm of patients in our myocardial infarction research unit.[8]

Tracing analysis: In all tracings, the isoelectric base line was determined by drawing a straight line between P-R segments of adjacent beats. All measurements were made with reference to this isoelectric line and were recorded in millivolts. The termination of the QRS complex was visually determined for each beat, and the S-T elevation 20 and 60 msec after termination of the QRS inscription were recorded for the 35 precordial leads and the X, Y and Z leads (Fig. 1). The sum of S-T elevations (in millivolts) for the 35 precordial sites was computed and termed ΣST. The number of sites in which S-T segment elevation exceeded 0.1 mv was also computed and termed NST.[5]

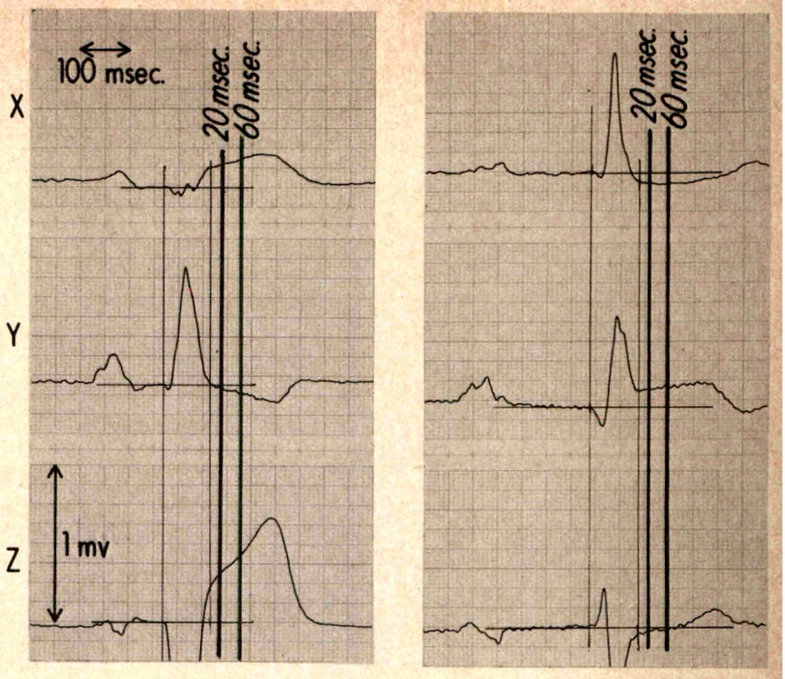
Calculation of the S-T segment vector: The magnitude, azimuth and elevation of the S-T vector were calculated using the following standard formulas:

$$\text{Magnitude (ST-VM)} = \sqrt{X^2 + Y^2 + Z^2}$$

$$\text{Azimuth (ST-AZ)} = \tan^{-1}\frac{Z}{X}$$

$$\text{Elevation (ST-EL)} = \tan^{-1}\frac{Y}{\sqrt{X^2 + Z^2}}$$

Magnitude is expressed in millivolts, and azimuth and elevation are expressed in degrees. We chose a reference system in which 0° azimuth is to the patient's left, 90° azi-



Acute Anterior Myocardial Infarction

	20 msec.	60 msec.
X	+0.15 mv	+0.175 mv
Y	-0.025 mv	-0.05 mv
Z	+0.30 mV	+0.425 mv
ST-VM	+0.34 mv	+0.46 mv
Azimuth	+63°	+68°
Elevation	-4°	-6°

Acute Inferior Myocardial Infarction

	20 msec.	60 msec.
X	-0.05 mv	-0.075 mv

ST-VM	+0.14 mv	+0.15 mv
Azimuth	+207°	+180°
Elevation	+66°	+59°

FIGURE 1. Representative Frank system X, Y and Z lead recordings in two patients with anterior **(left)** and inferior **(right)** wall myocardial infarction. The beginning and end of the QRS complex are indicated by the lighter vertical lines. Measurements were made 20 and 60 msec after QRS inscription, as indicated by the darker vertical lines. Below are shown the measured values (in millivolts) for each lead, as well as the calculated magnitude (ST-VM), azimuth and elevation for the S-T segment. In the X and Y leads, positive forces are upward, but this orientation has been reversed in the Z lead to aid orientation with the standard 12 lead electrocardiogram.

muth is anterior to the patient, 180° is to the patient's right and 270° is posterior to the patient. With respect to elevation, −90° is at the patient's head, 0° at the horizontal plane through the heart and +90° at the patient's feet.

Reproducibility and variability of the techniques: To test reproducibility of the techniques, simultaneous precordial mapping and Frank X, Y and Z recordings were made on two occasions, less than 30 minutes apart, in each of six patients in stable condition. Tracings for both tests were analyzed by the same person. Paired t test analysis revealed that there was no difference between the two recordings with respect to the ST-VM, ΣST or NST at 20 or 60 msec after QRS inscription. Because the tracings were analyzed by more than one person, on eight occasions the same tracings were analyzed independently by two observers to test variation among observers. No systematic differences were noted, and the maximal difference between the two observers was 13 percent (for ΣST at 60 msec after QRS inscription).

Data analysis: All data were punched onto cards, and analysis was performed on a digital computer (XDS Sigma 3). Standard statistical techniques were used to calculate correlation coefficients, regression equations and results of paired and unpaired t tests.[10]

Results

Correlation between ΣST and NST of precordial S-T mapping and ST-VM of the Frank X, Y and Z lead recordings: Data from 51 observations* of simultaneous precordial S-T mapping and the Frank X, Y and Z lead recordings are compared in Figures 2 and 3. Data from all three patient groups are included. Figure 2 demonstrates that there is a moderately strong correlation between the ST-VM and ΣST 20 and 60 msec after completion of the QRS complex inscription. Correlations were equally strong for both men and women (r = +0.871 and +0.865 for men and women, respectively, 20 msec after inscription). Figure 3 demonstrates that there is also a good correlation between ST-VM and NST at both times after QRS inscription. Again, correlations were equally good for both men and women (r = +0.781

* Data from 15 observations (2 in patients with inferior wall myocardial infarction, 6 from reproducibility tests and 7 from variability tests) were not included in the analysis of correlation between the two techniques.

and +0.842, respectively, at 20 msec). Since we found no systematic differences between the data obtained 20 and 60 msec after completion of QRS inscription, the subsequent results will refer only to data obtained 20 msec after inscription.

To show the correlation between the two techniques in individual patients, results of several simultaneous studies from two patients are compared in Figure 4. In both patients, significant changes in ΣST occurred during their clinical course, and these changes were reflected by concordant changes in ST-VM.

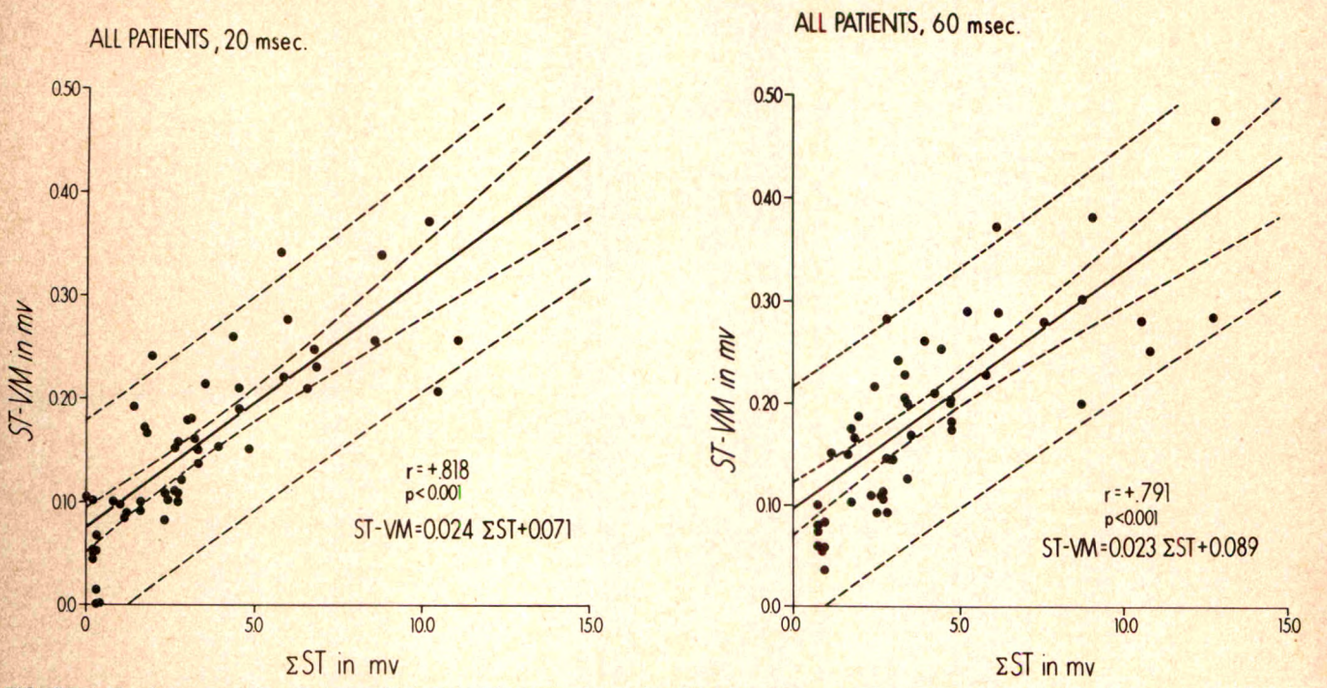

FIGURE 2. The S-T segment vector magnitude (ST-VM) obtained from Frank system X, Y and Z lead recordings is plotted against the sum of the 35 S-T segments (ΣST) obtained by chest wall mapping. The data, obtained 20 **(left)** and 60 **(right)** msec after completion of the QRS complex, are from all groups studied. Correlation coefficients and the regression equations are shown. The **solid line** is the regression line, the **inner dashed lines** are the confidence bands for the regression lines, and the **outer dashed lines** are the prediction bands.

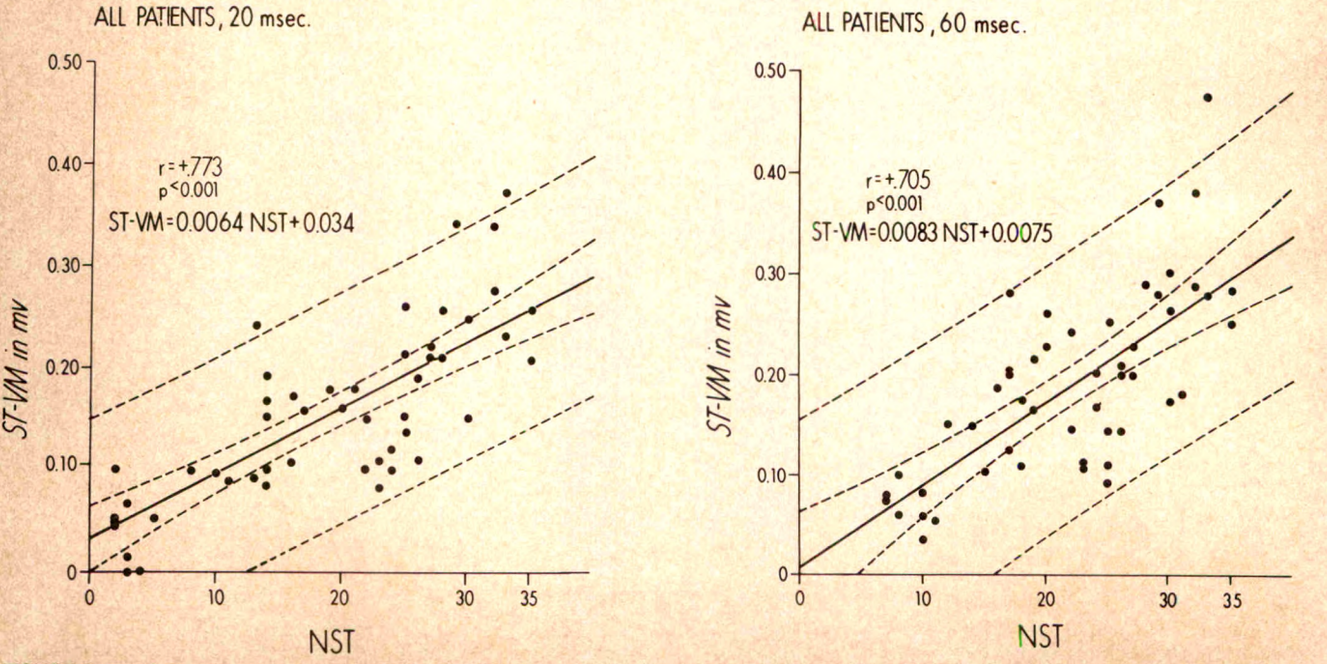

FIGURE 3. The S-T segment vector magnitude (ST-VM) obtained from Frank system X, Y and Z lead recordings is plotted against the number of sites (NST) on precordial S-T segment maps that exceeded 0.1 mv. Data, obtained 20 and 60 msec after completion of the QRS complex, are from all groups studied. Other notation as in Figure 2.

Correlation of changes in the distribution of S-T elevations in precordial mapping and the S-T vector direction: We also attempted to correlate the distribution of S-T segment elevations, as determined by S-T segment mapping, with the S-T vector direction, as determined from the Frank X, Y and Z recordings. Thus, in addition to ST-VM, the azimuth (ST-AZ) and elevation (ST-EL) of the S-T segment were calculated for each set of X, Y and Z lead tracings. Figure 5 shows serial data from S-T mapping and Frank leads in a patient with an anterior wall myocardial infarction. Peak voltages occurred in columns 2 and 3 of the chest mapping throughout the patient's course, and this was reflected by the S-T vector azimuth, which remained within a narrow range of 78° to 90°, whereas S-T vector elevation did not change significantly.

In contrast to Figure 5, from a patient in whom the precordial location of S-T segment elevations did not change, the data in Figure 6 are from a patient with

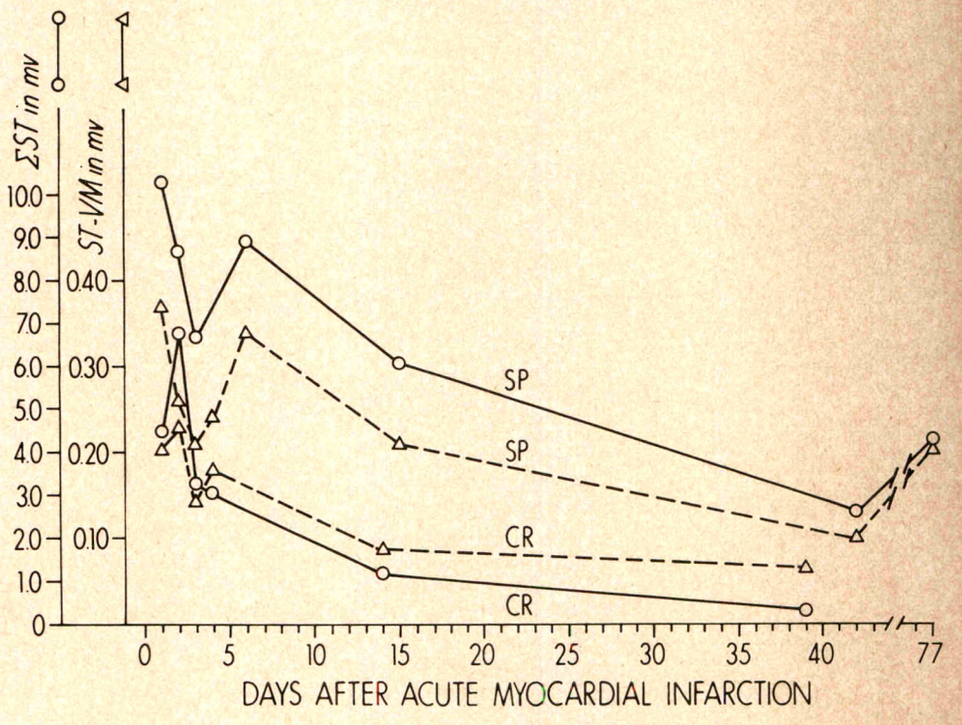

FIGURE 4. Serial data for ST-VM (Δ) and ΣST (O) in two patients (CR and SP) are shown. Note the close correlation between the changes calculated by the two techniques.

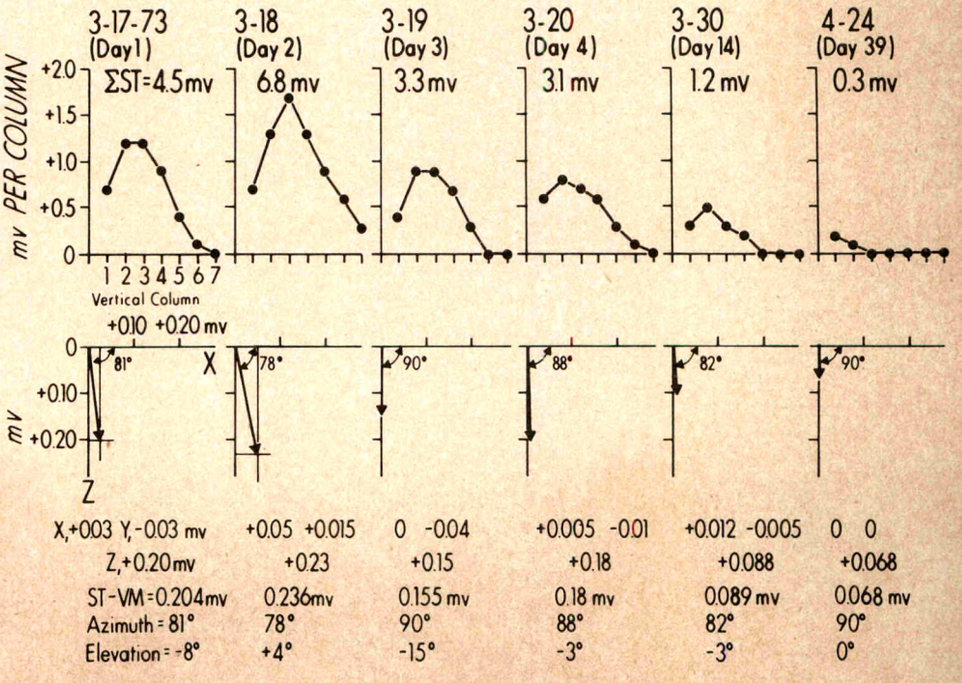

FIGURE 5. Serial data are shown for precordial S-T mapping **(upper row)** and Frank X, Y and Z lead recordings **(lower row)** in a patient with anterior myocardial infarction. In each panel of the upper row, the sum (in millivolts) of the S-T segments for each S-T mapping vertical column is plotted. For example, the sum of S-T elevations on day 1 in vertical column 1 (the most rightward column on the patient's chest) was 0.7 mv. On the same day, the sum in vertical column 4 was 0.9 mv. In the Frank leads recorded at the same time **(lower row)**, the S-T elevation was 0.2 mv in lead Z and 0.03 mv in lead X. Plotting of these data reveals a vector magnitude of 0.204 mv and an azimuth of 81° in the horizontal plane. Notation as in Figure 1.

anterior wall infarction who manifested significant changes in the distribution of S-T elevation on S-T mapping. Peak voltage shifted from column 3 to column 5 on the 5th hospital day, when clinical signs of pericarditis developed. This was reflected in the Frank leads by a significant shift in S-T azimuth from 60° to 17°, with only a slight change in S-T vector elevation (Fig. 6). With clinical resolution of the pericarditis 2 weeks later, peak voltage on S-T mapping shifted back to column 3, and S-T vector azimuth returned to the previous direction as well. Thus, shifts in the distribution of S-T elevations as measured by precordial mapping are simultaneously reflected by changes in S-T elevation and azimuth, as measured by Frank X, Y and Z leads.

Validity of Frank X, Y and Z system in inferior wall myocardial infarction: Data from a patient with an inferior wall myocardial infarction are shown

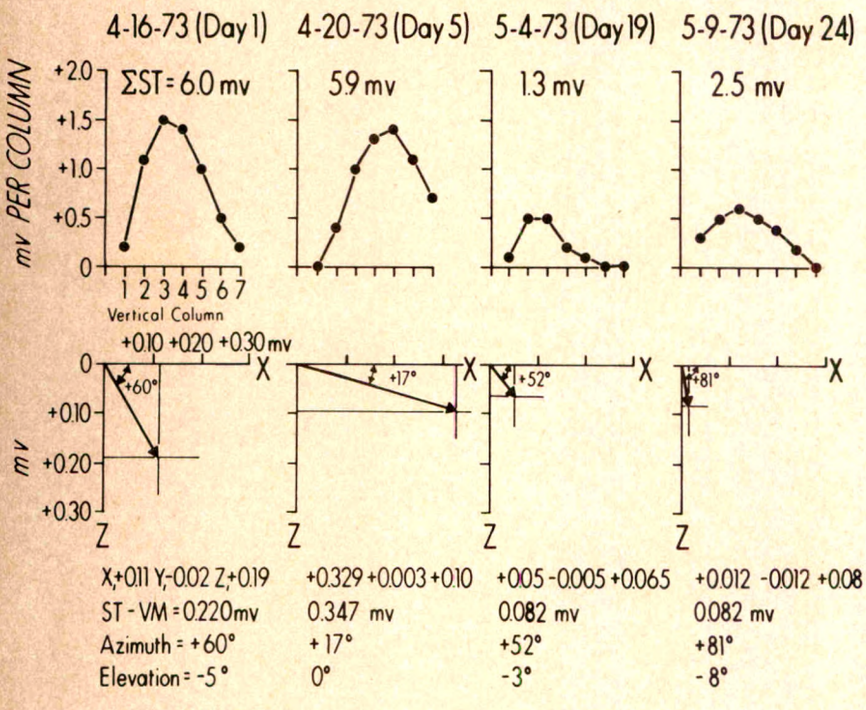

FIGURE 6. Serial data are shown for precordial S-T mapping **(upper row)** and Frank X, Y and Z lead recordings **(lower row)** in a patient with anterior wall infarction who manifested significant changes in the distribution of S-T segment elevations on the 5th hospital day. Both techniques reflect shifts in distribution and direction of S-T elevation. See text for explanation. Notation as in Figures 1 and 5.

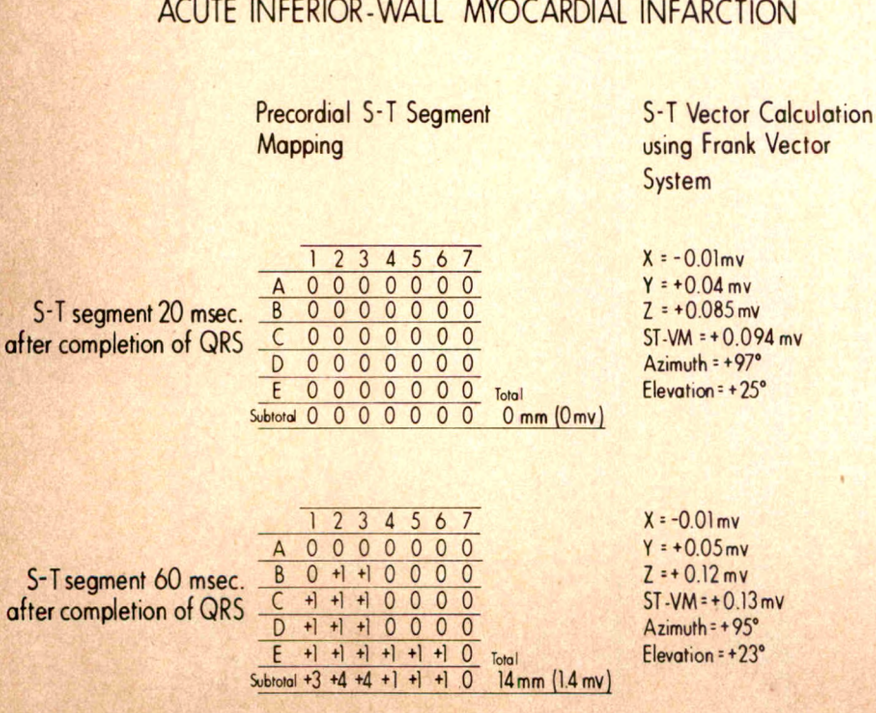

FIGURE 7. Comparison of S-T segment mapping **(left)** and Frank X, Y and Z leads **(right)** in a patient with inferior wall acute myocardial infarction. Values (in millimeters) for each of the 35 precordial sites are shown for both 20 and 60 msec after completion of the QRS complex. Other notation as in Figure 1.

in Figure 7. Precordial S-T segment mapping revealed no S-T elevations 20 msec after QRS inscription, and only minimal S-T elevations 60 msec after QRS inscription. However, the extent and location of S-T elevation were reflected in the simultaneously recorded Frank X, Y and Z leads. The magnitude of the S-T vector was 0.094 mv 20 msec after QRS inscription, and the inferior location of the infarct was reflected by an S-T vector elevation of +25°.

Utility of Frank X, Y and Z leads for serial studies: Because the Frank X, Y and Z leads can be continuously recorded, the magnitude and direction of the S-T segment vector can be easily determined at any time without disturbing the patient. An example of the utility of the technique is shown in Figure 8. In this patient, who had an inferior wall infarction, the Frank leads were continuously recorded on a frequency modulation analog tape recorder (Honeywell 7600, Honeywell Corp., Denver, Colo.). At a later time, strip chart recordings were made of the leads at significant periods in the patient's course, and S-T vector magnitude, azimuth and elevation were calculated. On admission, the patient had third-degree atrioventricular (A-V) block, and the S-T magnitude was at a maximal value. Subsequently, 16 other calculations of vector magnitude were made over a 48 hour period, without disturbing the patient at any time. Intermediate levels of vector magnitude were noted when the patient had second degree block of the Wenckebach type. A direct correlation was noted between the S-T vector magnitude and the P-R interval when the patient had first degree A-V heart block ($r = +0.90$, $P < 0.001$). Although the data suggest that in this patient there was a direct relation between myocardial ischemia and the extent of A-V heart block, no conclusions should be drawn from this single study. These data are shown merely to illustrate the flexibility and utility of this technique.

Discussion

The amount of S-T segment elevation in a QRS-T complex is thought to correlate with myocardial ischemia. In 1949, Wegria et al.[1] showed that epicardial S-T segment elevation in dogs correlated well with induced reductions in coronary blood flow. More recently, Maroko et al.[2] recorded epicardial electrocardiograms on the anterior surface of the left ventricle in the distribution and vicinity of an occluded branch of the left anterior descending coronary artery. They found that elevation of the S-T segment accurately reflected the severity and extent of myocardial ischemic injury. In other canine experiments,[5] the same group demonstrated good correlations between myocardial ischemia and S-T segment elevations recorded from the chest surface.

Several recent studies have documented the clinical usefulness of quantitating S-T segment elevation in precordial electrocardiographic leads. Pelides et al.[6] and Maroko et al.[5] showed the value of precordial S-T segment mapping in delineating alterations in myocardial ischemia and in examining the effect of therapy on the extent of ischemia in patients with myocardial infarction. Reid et al.[7] found such mapping useful in detecting extensions of myocardial infarction, some of which were not detected by routine 12 lead electrocardiogram. Nielsen[11] and Wilson and Pantridge[12] found that the magnitude of S-T elevation gave valuable prognostic information that was useful in selecting patients for prolonged monitoring.

In light of these findings, we believed that evaluation of the S-T segment would be a useful clinical and research tool. However, because precordial S-T segment mapping is a relatively time-consuming and laborious procedure, we examined the possibility of using determination of the magnitude and direction of the S-T vector in the Frank system vectorcardiogram as a substitute technique. Our data reveal that

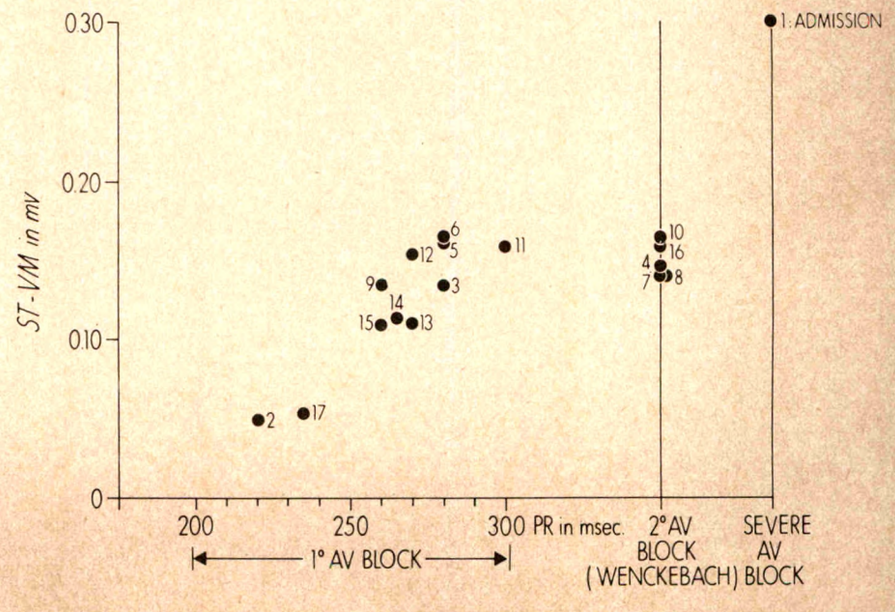

FIGURE 8. Relation between the severity of A-V block and serial S-T vector magnitudes (ST-V-M) in a 51 year old man with an inferior wall myocardial infarction. The numbers refer to the chronologic order in which the data were gathered, from 1 (admission) to 17 (48 hours after admission). When the patient had first-degree A-V block, there was a strong correlation between the P-R interval and ST-VM ($r = +0.90$, $P < 0.001$). AV = atrioventricular; PR = P-R interval.

the technique is a reasonable substitute, and that the data obtained have a moderately strong positive correlation with those obtained from S-T segment maps recorded by usual methods. The method is feasible in patients with acute inferior wall infarction (Fig. 7), and can also be used for multiple serial studies (Fig. 8). In addition, since the magnitude and direction of the S-T segment are calculated on a single beat (using the three simultaneously recorded leads), even beat to beat changes in S-T segment elevation can be evaluated. This latter feature should be helpful in evaluating the time course of interventions such as nitroglycerin that might be expected to rapidly affect myocardial ischemia. Furthermore, the method reflects changes in direction in the S-T segment (Fig. 5 and 6). In view of these advantages, the technique should be useful for monitoring the S-T segment in clinical and research studies.

Causes of variations in the two techniques: In comparing data from our technique with data obtained using S-T segment mapping, we noted correlation coefficients in the range of 0.8 (Fig. 2 and 3), indicating that approximately 64 percent (0.8^2) of the variation in our technique could be explained by variation in the standard S-T segment mapping technique.[13] Causes for the other 36 percent of the variation may include the following: (1) *Experimental error,* including measurement error (different standardizations and paper speeds were used in the two techniques) as well as errors in recording and placement of electrodes. (2) *Assumption of a single cardiac dipole.* Vectorcardiography (and thus our technique) assumes a single cardiac dipole, whereas S-T segment mapping, utilizing individual body surface recordings, does not. On the basis of recently reported studies,[14,15] we believe that this source of error probably accounts for less than 15 percent of differences. (3) *Errors due to infarct location.* Our technique is influenced by all changes in the S-T segment, whereas S-T segment mapping is influenced mostly by those changes that occur in the area being mapped. Thus, an anterolateral myocardial infarction might produce S-T segment elevation over parts of the chest wall not being mapped; this event would presumably be reflected by our technique, but not, of course, by S-T segment mapping, and would thus contribute to the variation noted in Figures 2 and 3.

Clinical implication: We used continuous recordings of Frank X, Y and Z leads to calculate the magnitude and direction of the S-T segment in normal people and in patients with new and old myocardial infarction. The data thus obtained were compared with data obtained from standard precordial S-T segment mapping techniques, and moderately strong correlations were found between the two approaches. The Frank technique is simple, easy to use and useful in all locations of myocardial infarction. It should prove useful in clinical and research studies in patients with myocardial infarction.

Reappearance of Anterior QRS Forces After Coronary Bypass Surgery

An Electrovectorcardiographic Study

This report describes the reappearance of anterior QRS electrical forces in six patients after direct coronary arterial bypass surgery. Each patient had severe coronary artery disease including a segmental stenosis of the left anterior descending artery. Revascularization was performed by direct anastomosis of the left internal mammary artery to the left anterior descending coronary artery and saphenous vein bypass of other stenotic coronary arteries. Preoperative electrocardiograms and vectorcardiograms showed patterns of anterior wall myocardial infarction with absent or diminutive anterior QRS forces. In each case, postoperative studies demonstrated the regeneration of anterior QRS forces within 10 days of operation. Although these patients represent a small percent of those with a preoperative pattern of infarction who undergo coronary revascularization, the findings demonstrate that electrically silent areas of myocardium may be altered and are not always synonymous with myocardial cell death. Chronic myocardial ischemia may in certain instances produce electrocardiographic and vectorcardiographic patterns of myocardial infarction that may be reversible upon reestablishment of perfusion to ischemic areas.

Vectorcardiography has become a useful adjunct in the pre- and postoperative evaluation of patients undergoing coronary arterial surgery and in conjunction with standard electrocardiography has been used to assess the incidence of perioperative myocardial infarction.[1,2]

In the study described here, vectorcardiography demonstrated early after direct coronary arterial bypass surgery abolition of the preoperative pattern of anterior wall myocardial infarction. Although previous reports[3,4] have shown that Q waves in standard electrocardiograms may be transient and are not always associated with irreversible myocardial damage, the reversible nature of electrically silent areas of myocardium[3] has not previously been documented after coronary bypass surgery or corroborated by vectorcardiography.

This report describes six patients with obstructive coronary artery disease, including severe proximal segmental stenotic lesions in the left anterior descending artery, who underwent direct coronary bypass surgery. Preoperative electrocardiograms and vectorcardiograms showed patterns of anterior wall myocardial infarction with absent or diminutive anterior QRS forces. In each instance, postoperative studies demonstrated the reappearance of more normal anterior forces within 10 days of operation. Specific examples are shown and the implications of these observations discussed.

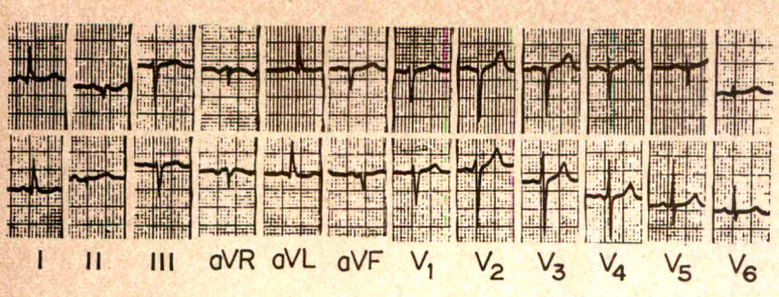

FIGURE 1. Case 2. The preoperative electrocardiogram **(top)** shows a pattern of anterior wall myocardial infarction with Q waves in leads V_2 and V_3 and "poor R wave progression" across the precordium. The postoperative record **(bottom)** demonstrates reappearance of normal R wave progression and loss of the pattern of anterior infarction. Left anterior hemiblock is evident in both the pre- and postoperative tracings.

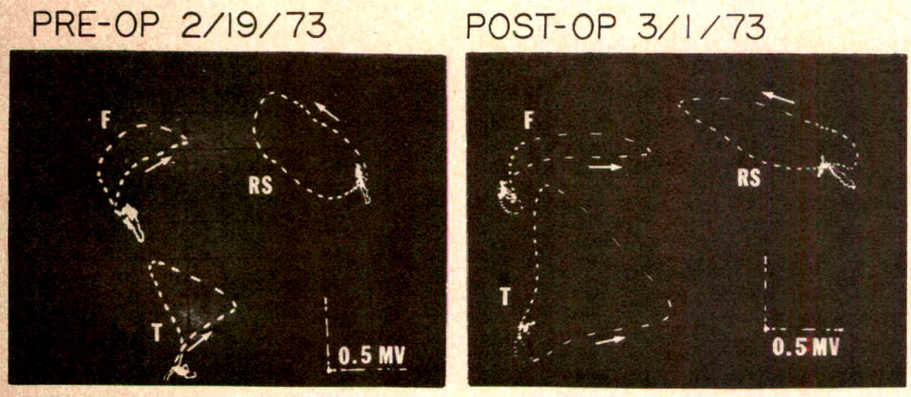

FIGURE 2. Case 2. Vectorcardiograms before **(left)** and after **(right)** operation, in the frontal (F), right sagittal (RS) and transverse (T) planes. The interval between dashes is 2.5 msec. The preoperative tracings show a pattern of anterior wall infarction with the 20 msec vector posterior to the null point. The postoperative tracings demonstrate regeneration of anterior QRS forces, best visualized in the transverse plane. Inferior wall myocardial infarction and left anterior hemiblock are evident in both tracings.

TABLE I

Clinical Characteristics

Case no.	Age (yr) & Sex	Angina	Past MI	Arrhythmia
1	42M	Yes	Yes	No
2	43M	Unstable	No	No
3	57M	Unstable	No	PVCs
4	44M	Unstable	No	No
5	56M	Yes	No	No
6	55M	Yes	Yes	No

MI = myocardial infarction; PVCs = premature ventricular contractions.

Methods

Pertinent clinical characteristics of the six patients are summarized in Table I. All patients were symptomatic with angina pectoris. Three patients had rapidly progressive symptoms and an unstable anginal pattern; two had a clinical history of a previous myocardial infarction. In all six patients preoperative electrocardiograms showed a pattern of anterior wall myocardial infarction with Q waves in the precordial leads. In two patients (Cases 1 and 2), electrocardiograms showed associated patterns of inferior wall infarction. The six patients represent approximately 1 percent of all patients with preoperative electrocardiographic and vectorcardiographic patterns of myocardial infarction who underwent direct coronary arterial surgery at our institution between January 1973 and June 1974.

Vectorcardiograms, recorded on a Hewlett-Packard vector programmer using the Frank lead system, were obtained in the transverse, right sagittal and frontal planes at 0.5 and 0.2 mv standardizations. They were recorded within 3 days before the coronary bypass procedure and again within 10 days after the procedure. Standard 12 lead electrocardiograms were recorded on the same day as the vectorcardiograms.

Vectorcardiographic criteria for an anterior or anteroseptal myocardial infarction, as outlined by Benchimol,[5] were present in each patient preoperatively. In the transverse plane, the 20 msec QRS vector was directed posteriorly and to the left. The rotation of the main body of the QRS loop in the transverse plane was counterclockwise. The posterior position of the 20 msec QRS vector was confirmed in the sagittal plane. Vectorcardiographic criteria for inferior wall infarction[5] were present in three patients (Cases 1 to 3) with the 25 msec QRS vector being superior to the null point in the frontal and sagittal planes in these cases.

Right and left heart catheterization, ventriculography in the right anterior oblique projection and selective coronary arteriography in multiple oblique views were performed by standard techniques. Table II summarizes the

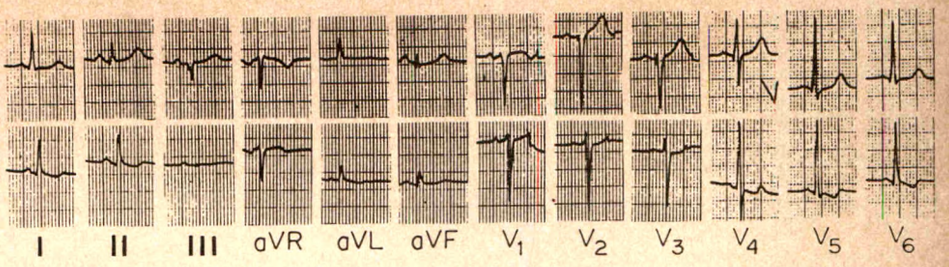

FIGURE 3. Case 3. The preoperative electrocardiogram **(top)** shows Q waves and diminutive R waves in leads V_1 through V_3. In the postoperative tracing, **(bottom)** the Q waves in the right precordial leads have disappeared and more normal R wave progression is evident.

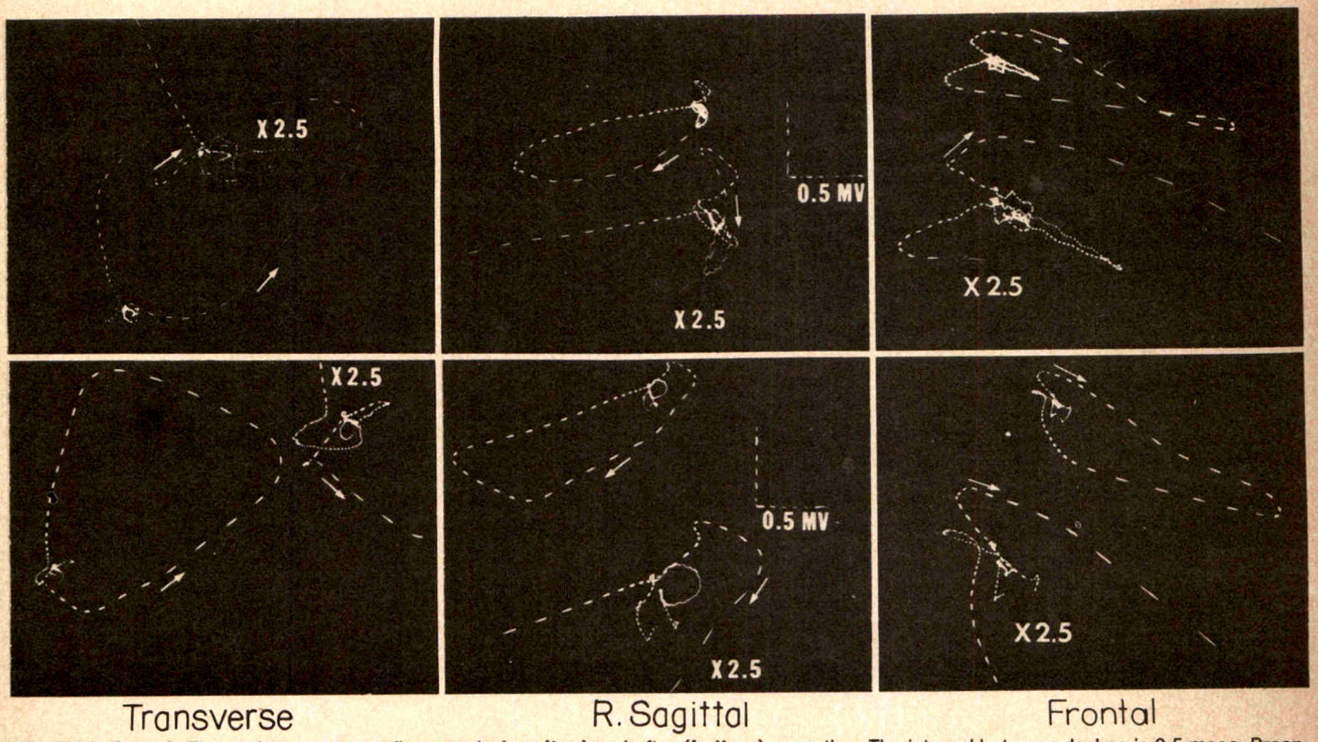

FIGURE 4. Case 3. Three-plane vectorcardiograms before **(top)** and after **(bottom)** operation. The interval between dashes is 2.5 msec. Preoperatively, there are patterns of anterior and inferior wall infarction. In the transverse plane the 20 msec vector is posterior to the null point. The postoperative tracings show augmentation of the anterior QRS forces, best seen in in the transverse plane. The abnormal superior direction of the initial forces is less marked postoperatively (right sagittal plane). Abnormal slowing of the initial and terminal forces is present in both the pre- and postoperative tracings.

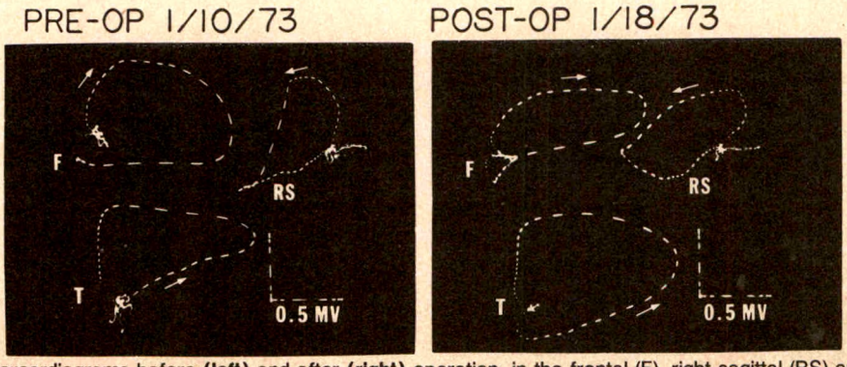

FIGURE 5. Case 1. Vectorcardiograms before **(left)** and after **(right)** operation, in the frontal (F), right sagittal (RS) and transverse (T) planes. The interval between dashes is 2.5 msec. In the preoperative record, the initial forces are clearly abnormal with the 20 msec vector posterior to the null point. Postoperatively, there has been regeneration of anterior QRS forces, best seen in the transverse plane. Both tracings demonstrate changes of an inferior wall myocardial infarction and superiorly directed forces (left axis deviation). Abnormal slowing of the initial and terminal forces is present in both the pre- and postoperative tracings.

pertinent cardiac catheterization findings. Right heart and pulmonary arterial pressures and resting values for cardiac output were normal in all patients. The left ventricular end-diastolic pressure at rest was normal in five patients and slightly increased in one patient (Case 6). Right anterior oblique ventriculograms revealed moderate to severe hypokinesia of the middle or distal anterior wall segments in four patients; abnormalities of contractility in the posteroinferior wall of the left ventricle were noted in two. Two patients (Cases 4 and 6) had normal preoperative ventriculograms.

Selective coronary arteriograms demonstrated severe proximal obstructive lesions in the left anterior descending coronary artery in all six patients. Triple vessel coronary disease was seen in two patients; three had severe disease of the right coronary artery.

All six patients underwent coronary arterial bypass surgery[6,7] with direct bypass of the severely stenosed left anterior descending coronary artery using the left internal mammary artery.[6] In two patients, vein bypass grafts to large anterior diagonal branches were also performed. In addition, vein bypass grafts were performed to major branches of the circumflex system in five patients and to the right coronary artery in two patients. Five of the six patients had multiple bypass grafts.

Results

Preoperative: All electrocardiograms showed typical patterns of transmural anterior wall myocardial infarction with Q waves in the right precordial leads. Postoperatively, in each instance, there was regeneration of R waves in these leads and loss of the pattern of definite infarction. Preoperative vectorcardiograms of the QRS loop showed abnormal initial forces compatible with an anterior wall myocardial infarction. In each case, the transverse and right sagittal planes showed the 20 msec QRS vector posterior to the null point.

Postoperative: Vectorcardiograms after operation showed return of normal initial anterior forces and loss of the preoperative pattern of anterior wall infarction. Postoperative transverse plane vectorcardiograms showed early initial forces to be rightward and anterior and the 20 msec QRS vector leftward and anterior to the null point. Pre- and postoperative scalar electrocardiograms and three-plane vectorcardiograms from two patients (Cases 2 and 3) are illustrated in Figures 1 to 4. Pre- and postoperative vectorcardiograms from Patient 1 are illustrated in Figure 5.

Postoperative vectorcardiograms demonstrated regeneration of anterior QRS forces without a significant change in the frontal plane QRS axis (Fig. 2, 4 and 5). Although left axis deviation was evident in the preoperative tracings (Fig. 2 and 5), it persisted in the postoperative vectorcardiograms. The lack of significant change in the frontal plane QRS axis precludes the possibility that improved conduction in the left anterior fascicle postoperatively or damage to the left posterior fascicle at operation caused the reappearance of anterior QRS forces in the sagittal and transverse plane vectorcardiograms. The slowing of the initial QRS forces, present in the preoperative vectorcardiograms of all six patients (Fig. 2, 4 and 5), might suggest that the abnormal posteriorly directed QRS forces were the result of aberrant ventricular conduction, but the persistence of slow initial QRS forces despite their more normal anterior direction postoperatively provides evidence against this suggestion. However, one cannot exclude with certainty the possibility that the postoperative vectorcardiograms represented a different form of aberrancy rather than normalization of the preoperative tracings.

Follow-up: All six patients have been free of symptoms of angina pectoris 3 to 18 months postoperatively. Two patients underwent cardiac catheterization 2 weeks and 3 months, respectively, after operation. In both cases, the left internal mammary artery bypass graft to the left anterior descending coronary artery was patent and functioning well. Vein bypass grafts to the circumflex system and to the right coronary artery were also patent. In both cases, ventriculography demonstrated improved motion of the hypokinetic anterior wall segments. The remaining four patients are asymptomatic but have been reluctant to undergo postoperative catheterization studies.

Discussion

Several studies have utilized pre- and postoperative electrocardiograms and vectorcardiograms to assess the incidence of myocardial infarction after coronary arterial bypass surgery. QRS changes of transmural myocardial infarction have been reported in 8 to 30 percent of patients having such surgery.[1,2,8–10] Despite the development of new Q waves many of these patients have an uncomplicated postoperative course[8,11] and many have unchanged or even improved left ventricular contraction on postoperative angiography.[11] Bassan et al.[11] suggested that in some patients after coronary arterial surgery new Q waves developed in the inferior leads as the result of relief of the anteroapical ischemia that had been canceling[12] the loss of opposing forces of an old infarcted area in the posteroinferior wall. They[11] also presented two cases of enhanced R waves in the precordial leads in electrocardiograms after bypass to the left anterior descending coronary artery. Our report describes six patients whose electrocardiographic patterns of anterior wall myocardial infarction were abolished after coronary bypass surgery and whose vectorcardiograms corroborated the loss of the infarction patterns and the return of normal anterior QRS forces postoperatively. The pre- and postoperative vectorcardiograms in our six cases clearly exclude the possibility that differences in lead placement or a canceling effect[12] of a new posterior wall infarction caused the electrocardiographic changes. Our observations suggest that the preoperative electrocardiographic and vectorcardiographic patterns of infarction were secondary to myocardial ischemia rather than an indication of frank infarction and that with revascularization surgery and improved perfu-

sion to ischemic areas anterior QRS forces returned to normal.

Myocardial ischemia and reversible electrical patterns of infarction: Earlier experimental and clinical reports[13–18] have shown that myocardial ischemia can produce electrically silent areas and reversible electrocardiographic patterns of myocardial infarction. Gross et al.[13] produced experimental myocardial ischemia in dogs by ligating either the circumflex or anterior descending coronary artery. In one third of their animals, typical Q waves appeared that disappeared within 3 to 5 minutes after removal of the ligature; subsequent pathologic studies failed to demonstrate significant myocardial necrosis. They concluded that the transitory Q waves represented a reversible stage of metabolic aberration of the myocardium during acute ischemia. Clinically, transient Q waves have been documented during coronary insufficiency[15] and attacks of angina pectoris[16] and during or after supraventricular or ventricular tachycardia.[17] Haiat and Chiche[4] have suggested that electrocardiographic patterns of myocardial infarction may disappear when there is recovery of superficial layers of ischemic myocardium surrounding an old infarcted area and that old patterns of infarction may reappear with subsequent ischemia to surrounding superficial layers of myocardium. Klein et al.[18] described transient electrocardiographic patterns of myocardial infarction including abnormal Q waves during open heart surgery. They attributed these transient patterns to reversible myocardial ischemia as the result of cross-clamping of the aorta, cardiopulmonary bypass, perfusion of the coronary arteries with cooled blood and localized abnormalities of membrane potentials and electrolytes. Their observations as well as our findings strengthen the concept that electrically inert areas of myocardium may be altered and do not always imply myocardial cell death. It appears that myocardial ischemia in certain instances can produce electrical patterns of infarction that may be reversible upon reestablishment of perfusion to ischemic areas.

Role of fascicular conduction defects: Left anterior fascicular block may be associated with diminutive anterior QRS forces and Q waves in the right precordial leads in scalar electrocardiograms in the absence of anterior myocardial infarction.[19,20] Theoretically, improved anterior fascicular conduction might lead to an augmentation of anterior QRS forces. Patient 2 (Fig. 1 and 2) had left anterior hemiblock preoperatively; postoperatively, left axis deviation was less marked although still present, and anterior QRS forces were dramatically increased. Since left axis deviation persisted in the postoperative frontal plane vectorcardiogram, improved anterior fascicular conduction is not a likely explanation for the generous augmentation of anterior QRS forces. The development of left posterior fascicular block in patients with anterolateral infarction may, in certain instances, cause disappearance of Q waves in the precordial leads of standard electrocardiograms.[21] In our six patients, postoperative vectorcardiograms did not show significant right axis shift in the frontal plane to implicate posterior fascicular damage. Hence, fascicular block contralateral to the infarcted area could not explain the disappearance of precordial lead Q waves in the scalar electrocardiograms or the appearance of more normal anterior QRS forces in the postoperative vectorcardiograms.

Focal intraventricular block involving septal forces: Abnormal slowing of initial QRS forces was noted in the preoperative vectorcardiograms of our patients. In all cases slow initial activation persisted in the postoperative vectorcardiograms in association with augmentation of anterior forces. One might conclude that the abnormal initial forces are the result of an intraventricular conduction disturbance and that postoperatively different electrical pathways are utilized. Gambetta and Childers[19] described two patients with coronary artery disease who had rate-dependent pathologic Q waves in leads V_1 to V_3 of scalar electrocardiograms. They suggested that these patients had a focal block in septal fibers of the left bundle branch system and that such a defect could underlie the development of transient right precordial lead Q waves seen in myocardial ischemia without frank infarction. There is now evidence to support the existence of such septal ramifications of the left bundle and, theoretically, block could take place at this level.[22] One might postulate that ischemia secondary to coronary arterial stenosis produced block in fibers responsible for normal septal activation and that successful revascularization allowed more normal or alternate conduction patterns to ensue. Whether abnormal initial QRS patterns simulating myocardial infarction and secondary to ischemia are the result of block in normal septal pathways or block at the level of the myocardium, these patterns are potentially reversible and do not always imply necrosis of heart muscle.

Electrical patterns of infarction and ventricular asynergy: In selecting patients for coronary arterial bypass surgery, it may be difficult to determine whether or not abnormalities of myocardial contraction on ventriculography are secondary to myocardial fibrosis or myocardial ischemia. Jacob et al.[23] recently attempted to utilize preoperative electrocardiograms and vectorcardiograms to predict the effect of coronary bypass surgery on localized areas of ventricular asynergy. They found that hypokinetic segments on ventriculography associated with electrocardiographic or vectorcardiographic patterns of infarction were less likely to improve after coronary bypass surgery than hypokinetic segments not associated with such patterns of infarction. Although our study reflects only a small percent of patients undergoing coronary arterial surgery, our observations indicate that preoperative electrocardiographic and vectorcardiographic patterns of infarction do not always imply irreversible myocardial damage. For example, before operation two of our patients had both a QRS pattern of anterior wall infarction in electrocardiograms

and vectorcardiograms and a normal pattern of anterior wall contraction in ventriculograms. Two additional patients who underwent postoperative cardiac catheterization studies manifested improved motion of hypokinetic anterior wall segments in ventriculograms as well as regeneration of anterior QRS forces in electrocardiograms and vectorcardiograms.

Clinical implications: The reappearance of anterior QRS forces in both the electrocardiograms and vectorcardiograms of six patients after coronary revascularization surgery supports previous clinical observations and experimental data suggesting that electrically silent areas of myocardium are not always synonymous with myocardial cell death. In certain patients, chronic myocardial ischemia may produce electrocardiographic and vectorcardiographic patterns indistinguishable from those of anterior wall myocardial infarction. In view of modern surgical techniques that, in selected cases, allow for successful myocardial revasulcarization, it is important to distinguish between myocardium that is chronically ischemic and that which is fibrotic and irreversibly damaged. The commonly held belief that Q waves in standard electrocardiograms can be equated with myocardial fibrosis and irreversible scarring is not always valid. Such electrocardiographic changes must be cautiously weighed along with other objective data in the evaluation of patients who are symptomatic with angina pectoris.

Significant Sex Differences in the Correlation of Electrocardiographic Exercise Testing and Coronary Arteriograms

MICHAEL H. SKETCH, MD, FACC
SYED M. MOHIUDDIN, MD, FACC
JOSEPH D. LYNCH, MD, FACC
ALLEN E. ZENCKA, MD
VINCENT RUNCO, MD, FACC

Omaha, Nebraska

Two hundred fifty-one patients (195 male and 56 female) referred for evaluation of chest pain were studied by multistage submaximal stress testing and selective coronary arteriography. In men with positive exercise tests the incidence rate of true positive exercise test results—that is, positive tests associated with 75 percent or greater coronary stenosis—was 89 percent in contrast to a 33 percent incidence rate of true positive exercise test results in women. The incidence rate of false positive excercise test results—that is, positive tests associated with no coronary stenosis or less than 50 percent stenosis—was 8 percent in men in contrast to 67 percent in women. Conversely, the incidence rate of false negative exercise test results (that is, negative exercise tests associated with 75 percent or greater coronary stenosis) was higher in men (37 percent) than in women (12 percent). It is concluded that in men a positive multistage stress test is useful in predicting the presence of significant coronary artery disease although a negative stress test cannot be relied upon to rule out the presence of significant disease. In women, a positive exercise test is of little value in predicting the presence of significant coronary artery disease, whereas a negative test is quite useful in ruling out the presence of significant disease. New criteria should be developed for stress testing of women.

The accuracy of different methods of stress testing in predicting the presence or absence of significant coronary artery disease has been variously reported.[1–8] Differences in the reported incidence of true positive and false positive exercise test results may be due to the type of exercise performed, the electrocardiographic leads recorded after exercise, the criteria by which an exercise test is interpreted as "positive" or "negative," or judged to be truly positive or falsely positive, and other factors such as drugs, electrolyte imbalance or associated disease. The studies of Lepeschkin[9] and Astrand[10,11] as well as the reviews by Bruce[12] and Blomqvist[5] suggest an important difference between men and women in their response to exercise. To our knowledge the influence of sex on the correlation between submaximal stress tests and selective coronary arteriographic results has not been reported.

This retrospective study describes our experience in correlating 12 lead electrocardiographic submaximal stress test results with the results of selective coronary arteriographic studies specifically evaluating the influence of sex upon this correlation.

TABLE I

Method of Scoring Severity of Coronary Disease

Single Lesion		Multiple Lesions	
Degree of Narrowing (%)	Index Score	Most Severe Degree of Narrowing (%)	Index Score
50–74	1	50–74	2
75–94	2	75–94	3
95–99	4	95–99	4
100	4	100	4

Each major coronary vessel received an index score according to this table. The sum of scores from all vessels represented the "severity index."

TABLE II

Distribution of Results of Exercise Tests and Coronary Arteriograms

Subjects	Total		Men		Women	
	no.	%	no.	%	no.	%
Total group	251	100	195	78	56	22
With positive exercise test (≥1 mm S-T depression)	77	31	62	32	15	27
With significant coronary artery disease (≥75 percent narrowing)	114	45	104	53	10	18
With narrowing of one or more vessels (≥50 percent)	122	49	111	57	11	20

Methods and Material

Patients: Two hundred fifty-one subjects referred for evaluation of chest pain were studied. There were 195 men (78 percent) and 56 women (22 percent). The mean age of the male subjects was 48.4 years (±9.2 standard deviation) and of the female subjects, 50.0 years (±8.4). Patients suffering from valvular heart disease, myocarditis or pericarditis, primary myocardial disease, anemia, thyroid disease or electrolyte imbalance were excluded. No patient was receiving digitalis, propranolol or quinidine sulfate during the 2 weeks preceding exercise testing.

Exercise testing: All patients performed graded treadmill stress testing according to the method of Bruce and Hornsten.[13] Exercise was discontinued when the patient attained a heart rate of 85 percent of maximal predicted for age,[14] complained of significant chest pain, shortness of breath, dizziness or lightheadedness or had S-T segment depression in excess of 3 mm. The mean postexercise heart rate in men was 141 beats/min (±19) and in women, 146 beats/min (±17). Standard 12 lead electrocardiograms were recorded at rest before exercise, immediately after exercise (within 30 seconds) and 2 and 6 minutes after exercise. Subsequent electrocardiograms were obtained if the 6 minute postexercise tracing revealed that the S-T segments had not returned to the preexercise configuration. The electrocardiograms were recorded with a Sieman Mingograph 6t recorder with patients in the supine position.

Postexercise electrocardiograms were classified as showing: (1) no S-T segment depression, (2) 0.5 to 0.9 mm S-T segment depression, (3) 1 to 1.9 mm S-T segment depression, (4) 2 to 2.9 mm S-T segment depression, or (5) 3 mm S-T segment depression. Only those postexercise electrocardiograms with 1 mm or greater S-T segment depression of at least 0.8 second's duration were considered positive tests. An additional requirement for a positive test was that the S-T segments be flat or downward sloping. If the resting electrocardiogram manifested nonspecific S-T segment depression at rest, a flat or downward sloping depression of 0.8 second's duration and at least 1 mm greater than that present at rest was also considered to represent a positive test. These changes could be present in any lead and at any time interval after exercise. Negative test results were recorded when the S-T segment depression was 0.9 mm or less.

Coronary arteriography: Selective coronary arteriographic studies were performed in all patients by the method of Sones and Shirey,[15] using a solution of 29.1 percent sodium diatrizoate and 28.5 percent meglumine diatrizoate containing 31 percent iodine (Renovist II®, E. R. Squibb and Sons) as the opacifying medium. Opacification was visualized with a General Electric 6 and 9 inch image intensifier, the output of which was recorded in both modes on 35 mm film at a rate of 60 frames/sec and on 105 mm film at a rate of 2 frames/sec. Multiple views of the coronary arteries in both the right and left anterior oblique projections were obtained in each case. All lesions were classified as single or multiple, and the severity of the lesions classified as narrowing of a vessel's diameter by less than 50 percent, 50 to 74 percent, 75 to 94 percent, more than 95 percent or total occlusion. A coronary arteriogram was considered positive and to indicate significant coronary artery disease if one or more major vessels manifested a stenotic lesion equal to or greater than 75 percent of its diameter in any projection. Patients with no angiographically visualized lesion or with stenosis of 49 percent or less of a vessel's diameter were considered, for the purpose of this study, to have normal coronary arteriograms or insignificant coronary artery disease. The severity of occlusive coronary artery disease was determined by calculating the "severity index" as outlined in Table I.

Results

Thirty-two percent of male subjects (62 of 195) and 27 percent of female subjects (15 of 56) had positive exercise tests. In contrast, 53 percent of men (104 of 195) as compared with only 18 percent of women (10 of 56) had positive coronary arteriograms manifesting significant coronary artery disease (that is, 75 percent or greater narrowing) (Table II).

False positive results: The correlation between exercise test results and arteriographically visualized coronary occlusive lesions is depicted in Table III. Overall, 78 percent (60 of 77) of the subjects (male and female) with positive exercise tests had angiographically demonstrated significant coronary occlusive lesions (75 percent or greater narrowing). This positive relation is due primarily to the high rate of correlation in men. In men, the incidence rate of true positive exercise test results was 89 percent (55 of 62), whereas in women it was only 33 percent (5 of 15). This difference is highly significant statistically

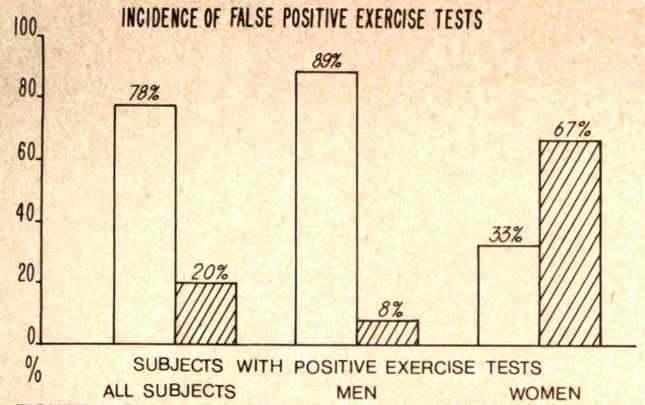

FIGURE 1. The marked difference in the incidence of false positive exercise tests between men and women is statistically significant (Table III). **Hatched bars** indicate percent of positive exercise tests associated with normal coronary arteries or less than 50 percent stenosis (false positive tests). **Open bars** indicate percent of positive tests associated with 75 percent or greater coronary stenosis.

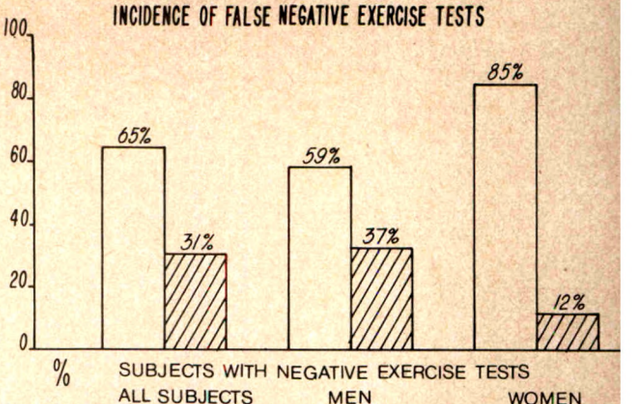

FIGURE 2. The difference in the incidence of false negative exercise tests between men and women is statistically significant (Table III). **Hatched bars** indicate percent of negative exercise tests associated with 75 percent or greater coronary stenosis (false negative). **Open bars** indicate percent of negative tests associated with normal coronary arteries or less than 50 percent stenosis.

(P <0.001). If one accepts 50 percent or greater narrowing as a significant lesion the relation remains essentially unchanged (Table III). From these incidence rates of true positive exercise tests, it follows that the overall incidence rate of false positive exercise tests is 22 percent, with an 11 percent incidence rate in men and a 67 percent incidence rate in women. This assumes, however, that all lesions in which a vessel was narrowed by less than 75 percent of its diameter were insignificant. If one accepts only lesions of less than 50 percent narrowing as insignificant the overall incidence rate of false positive exercise test results is 20 percent (15 of 77), with an 8 percent rate (5 of 62) in men and a 67 percent rate (10 of 15) in women. In both instances, the difference between sexes is again highly significant statistically (P <0.001) (Table III, Fig. 1).

False negative results: Overall, 31 percent (54 of 174) of the subjects (male and female) with negative exercise tests had angiographically demonstrated significant coronary occlusive lesions (75 percent or greater narrowing). In contrast to false positive exercise test results, the false negative exercise tests occurred primarily in male subjects. The incidence rate of false negative exercise test results was 37 percent (49 of 133) in men but only 12 percent (5 of 41) in women. Again the difference in incidence between sexes is statistically significant (P <0.01) (Table III, Fig. 2). These results are not significantly altered if one accepts 50 percent stenosis of a vessel as significant disease (Table III).

There was no significant difference in either the number of vessels involved or the severity of disease between men and women who were demonstrated to have either false positive or false negative exercise test results (Tables I and IV).

Electrocardiographic leads involved: The leads in which significant S-T segment depression (1 mm or more) occurred are depicted in Table V. In all

TABLE VI

Relation of Coronary Arteriographic Findings to Postexercise S-T Segment Depression

Coronary Arteriographic Findings	Degree of S-T Segment Depression					
	1–1.9 mm		2–2.9 mm		>3 mm	
	Men	Women	Men	Women	Men	Women
One or more vessels with ⩾50% narrowing	25	4	18	0	14	1
One or more vessels with ⩾75% narrowing	23	4	18	0	14	1
No narrowing or <50% narrowing	3	9	1	1	1	0

percent of men. This difference is statistically significant at the 95 percent confidence level. Further, 90 percent of women with false positive exercise tests had significant S-T segment depression in lead II in contrast to 40 percent of women with true positive exercise tests. This apparently useful point of differentiation is derived from a small population and is not statistically significant.

Comments

Exercise testing has proved to be one of the most useful noninvasive methods of evaluating ischemic heart disease. Unfortunately, discrepancy exists in reports that have evaluated the accuracy with which the results predict the presence of significant coronary artery disease.[1–7] To our knowledge, although the Master exercise test differentiates between male and female subjects,[16] there have been no reports as to the significance of sex in the interpretation of submaximal stress tests. Nevertheless, previously cited reports[5,9–12] suggest an important difference in the physiologic response of men and women to exercise.

Our study strongly supports the contention that there is a significant difference in the results obtained in the exercise testing of men and women. This difference may, at least in part, explain the discrepancies in the reported incidence of true and false positive exercise test results.

In our study, significant coronary artery disease was correctly predicted by exercise testing in 78 percent of all patients, both male and female, a statistic not differing greatly from data in other reported series.[3,6,7] However, separate analysis of our data indicates that the ability of an exercise test to predict correctly the presence of significant coronary artery disease is appreciably better in men (89 percent true positives) than in women (33 percent true positives). The overall incidence rate of false positive exercise test results in our series was 20 percent, which again is not very different from that of other reported series. It is extremely important to note, however, that the incidence rate in men was only 8 percent as compared with 67 percent in women. Further, our study reveals an overall occurrence of false negative exercise tests of 31 percent, but, in contrast to false positive exercise test results, the incidence was appreciably higher in men (37 percent) than in women (12 percent).

Neither the severity of disease nor the number of vessels significantly occluded correlated with these differences between the sexes. Although significant S-T segment depression occurred more frequently in leads II, III and aVF in women than in men, its presence in these leads did not aid in differentiating true and false positive exercise tests.

Although false positive exercise test results were rarely seen in the presence of greater than 2 mm of postexercise S-T segment depression, a depression in excess of 2 mm or even 3 mm is not an absolute predictor of the presence of significant coronary artery disease (Table VI).

Clinical implication: We conclude that, in men, a positive multistage exercise test is useful in predicting the presence of significant coronary artery disease; but a negative test cannot be relied upon to rule out such disease. In women, a positive exercise test is of little value in predicting the presence of significant coronary artery disease although a negative test is useful in ruling out its presence. We believe that new criteria should be developed for exercise testing of women and are investigating this possibility.

Cause of false positive tests in women: The explanation for this high and unacceptable incidence rate of false positive exercise test results in women is unclear. However, Bruce[12] has pointed out that postexertional S-T segment depression in middle-aged women may partly be due to lower levels of hematocrit and total circulating red cell mass. Further, recent unpublished observations by Kusumi and Bruce[12] have revealed "higher pulmonary and systemic resistances with higher pressure-rate products in asymptomatic middle-aged women who exhibit S-T depression after maximal exercise."

The use of digitalis glycosides is known to be associated with an increased incidence of false positive exercise test results.[17] Digitalis and estrogen have a similar chemical structure. One of the side effects of digitalis mimics an estrogen effect, that is, gynecomastia. Theoretically, therefore, it is conceivable that estrogens may at least be partially responsible for the high incidence rate of false positive exercise test results in women.

Acknowledgment

We most gratefully acknowledge the invaluable guidance and recommendations of Dr. Gunnar Blomqvist, University of Texas, during the preparation of this manuscript. Gratitude is also extended to Ms. Patricia Egge for her assistance in computer analysis of the data and to Ms. Sharon Sargent and Rhonda Jensen for technical assistance.

Addendum

A recent article (Cumming GR, Dufresne C, Kich L, et al: Exercise electrocardiogram patterns in normal women. Br Heart J 35:1055–1061, 1973) also noted a very high incidence rate of false positive exercise test results in women and stated that "exercise electrocardiography is of limited value in women."

Comparison of Angiographic and Postmortem Findings in Patients with Coronary Artery Disease

JARED N. SCHWARTZ, MD
YIHONG KONG, MD, FACC*
DONALD B. HACKEL, MD†
ALAN G. BARTEL, MD, FACC

Durham, North Carolina

The accuracy of coronary cineangiography in predicting the degree of stenosis in coronary arteries was evaluated by comparing autopsy and premortem cineangiographic findings in 25 patients. Coronary cineangiograms and autopsy specimens were reviewed independently by two cardiologists and two pathologists. Identical diagrams dividing the coronary arteries into 12 segments were used by both groups to record the location and degree of stenosis observed. Cineangiographic findings were in agreement with pathologic findings (less than 25 percent difference in cross-sectional luminal area) in 178 (79 percent) of the 226 segments examined, but overestimated the degree of stenosis in 13 (6 percent) and underestimated it in 34 (15 percent). Thus, cineangiography appears to be a reliable tool in evaluating coronary artery disease. When diagnostic errors are made, they are usually underestimations of the degree of disease; common causes of error are circumferential stenosis, eccentric lesions, obstruction of view by artificial valves and poor opacification due to severe proximal stenosis.

Successful application of surgical treatment of coronary artery disease greatly depends on accurate determination of the severity and location of the occlusive lesions in the coronary arterial system. The accuracy of coronary cineangiography is of critical importance not only in the diagnosis but also in the proper management of patients with coronary artery disease.

Angiography is generally accepted as a reliable tool in estimating the degree and extent of arterial disease although there are only a few studies correlating angiographic with anatomic findings.[1–6] These reports generally agree that when angiographic errors occur, they are usually underestimations of the stenotic lesions. However, there is no agreement on either the reliability of the technique or the cause of major errors.

This study of 25 patients was undertaken to compare premortem angiographic data with data on postmortem anatomic specimens of the coronary arteries. The reliability and accuracy of angiography, reasons for error and problems encountered due to poor visualization of vessels are analyzed.

Methods

Twenty-five patients who died after either aortocoronary bypass or valvular surgery, or both, between October 1968 and January 1973 were included in the study. All patients had selective coronary cineangiograms before surgery and only one did not have severe coronary artery disease. The interval between angiography and postmortem examination was less than 1 month in 16 cases, 1 to 4 months in 7 and greater than 4 months in 2 cases (the longest interval was 10 months).

Selective coronary cineangiograms in multiple projections were obtained with use of the Judkins transfemoral technique[7] and filmed at 60 frames/sec

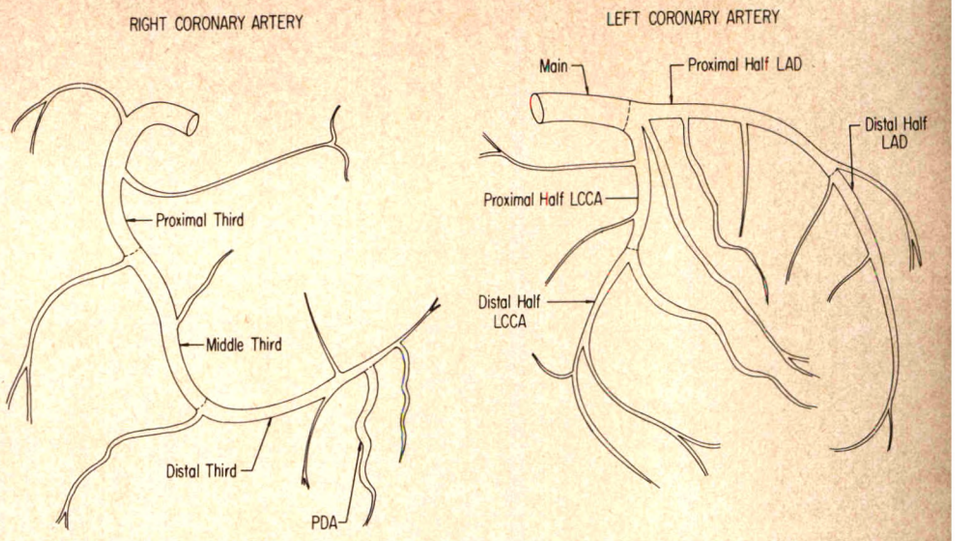

FIGURE 1. Diagram used to record lesions found in the coronary arteries by both anatomic dissection and cineangiography. LAD = left anterior descending artery; LCCA = left circumflex artery; PDA = posterior descending artery.

on 35 mm Kodak double X film. A Phillips cinefluorographic unit with a 5 inch image intensifier was used in eight cases and a Picker biplane unit with 9 inch image tubes and overframing lens was employed in nine; the remaining eight cases were studied with a Picker biplane Pulsar cinefluorographic unit with 6 inch image tubes and additional photographic magnification with zoom lenses. Since the result was not significantly different with respect to the cinefluorographic unit used, the data of all patients were analyzed as one group.

All cine films were reviewed independently by two angiographers without prior knowledge of the anatomic findings. The severity and location of all stenotic lesions were recorded on the diagrams shown in Figure 1. The degree of stenosis was estimated in percent decrease in luminal diameter. From these data, the percent decrease in cross-sectional area was then calculated for comparison with pathologic findings.

At the time of postmortem examination, the heart was removed in toto, photographed and weighed, and X-ray films were taken. Polyethylene catheters were then inserted into the coronary arterial orifices and tied into place. After flushing with normal saline solution, a fine colloidal suspension of barium (micro-opaque) was injected at 100 mm Hg of pressure over a 20 minute period. After fixation in 20 percent phosphate-buffered 0.02 molar formalin, radiographs of the heart were again obtained. If the coronary arteries were not calcified, they were examined in 2 to 3 mm serial sections. If calcium was present, the arteries were dissected free of the heart in toto and decalcified; X-ray films were taken and 2 to 3 mm serial sections examined. The specimens were reviewed by two pathologists, and the location and severity of stenosis in terms of percent decrease in cross-sectional area were recorded on diagrams identical to those used by the cardiologists.

The angiographic and pathologic findings were then compared using the latter as the standard of accuracy. Whenever, for technical reasons, an accurate evaluation of a segment could not be made from either the angiogram or the pathologic specimen, that segment was not included in the comparison. For example, segments were excluded for the following reasons: (1) inadequate opacification during premortem angiography, (2) surgical removal of lesions by endarterectomy, (3) distortion of the ostium as a result of postmortem insertion of a cannula, and (4) inadequate postmortem decalcification resulting in distortion of the lumen.

Correlation between the studies was recorded as follows: Complete agreement was designated if the anatomic and angiographic estimations of luminal area were within 25 percent of each other. When the in vivo angiographic estimation of luminal area was less than that found postmortem, the underestimation was quantified as −1 when the difference was 25 to 49 percent, −2 when it was 50 to 74 percent and −3 when it was 75 percent or more. When angiography overestimated the degree of stenosis, overestimations were similarly graded from +1 to +3.

Results

Table I shows the segments examined, the frequency of agreement between the findings and the degree of error when disagreement occurred. In both the right and left coronary arteries the correlation between angiographic and anatomic findings was significantly greater in the proximal than in the distal segments ($P < 0.05$). Among 226 segments studied the findings were in agreement in 179 (79 percent); overestimations occurred in 13 (6 percent) and underestimations in 34 (15 percent). Thirteen of the latter (6 percent) were underestimations of 75 percent or greater.

Since 75 percent stenosis of a vessel is generally accepted as the point where blood flow is significantly decreased,[8] we examined the reliability of angiographic estimates in relation only to vessels with 75 percent or greater narrowing (Table II). No statistically significant difference was found in the accuracy of angiographic estimates between proximal and distal segments, perhaps because of the small number of these segments with severe lesions. However, the disagreements that did occur in this group were almost always underestimations of 75 percent or greater.

There were 17 segments that could not be visualized by cineangiography but were examined anatomi-

*−1, −2 and −3 indicate angiographic underestimations of 25 to 49, 50 to 74, 75 or greater percent, respectively. +1 and +2 indicate angiographic overestimations of 25 to 49 and 50 to 74 percent, respectively.

Dist = distal; LAD = anterior descending branch of left coronary artery; LCA = left coronary artery; LC = left circumflex artery; Mid = middle; PDA = posterior descending artery; Prox = proximal; RCA = right coronary artery.

cally (Table III). Except for the diagonal branch, all segments not visualized were in more distal parts of the vessel, and all 17 segments were distal to a stenosis of 75 percent or greater in the more proximal segment. Within the nonvisualized segments stenotic lesions of 75 percent or greater were found in 10 (59 percent), and stenosis of 50 to 74 percent was found in 6 (35 percent).

Reasons for major errors: The 13 segments in which underestimations of 75 percent or more occurred were examined to determine the reason for these major errors. Figure 2 illustrates some of the sources of error that were found. Vessels with elongated circumferential lesions were often interpreted as "small but otherwise normal" on the basis of angiograms, but anatomically some of these vessels were 90 percent occluded; two of the 75 percent underestimations were made because of this type of lesion. Eccentric, slitlike or "fish mouth" lesions were implicated in four underestimations. In two hearts prosthetic valves were the cause of major errors due to obstruction of view. The probable cause of some misinterpretations was a severe proximal lesion. If a proximal vessel was obstructed by a lesion of only 25 percent or less, there was 82 percent agreement in the findings in the distal vessels. However, when there was a stenotic lesion of 75 percent or more in the proximal vessel, the accuracy of angiographic interpretation of distal vessels decreased to 63 percent.

Discussion

This study demonstrates that cineangiography is a reliable tool in the evaluation of coronary artery disease. However, occasional major errors do occur, usually underestimations of the obstruction of the luminal area, predominantly in vessels that have severe disease. There is also a greater incidence of error in distal segments, which may be due to the smaller caliber of vessels distally and to the streaming of contrast medium and inadequate opacification distal to lesions in the proximal segments.

Although the exact reasons for some of the misinterpretation could not be determined, the cause of error was found in many cases. Circumferential lesions with a central lumen involving a long segment were a frequent source of error. This problem occurred because angiography visualizes the vessel lumen but not the vessel wall, and the luminal size in areas adjacent to the lesion is frequently used as normal reference in determining luminal diameter. When the entire artery, or even many vessels in the same heart, is diseased, these comparisons can be misleading because of the lack of a true normal frame of reference. Eccentric or "fish mouth" lesions also accounted for a few errors. When viewed from one angle, the eccentric lesions may appear normal and thus lead to serious error. Artificial valves in this series were related to two errors caused by obstruction of view. The last major reason for error was the presence of severe proximal lesions because contrast medium does not always fill the distal segment adequately for proper evaluation. One must be cautious, therefore, when interpreting luminal patency distal to a severe proximal lesion. This is particularly important when aortocoronary bypass surgery is contemplated. In this regard, it is also important to note that 17 segments that could not be visualized on angiography had significant disease throughout their

entire length and were not suitable for bypass grafting.

Review of previous correlative studies: Although there are several reported studies correlating the angiographic and anatomic findings in patients with coronary artery disease, many include only a small number of patients, compare only the postmortem angiogram with the anatomic findings, or include patients with a prolonged time interval between angiography and death. In 1962, Grey et al.[1] compared postmortem coronary angiograms with anatomic findings in 13 patients. Among 93 segments that appeared normal or minimally diseased (questionable narrowing) in postmortem angiograms, 39 (42 percent) were found to have more severe disease on postmortem dissection. Eusterman et al.[2] carried out a similar study in 50 postmortem hearts. With focal stenosis, there was an excellent correlation between the angiographic and the anatomic findings. However, in arteries with diffuse disease, they found that the angiographic data underestimated the severity of disease in 86 percent of the segments and overestimated it in 3 percent. In 1963, Hale et al.[3] concluded from a study of four patients that "the worst possible assessment of a lesion demonstrated in life is probably the more accurate." Kemp et al.[4] in 1967 evaluated the accuracy of 29 premortem angiograms with postmortem anatomic data. They divided arteries into five segments, and found only three errors of functional significance. The quality of the arteriogram was judged the most important factor in accurate evaluation. Vlodaver et al.[5] studied 10 cases, comparing premortem angiograms with postmortem examination of the anatomic lesions. They called an

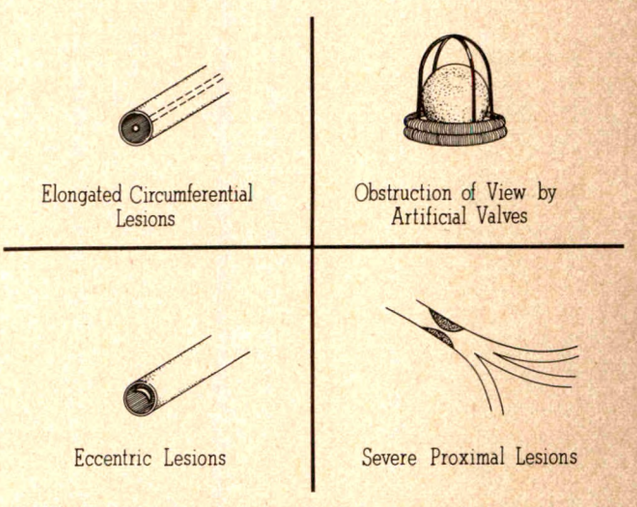

FIGURE 2. Pictorial representation of causes of cineangiographic underestimations with 75 percent or more stenosis.

error false negative if the coronary arteriogram showed less than 50 percent obstruction of luminal diameter when the anatomic lesion was actually more than 50 percent obstructed. An error was called false positive if the reverse was true. They divided vessels into six segments. Of a total of 134 segments examined, data were in agreement in 86 (64 percent); there were 44 (33 percent) false negatives and 5 (4 percent) false positives. In their study the intermediate segment of the right coronary artery (our middle third), the main left coronary artery and the proximal half of the circumflex artery were all particularly prone to underestimation. Slitlike or eccentric lesions were also common sources of error.

Grondin et al.[6] studied 28 patients who died after saphenous vein bypass grafting. In only 23 of these cases were both the preoperative angiograms and postmortem specimens suitable for comparison. They found nine instances of major disagreement between the two techniques. A variety of explanations were given, including circumferential lesions, overlapping of vessels, diffuse disease and short takeoffs of vessels.

Our data agree with previous findings that coronary cineangiography is an accurate tool in defining coronary anatomy. When error occurs, angiography frequently underestimates the lesion. In addition, accuracy is reduced in more distal parts of the arterial tree, especially in the presence of severe stenosis in the proximal segment. When a segment cannot be opacified either by antegrade or retrograde filling, it is usually found to be severely diseased on postmortem dissection.

Clinical implications: To improve the accuracy of coronary cineangiography, it is imperative to opacify the coronary arteries selectively and in appropriate projections to assure that all segments of the arterial tree are adequately visualized in a plane perpendicular to the X-ray beam. In addition to the multiple still projections, we have found that cineangiograms obtained while the patient is being rotated on a cradle are very helpful in detecting lesions that can be identified only at certain angles of rotation. The half-axial projection, as recently described by Bunnell et al.,[9] and the sagittal angulated view, as described by Lesperance et al.,[10] are also useful, especially for evaluating the proximal segment of the left coronary artery. A thorough examination of the coronary arterial trees and their lesions through a video recording system before the completion of the procedure is also essential in assuring the adequacy and accuracy of the study.

Effect of Practolol on Left Ventricular Dimensions During Coronary Occlusion

JON LEKVEN, MD

Oslo, Norway

Beta adrenergic blockade has been suggested to improve the myocardial oxygen balance during ischemic conditions. This investigation was undertaken to examine the effects of practolol, a relatively cardiospecific beta adrenergic blocking agent, on regional myocardial dimensions and shortening during acute coronary arterial occlusion in dogs. Local myocardial dimensions were measured ultrasonically in ischemic and nonischemic regions of the left ventricle. Myocardial dilatation and marked reduction in systolic shortening occurred in ischemic regions after occlusion, whereas nonischemic regions were only moderately dilated. Administration of 10 to 20 mg of practolol exerted different effects in the two ventricular regions; myocardial dilatation was reduced and the systolic shortening increased by practolol in ischemic regions, whereas further dilatation and diminished shortening occurred in nonischemic control regions. Similar results were obtained when heart rate was kept constant by atrial pacing during beta adrenergic blockade. Thus, practolol improved the function in ischemic ventricular regions, and restored ventricular stroke volume to preocclusion levels, probably as a result of improved myocardial oxygen balance.

Favorable effects of the cardioselective beta adrenergic blocking agent practolol, 4-(2-hydroxy-3-isopropyl amino-propoxy) acetanilide, in patients suffering from acute myocardial infarction have recently been reported.[1] Although this effect might to some extent be attributed to the antidysrhythmic properties of practolol,[2] improvement of the myocardial oxygen balance is suggested from the finding that practolol reduced S-T segment elevation after acute coronary occlusion.[3,4]

Although beta adrenergic blockade is known to cause an overall reduction in myocardial oxygen consumption,[5,6] a concomitant rise in ventricular volume has been demonstrated,[7] which might increase myocardial oxygen demands.[8] However, little is known about the mechanical events in ischemic myocardial tissue as influenced by beta adrenergic blocking agents. Reduced myocardial oxygen supply leads to myocardial dilatation in end-diastole and reduced myocardial shortening.[9] Interventions leading to improved myocardial shortening or reduced ischemic dilatation should thus be regarded as favorable for ventricular function. In this investigation the effects of practolol on myocardial shortening and end-diastolic myocardial dilatation in left ventricular regions acutely deprived of coronary blood supply were studied utilizing ultrasonic measurements of local myocardial dimensions.[10]

Methods

Animal preparation: Twelve healthy mongrel dogs, weighing 17 to 29 kg, were anesthetized by intravenous administration of sodium pentobarbital, 25 mg/kg body weight, followed by maintenance doses of 50 mg at intervals. The heart was exposed through incision in the fifth left intercostal space, and ventilation maintained by a positive pressure respirator (Cyclator Mk. II, British Oxygen Co., London). The left anterior descending coronary artery was dissected free 0.5 to 2 cm from its origin and a ligature placed loosely around the vessel. Instantaneous myocardial dimensions were measured by ultrasonic transmission between two piezoelectric crystals of lead zirconate titanate (0.5 by 1 by 3 mm) sewn into the left ventricular wall 9 to 11 mm apart at a depth of 5 to 8 mm from the epicardial surface[10]; the frequency response was 40 cycles/sec. The distance between the elements is called myocardial chord length and represents the resultant movement of the muscle fibers between the elements. Provided that postoperative examination showed that myocardial chord length was parallel to the predominating local fiber orientation, high correlation existed between myocardial chord length and thermodilution determinations of left ventricular volume during great variations in ventricular preload and contractility.[10] One pair of elements was placed in the region supplied by the coronary artery to be occluded, and another pair clearly outside this region for control purposes.

Left ventricular pressure was measured by a Statham P23Gb transducer connected to a short catheter introduced through the apex, and the first derivative of left ventricular pressure, dP/dt, was continuously recorded from the pressure channel. Phasic blood flow in the ascending aorta was measured by an electromagnetic flowmeter (Nycotron, model 367, Oslo), and left ventricular stroke volume was determined by beat to beat integration of the flow signals. In three dogs heart rate was kept constant by pacing the right atrium (Grass Instruments model S4G) with pulses of 1 msec at an effective voltage of 1.5 to 2.5 v.

Experimental procedure: After control observations were recorded, the coronary artery was occluded by a May-

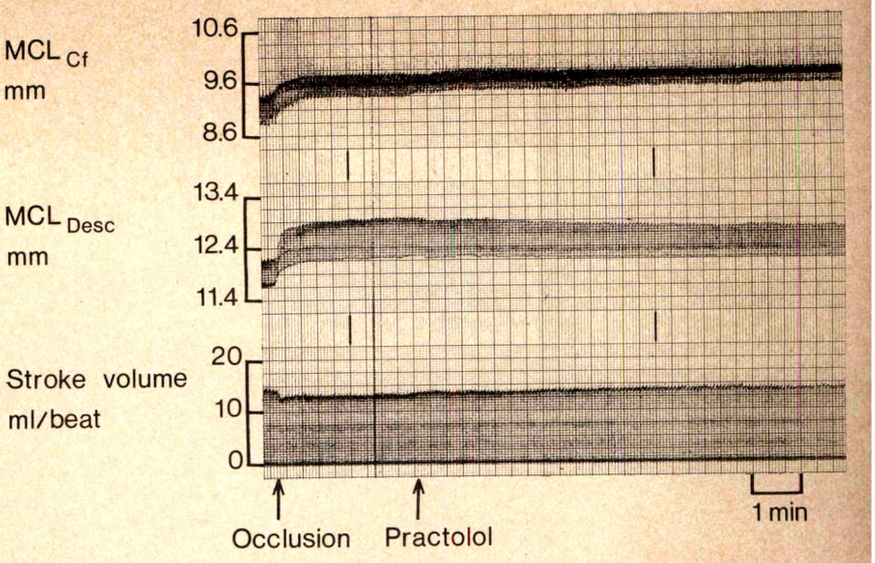

FIGURE 1. Dog 2. Effects of practolol during occlusion of the left anterior descending coronary artery. Recordings of local myocardial chord lengths (MCL) in the ventricular region supplied by the occluded left anterior descending coronary artery (Desc) and by the left circumflex coronary artery (Cf), which was not occluded. Upper margin of tracing denotes the end-diastolic myocardial chord length.

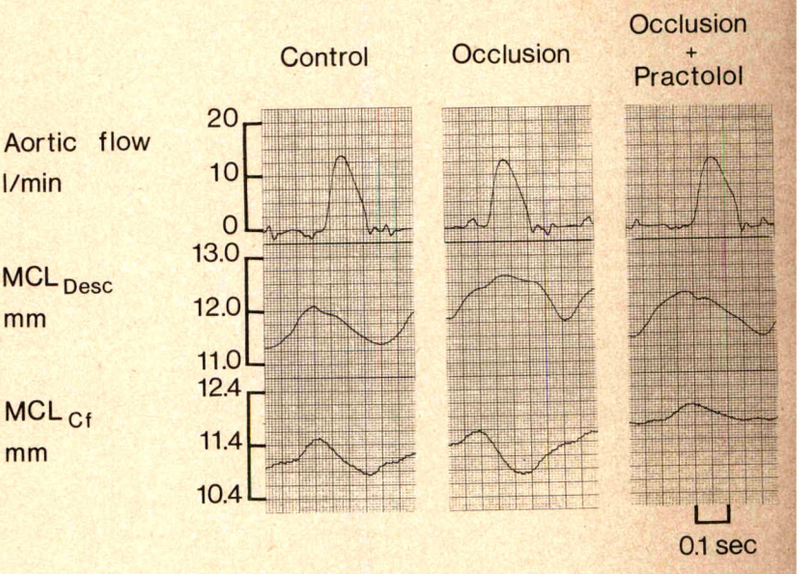

FIGURE 2. Dog 6. Pattern of myocardial shortening during occlusion of the left anterior descending coronary artery before and after administration of practolol. Local myocardial chord lengths (MCL) were recorded in the ventricular region supplied by the descending artery (Desc) and by the nonoccluded left circumflex coronary artery (Cf).

field clip. Redetermination of ventricular dimensions, pressures and flow was performed 3 to 5 minutes after occlusion. Then 10 to 20 mg of practolol (Eraldin, Imperial Chemical Industries, London) was given intravenously over 1 to 3 minutes, and new determinations were made 10 minutes after administration of practolol. All recordings were made during steady hemodynamic conditions.

Immediately after the dogs were killed by administration of an overdose of sodium pentobarbital, Evans blue dye was injected into the coronary artery at the site of former occlusion and colored tissue was isolated and weighed. On average, 34.3 percent of left ventricular weight (range 21.8 to 41.5 percent) had been rendered ischemic by coronary occlusion.

Statistical analysis: Each dog served as its own control. Student's t test for paired data was used to calculate probability values (P).[11] A value of $P > 0.05$ was regarded as not statistically significant.

Results

Tables I and II present the hemodynamic and dimensional effects of coronary arterial occlusion and intravenous administration of practolol in nine dogs with spontaneous cardiac rhythm.

Effects of coronary occlusion: Occlusion of the left anterior descending coronary artery was followed by marked end-diastolic dilatation in regions supplied by this artery (Fig. 1). Myocardial dilatation also occurred in nonischemic control regions supplied by the left circumflex coronary artery, and left ventricular end-diastolic pressure was increased by 2.8 ± 0.5 mm Hg ($P < 0.001$). However, end-diastolic dimensions as estimated by myocardial chord length increased more in ischemic than in nonischemic regions ($P < 0.001$).

A changed contraction pattern of the ischemic myocardium was observed during coronary arterial occlusion. In this part of the left ventricle shortening during ventricular systole was largely reduced (Table II), whereas considerable myocardial shortening occurred in early diastole (Fig. 2). Total amplitude was thus apparently increased in ischemic regions during

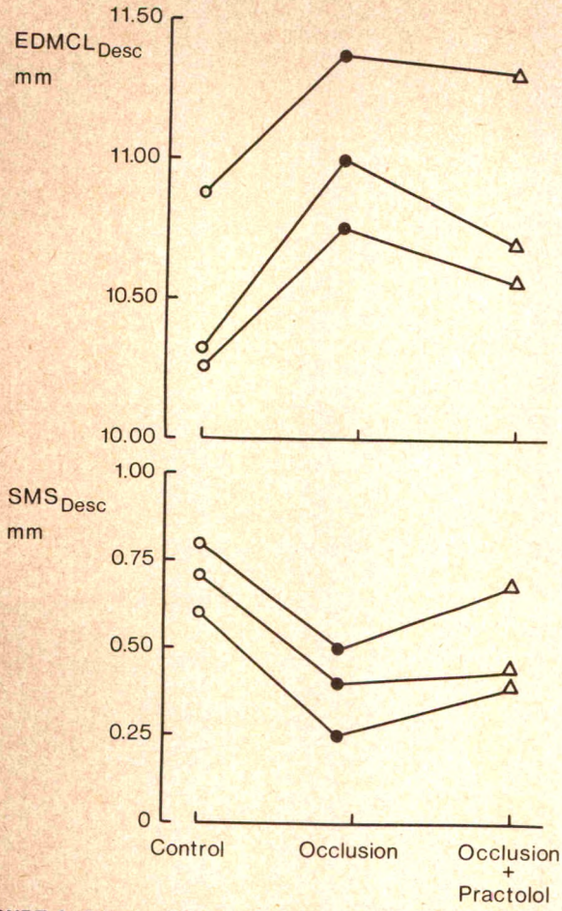

FIGURE 3. Effects of practolol during occlusion of the left anterior descending coronary artery in three dogs with a heart rate kept constant by right atrial pacing. End-diastolic myocardial chord length (EDMCL) and systolic myocardial shortening (SMS) were measured in ventricular regions supplied by the anterior descending artery (Desc).

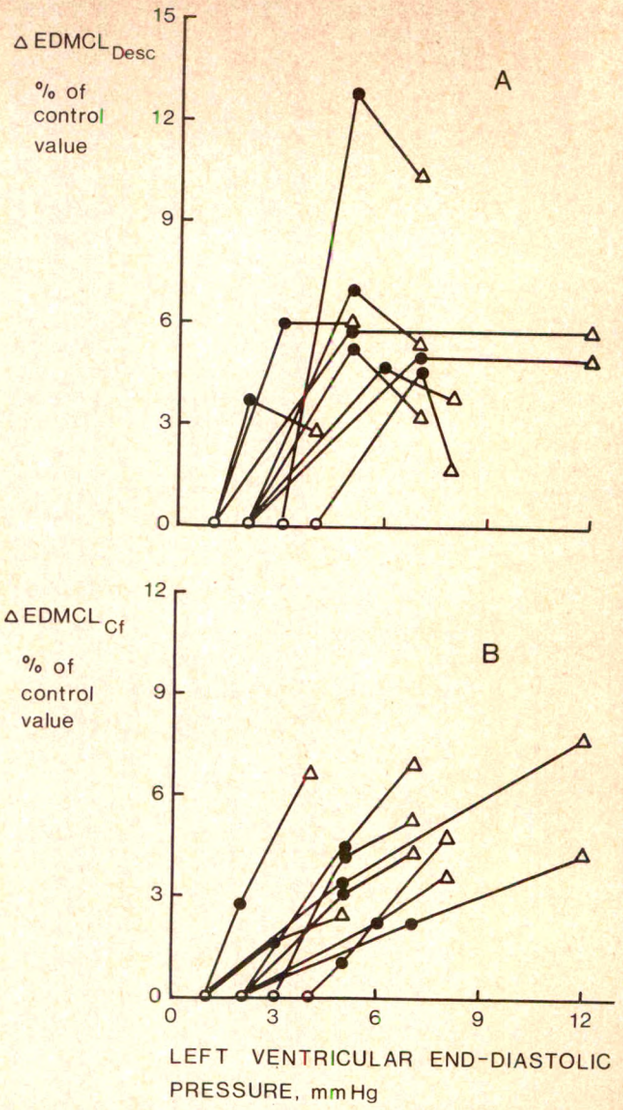

FIGURE 4. Relation between left ventricular end-diastolic pressure and changes in end-diastolic myocardial chord length (ΔEDMCL). **A,** measurements from ventricular regions supplied by the occluded left anterior descending coronary artery (Desc). **B,** measurements from control regions supplied by the nonoccluded left circumflex coronary artery (Cf) Open circles = prior to occlusion; closed circles = during occlusion; triangles = after administration of practolol.

occlusion in most of the experiments (Fig. 1). In nonischemic control regions the systolic myocardial shortening remained unchanged during occlusion.

Left ventricular performance was reduced by coronary occlusion, as evidenced by lower values for stroke volume, cardiac output, dP/dt and left ventricular systolic pressure (Table I).

Effects of practolol: With the coronary artery still occluded, administration of practolol restored stroke volume almost to control levels, although dP/dt was further reduced (Table I). End-diastolic ventricular dimensions in nonischemic regions—and the end-diastolic ventricular pressure—increased further from the values obtained during occlusion alone, whereas the ischemic myocardial dilatation in occluded areas was reduced; however, control levels were not regained during beta adrenergic blockade in any experiment. Practolol diminished the early diastolic myocardial shortening in occluded areas, and a significantly greater portion of shortening occurred in ventricular systole (Fig. 2). In nonischemic regions practolol gave an opposite effect by reducing systolic myocardial shortening (Table II).

Left ventricular systolic pressure remained unchanged during beta adrenergic blockade with practolol. Cardiac output was reduced by 161 ± 47 ml/min ($P < 0.01$) after administration of practolol because the decrease in heart rate was greater than the increase in stroke volume.

In three dogs the heart rate was kept constant (average 141 beats/min) by right atrial pacing. The dimensional measurements are presented separately, and it appears from Figure 3 that the results obtained during administration of practolol were similar to results in the hearts with spontaneous rhythm.

End-diastolic pressure/dimension relation: End-diastolic myocardial chord length in ischemic

regions increased by an average of 6.1 ± 0.9 percent of control value after coronary occlusion, whereas nonischemic chord length increased by only 2.7 ± 0.4 percent (Table II). Although left ventricular end-diastolic pressure was not similarly increased in individual experiments (Fig. 4), the highly significant difference in regional dimensions ($P < 0.001$) indicates a changed pressure/dimension relation in end-diastole during acute myocardial ischemia because ventricular pressures were always identical in the two regions. The reduction of end-diastolic myocardial chord length in occluded regions affected by practolol brought the pressure/dimension curve in these regions close to that obtained in nonischemic ventricular regions (Fig. 5). The measurements therefore indicate that administration of practolol tends to normalize the changed end-diastolic pressure/dimension relation during acute coronary occlusion.

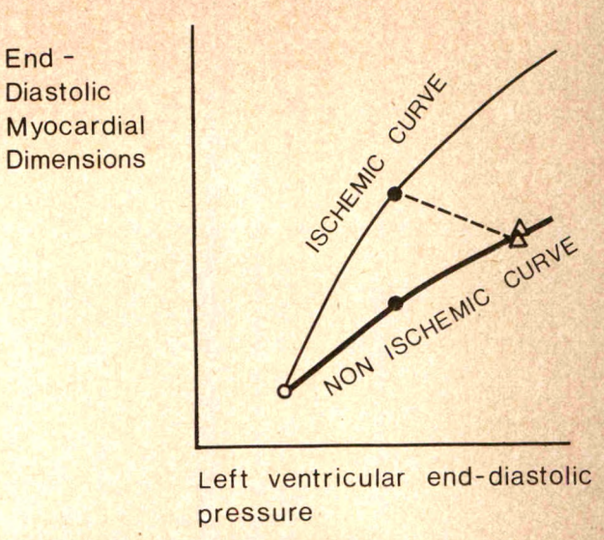

FIGURE 5. Scheme, calculated from the mean values in Figure 4, of the ventricular pressure/dimension relation in ventricular regions rendered ischemic by coronary arterial occlusion and in nonischemic control regions. Open circles = prior to occlusion; closed circles = during occlusion; triangles = after administration of practolol.

Discussion

Practolol and increased systolic myocardial shortening: The most important finding in this investigation was that practolol increased systolic myocardial shortening, which had been largely reduced by coronary occlusion. Although variable effects of practolol on stroke volume and contractility have previously been reported,[4,12] left ventricular dP/dt and systolic myocardial shortening in nonischemic control regions were clearly reduced by practolol in this study. It is therefore reasonable to attribute restoration of stroke volume to an increased myocardial shortening in the ischemic regions. This represents an obvious improvement of ventricular function by practolol during acute coronary occlusion.

Practolol and improved myocardial oxygen balance: It is generally believed that practolol does not increase myocardial oxygen supplies[13] but diminishes net myocardial oxygen requirements through reduction in the contractile state and heart rate,[5,6] although an accompanying ventricular dilatation[7] might increase the myocardial oxygen demands.[8] Recent studies[3,4] have revealed that S-T segment changes after coronary occlusion in dogs and myocardial infarction in patients were reduced by practolol, indicating an improved myocardial oxygen balance. Since a close relation between myocardial oxygen consumption and ventricular dilatation has been demonstrated during graded myocardial ischemia,[9] reduced ischemic dilatation by practolol indicates improved myocardial oxygen balance. A negative chronotropic action of practolol undoubtedly reduces myocardial oxygen demands.[8] However, since improved function of the ischemic myocardium could be demonstrated during constant atrial pacing, reduced end-diastolic dimensions and wall tension[8,9] might also represent a reduction in the myocardial oxygen requirements, thus permitting increased systolic shortening. Thus, in addition to the antidysrhythmic properties of practolol, its ability to improve myocardial oxygen balance through these mechanisms constitutes the rationale for use of this agent in patients with acute myocardial infarction.

Practolol and redistribution of myocardial blood flow: A relative redistribution of coronary blood flow to ischemic areas has been demonstrated after administration of propranolol to hearts with occluded coronary arteries.[14] If such a mechanism also applies to practolol, this could contribute to improved myocardial oxygen balance and function, mainly in ischemic subendocardial layers. The demonstration in this study that improvement of mechanical function within the ischemic third of the left ventricle after beta adrenergic blockade is associated with concomitant reductions of systolic myocardial shortening within the nonischemic two thirds, ventricular contractility as a whole and dP/dt might be explained by redistribution of myocardial blood flow.

Practolol and improved myocardial metabolism: On the other hand, could myocardial oxygen balance also be improved by beta adrenergic blocking agents through metabolic mechanisms? It has been demonstrated that antilipolytic agents reduce S-T segment elevation after acute coronary occlusion,[15] probably by inhibiting myocardial lipolysis evoked by release of endogenous catecholamines in acutely ischemic tissue[16] and leading to a relatively oxygen-expensive consumption of free fatty acids. Antilipolytic activity of practolol has been demonstrated in isolated fat cells[17] and, if this applies also to in vivo myocardial lipolysis, myocardial oxygen requirements might thus be reduced in acutely ischemic myocardial tissue. Furthermore, it has recently been reported[18] that beta adrenergic blockade with propranolol permitted enhanced glycogenolytic energy production during anoxia in rat hearts.

Thus, several mechanisms for improvement of myocardial oxygen balance by beta adrenergic block-

ing agents are proposed although it is not known which is the most important or why oxygen requirements of ischemic myocardial tissue are reduced if increased blood supply may be present. Although these measurements provide no direct information on myocardial oxygen balance, they indicate that the mechanical function of the acutely ischemic myocardium benefits from beta adrenergic blockade by practolol.

Practolol and changes in myocardial compliance: Use of left ventricular end-diastolic pressure measurements to assess cardiac failure has among its limitations dependence on a constant ventricular pressure/volume relation.[19,20] Whereas increased end-diastolic pressure during coronary heart disease is commonly interpreted as an indication of incipient heart failure, the measurements reported here describe a situation after administration of practolol in which improved function of acutely ischemic myocardial tissue is associated with increased ventricular end-diastolic pressure. This finding thus emphasizes the reservations to use of ventricular end-diastolic pressure as a reliable index of ischemia or heart failure. Decreased ventricular compliance has been demonstrated in patients within a few days of myocardial infarction and in patients with chronic coronary artery disease.[21] However, the observations in this study suggest an increased ventricular compliance in end-diastole in the ischemic regions immediately after coronary occlusion. Compliance is defined as dV/dP, where V is volume of the left ventricle and P its intracavitary pressure. Since myocardial chord length increased significantly more within ischemic regions than within control regions, dV/dP must be greater in ischemic areas because the two regions have identical—and increased—ventricular pressures. Although ventricular pressure and dimensions were obtained during steady hemodynamic conditions, they were measured within the time limit of 20 to 30 minutes for development of irreversible cell injury.[22] It is therefore credible that after acute coronary occlusion compliance is initially increased in affected ventricular regions and later decreased, a change that might be explained by the pathologic-anatomic alterations and cell death in the early healing phase.[23] The observations in this study also indicate that practolol normalizes the increased compliance during acute ischemia. This finding implies that the ischemic myocardial tissue becomes capable of operating a more propitious Frank-Starling curve after beta adrenergic blockade, as was indicated by increased systolic shortening and stroke volume ejection after administration of practolol.

This study examines the effects of graded reduction in regional coronary perfusion and changes in arterial oxygen concentration upon regional myocardial function and left ventricular function. In 14 open chest dogs, the distal left anterior descending coronary artery was cannulated and perfused at different pressures with blood equilibrated with either 21 or 95 percent oxygen, and regional function in the perfused myocardial segment was determined by use of the pressure-length loop. The mass of perfused left ventricular myocardium was determined by injection of sodium fluorescein at a constant pressure of 100 mm Hg. Regional function decreased minimally as coronary perfusion pressure and flow were reduced to 50 to 65 mm Hg and 25 to 55 ml/min per 100 g, respectively. When pressure and flow were reduced below these critical ranges, regional function decreased sharply. Changes in left ventricular function were comparable but of lesser magnitude. The relations between regional function or left ventricular function and coronary perfusion were not affected by changing arterial oxygen concentration, except at the low range of coronary perfusion pressures (22±6 mm Hg), at which pressure regional function was significantly lower ($P < 0.025$) in the experiments with 95 percent oxygen. Thus, the sensitivity of myocardial performance to a decrease in effective coronary perfusion pressure and flow is remarkably dependent upon whether pressure and flow are above a critical level.

Severe coronary arterial stenosis is frequently associated with a reduction in regional blood flow and myocardial ischemia. However, the precise relation between regional coronary perfusion and regional dysfunction is not firmly established. Although it has been shown that a substantial reduction in main left coronary arterial blood flow and perfusion pressure reduces total left ventricular performance,[1–5] insufficient information is available describing regional myocardial function at levels of coronary perfusion that are below normal. These measurements have recently assumed particular clinical relevance with the use of agents that reduce peripheral vascular resistance in the therapy of heart failure due to acute myocardial infarction.[6] Since such agents often reduce coronary perfusion pressure, it is important to know to what extent the perfusion pressure may be decreased before myocardial function in an ischemic area begins to deteriorate.

Although regional coronary perfusion in patients is dependent upon both the aortic pressure and the degree of coronary stenosis, an experimental model in which regional coronary perfusion is carefully controlled may give some insight into the clinical situation. In the experimental animal, regional myocardial function can be studied at various levels of regional coronary perfusion. A sensitive and reproducible method for quantitating regional myocardial contractile function has recently been developed in this laboratory.[7,8] The technique

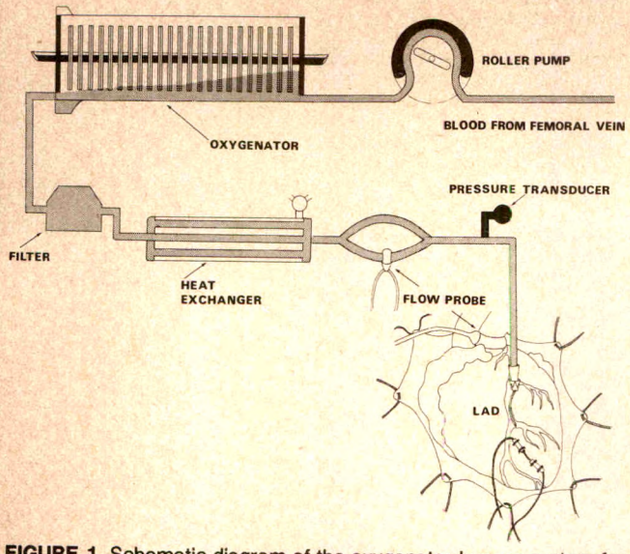

FIGURE 1. Schematic diagram of the oxygenator-bypass system for perfusion of the distal left anterior descending coronary artery (LAD). Blood was withdrawn from the femoral veins, pumped through a disc oxygenator in which the blood was equilibrated with either 21 or 95 percent oxygen, a filter, a heat exchange unit, cannulating electromagnetic flow probe and tap for measurement of perfusion pressure. Coronary perfusion pressure was controlled by adjusting the height of the disc oxygenator.

allows an examination of synchrony of contraction and a quantitation of the mechanical work performed by or dissipated into the myocardial segment under examination. Accordingly, in this study we investigated the relation of regional coronary perfusion to regional myocardial function and left ventricular function during graded decreases in left anterior descending coronary arterial perfusion pressure over a range of 100 to 16 mm Hg. In addition, we studied the effect of high levels of arterial oxygen tension, such as those employed clinically in acute myocardial infarction.

Method

Fourteen mongrel dogs (23 to 27 kg) were sedated with morphine sulfate (2.2 mg/kg body weight, intramuscularly) and anesthetized with ethyl carbamate (1.1 g/kg, intravenously). A left thoracotomy was performed through the fifth intercostal space. Aortic pressure was monitored with a Statham P23Db pressure transducer by means of a catheter passed through the femoral artery. Left ventricular pressure (both low gain and high gain) was recorded by a solid state catheter tip pressure transducer (model BT-7F2, Bio-Tech, Pasadena, Calif.) mounted on a no. 8F double lumen cardiac catheter passed retrograde across the aortic valve. Accuracy of the diastolic pressure determinations was assured by comparison with the magnified pressure wave form recorded from a Statham P23Db external pressure transducer by way of the second lumen. All pressures were referenced to the level of the mid-left ventricle.

A large bore cannula was positioned in the superior vena cava by way of the external jugular vein; a reservoir bottle was connected externally to the cannula and adjusted to the appropriate height to maintain a constant end-diastolic pressure of 5 to 10 mm Hg. Heart rate was not controlled and averaged 140 beats/min in these experiments.

Ascending aortic flow was measured in all experiments and coronary perfusion flow in 10 experiments by means of two electromagnetic flowmeters (model RC 1000, Micron Instruments, Los Angeles, Calif.). The signals were recorded for visual experimentation (Visicorder model 1505, Honeywell, Denver, Colo.) and recorded on magnetic tape for subsequent analysis (model GR-2900, Consolidated Electrodynamic Corporation, Pasadena, Calif.). Left ventricular function was evaluated from the following formula: LVSW = SV × (SP − LVEDP), where LVSW = left ventricular stroke work, SV = stroke volume, SP = mean systolic pressure and LVEDP = left ventricular end-diastolic pressure.

For assessment of regional myocardial function, a 1 cm long mercury-filled Silastic® length gauge (Parks Electronics, Beaverton, Ore.) was fixed in a direction parallel to that of the superficial myocardial fibers and placed within the distribution of the distal left anterior descending coronary artery. The artery was dissected free, cannulated proximal to its last diagonal branch and perfused by an oxygenator-bypass system (Fig. 1). The oxygenator was primed with the experimental dog's blood and removed as blood from a donor dog was transfused. Blood was pumped from the femoral vein with a finger pump into a disc oxygenator that could be raised or lowered to achieve any desired perfusion pressure. To evaluate the effects of high levels of arterial oxygen tension, such as may be employed clinically, the oxygenator was ventilated with gas mixtures containing 5 percent carbon dioxide and 21 or 95 percent oxygen, resulting in arterial oxygen partial pressures of 100 and 300 mm Hg, respectively. A filter, cannulating electromagnetic flow probe, heat exchanger and tap for measurement of perfusion pressure completed the circuit.

Regional myocardial function was evaluated using the pressure-length loop method previously described by this laboratory.[7,8] When left ventricular pressure is plotted simultaneously against epicardial segment length, a "pressure-length loop" is obtained that closely resembles the pressure-volume loop of the intact heart. The area within the pressure-length loop is an index of the work performed by or on the myocardial segment, and has been shown to correlate closely with total cardiac function during alterations in preload, afterload, contractility and heart rate.

Experimental Procedure

In each experiment, immediately after coronary cannulation, perfusion of the distal half of the left anterior descending coronary artery was continued at a perfusion pressure of approximately 100 mm Hg for at least 20 minutes. After this initial stabilization period, perfusion pressure was reduced in stepwise fashion with a return to the initial level (100 mm Hg) after each step. Each step consisted of a reduction in perfusion pressure of approximately 7–10 mm Hg that was maintained for 2 minutes, a period that previous studies[7,9] have indicated should permit stabilization of hemodynamics under ischemic conditions. This procedure was continued until a range of perfusion pressures between 100 and 16 mm Hg was obtained.

Finally, the heart was removed and sodium fluorescein was injected into the distal left anterior descending coronary artery by means of the perfusion cannula at a constant pressure of 100 mm Hg. The left ventricular myocardium was separated into stained and unstained portions by examination under ultraviolet light, and each portion was

weighed separately to estimate the amount of left ventricular myocardium perfused experimentally by the external circuit.

Although fluorescein has previously been used as a stain for the myocardium,[10] its use had certain limitations in this study. Injection of fluorescein was performed at the control pressure of 100 mm Hg and the stained area should represent the area of myocardium perfused during the control period. However, in this study, when coronary perfusion pressure was reduced over a range of pressures, the area of perfused myocardium may have changed accordingly. Therefore, there may be some error in the estimate of perfused area for coronary perfusion pressures below the control level of 100 mm Hg.

Data Analysis

Analysis of myocardial segment function was performed as follows: Coronary perfusion pressure levels were divided arbitrarily into seven ranges of 12 mm Hg each: 88 to 100, 76 to 87, 64 to 75, 52 to 63, 40 to 51, 28 to 39 and 16 to 27 mm Hg. Within each range of coronary perfusion pressure, a mean pressure-length loop area was determined. The mean area within the highest common pressure range, 64 to 75 mm Hg, was arbitrarily chosen as the control value (100 percent segment function); at any given pressure range, segment function was calculated as percent of mean loop area with respect to control loop area. Analysis of left ventricular function was performed similarly on the basis of values for left ventricular stroke work. From the perfusion pressure (CPP) and flow (CBF) data, the resistance to flow ("bed resistance") was calculated for each data point as r = CPP/CBF.

Results

Regional Myocardial Function

Figure 2 illustrates typical data obtained from an experiment in which the left anterior descending coronary artery was cannulated and perfused with blood equilibrated with 21 percent oxygen. In the control state (Fig. 2A) at a perfusion pressure of 95 mm Hg and a coronary blood flow rate of 99 ml/min per 100 g, the typical pressure-length loop was counterclockwise and completely normal with respect to the loop recorded before cannulation. Two minutes after reduction of coronary perfusion pressure to 47 mm Hg (Fig. 2B) and coronary blood flow to 21 ml/min per 100 g, there was a characteristic change in the length tracing consisting of late systolic lengthening and delayed shortening. The result was a decrease in the area of the pressure-length loop and the characteristic shape shown. Two minutes after reduction of the perfusion pressure to 22 mm Hg (Fig. 2C) and coronary flow to −4 ml/min per 100 g, the length tracing demonstrated epicardial segment lengthening throughout most of systole and shortening only at

pressures near the diastolic level. The pressure-length loop was inscribed in a clockwise direction, and the value for loop area was negative, indicating that work was expended in stretching the segment.

Figure 3 shows the relation of coronary perfusion pressure and coronary blood flow to the area of the pressure-length loop in a typical experiment in which the coronary perfusion blood was saturated with 21 percent oxygen. As coronary perfusion pressure was reduced from 100 to 50 to 60 mm Hg and coronary flow from 80 to 30 to 40 ml/min per 100 g, the loop area decreased to approximately 85 percent of the initial value. When pressure and flow continued to decrease, however, loop area decreased rapidly to approximately zero. In this experiment, the critical levels of coronary pressure and flow below which segment function decreased rapidly were 50 to 60 mm Hg and 30 to 40 ml/min per 100 g, respectively.

Relation of coronary perfusion pressure to segment function: Figure 4A illustrates this relation in 16 experiments, comparing the effects of 21 percent oxygen saturation (arterial PO_2 100 mm Hg) to 95 percent oxygen saturation (arterial PO_2 300 mm Hg). In the experiments with 21 percent oxygen saturation, as coronary perfusion pressure was reduced from the high range, 88 to 100 mm Hg, to a middle range, 52 to 63 mm Hg, segment function decreased at a rate of approximately 0.7 percent per mm Hg. As perfusion pressure was reduced below 52 to 63 mm Hg, segment function decreased rapidly at a rate of about 2.5 percent per mm Hg, to a value of zero at a range of perfusion pressures of 16 to 27 mm Hg. In the experiments with 95 percent oxygen saturation, segment function decreased in a parallel fashion except for a slight but significant enhancement of function in the range of 76 to 87 mm Hg. However, at the lowest level of perfusion pressure, segment function was reduced to a mean value that was significantly lower ($P < 0.02$) than that in the experiments with 21 percent oxygen saturation. The linear relation between perfusion pressure and flow in Figure 4B suggests that coronary resistance was minimal in each dog, even at the control levels of perfusion pressure (95 mm Hg); that is, there was no autoregulation in the coronary bed. Although normal segment function was present in the control state after coronary cannulation, the experimental procedure of cannulation may have caused the loss in autoregulatory capacity by producing a state of mild ischemia in which flow and function were preserved by autoregulation.

Coronary bed resistance: Coronary bed resistance (r = CPP/CBF), calculated in 14 dogs, ranged from 0.7 to 3.9 units. Since pH may affect vascular distensibility but was not controlled in this study, the variability in pH may have contributed to the wide range of coronary vascular resistance levels. Another possible cause of this variation in resistance values may have been release of vasodilator substances when blood of the donor dog was mixed with blood of the experimental dog. However, despite the wide range of values, there was a critical level of coronary blood flow in the narrow range of 25 to 55 ml/min per 100 g, below which function was markedly impaired (Fig. 5).

Relation between coronary blood flow and segment function: Figure 5 illustrates the individual relation between segment function and coronary blood flow (ml/min per 100 g) for five experiments with 95 percent oxygen saturation and five experiments with 21 percent oxygen saturation. There is

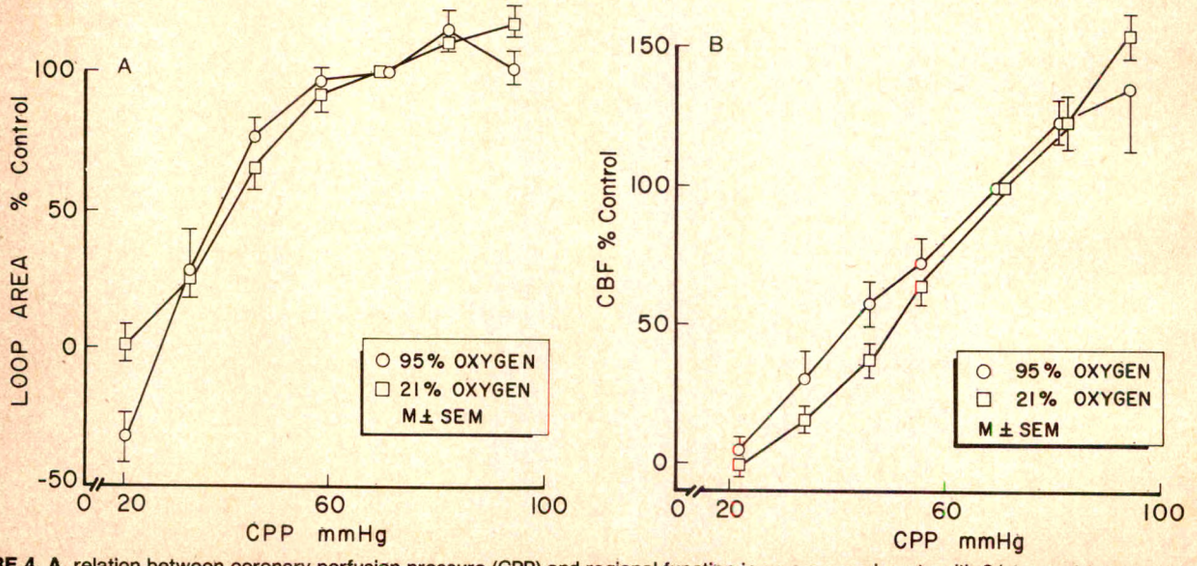

FIGURE 4. A, relation between coronary perfusion pressure (CPP) and regional function in seven experiments with 21 percent oxygen saturation (**squares**) and nine experiments with 95 percent oxygen saturation (**circles**). Regional epicardial function was determined as the pressure-length loop area in percent of control level (at a perfusion pressure of 70 ± 6 mm Hg) and plotted as the mean value ± 1 standard error of the mean. **B,** relation between coronary perfusion pressure (CPP) and coronary blood flow (CBF) for five experiments with 21 percent oxygen saturation (**squares**) and five experiments with 95 percent oxygen saturation (**circles**). Coronary blood flow was determined as a percent of control (at a perfusion pressure of 70 ± 6 mm Hg) and plotted as the mean value ± 1 standard error of mean. (See text.)

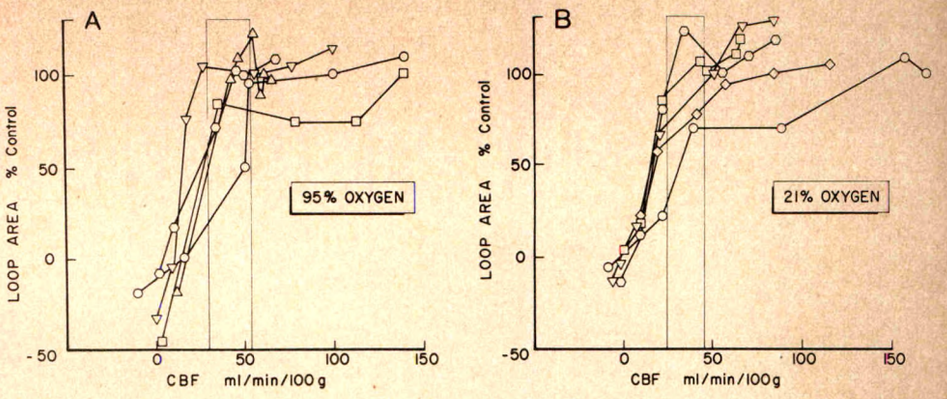

FIGURE 5. Individual relation between coronary blood flow (CBF, ml/min per 100 g) and regional epicardial function for five experiments with 95 percent oxygen saturation (**A**) and five experiments with 21 percent oxygen saturation (**B**). The **vertical lines** through each plot indicate the approximate critical ranges of coronary blood flow below which regional function declined sharply. The critical range was 30 to 55 ml/min per 100 g in **A**, and 25 to 45 ml/min per 100 g in **B**.

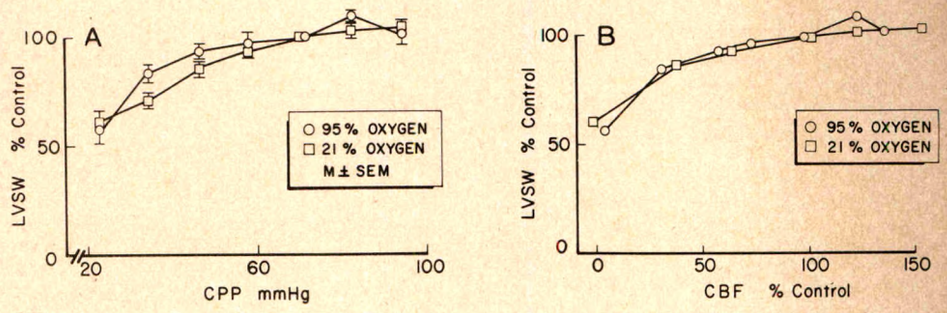

FIGURE 6. A, relation between coronary perfusion pressure (CPP) and left ventricular stroke work (LVSW) for seven experiments with 21 percent oxygen saturation (**squares**) and nine experiments with 95 percent oxygen saturation (**circles**). **B,** relation between coronary blood flow (CBF) (ml/min per 100 g) and left ventricular stroke work for five experiments with 21 percent oxygen saturation (**squares**) and five experiments with 95 percent oxygen saturation (**circles**). Left ventricular stroke work (LVSW) was determined as percent of control (at a perfusion pressure of 70 ± 6 mm Hg) and is plotted as the mean value ± 1 standard error of the mean. (See text.)

some individual variation in this relation, but it is evident that the ranges of flow within which segment function began to deteriorate were 30 to 55 ml/min per 100 g in the experiments with 95 percent oxygen saturation and 25 to 45 ml/min per 100 g in the experiments with 21 percent oxygen saturation. At higher flow ranges, segment function was well maintained, and at lower ranges segment function greatly deteriorated. Retrograde flow was more often observed in experiments with 21 percent oxygen saturation (Fig. 5).

Left Ventricular Function

Figure 6 illustrates the effects of coronary perfusion pressure and flow on left ventricular function. As pressure was decreased from the highest levels to 52 to 63 mm Hg and flow decreased to 40 to 50 percent of control values, left ventricular stroke work decreased gradually. However, in the experiments with 95 percent oxygen saturation, there was an initial enhancement of left ventricular stroke work similar to the enhancement of segment function seen at the same pressure and flow levels. Below the critical level of coronary perfusion pressure, 52 to 63 mm Hg, segment function began to decrease rapidly, reaching maximal rates of 2.1 percent per mm Hg with 95 percent oxygen saturation and 1.3 percent per mm Hg with 21 percent oxygen saturation. At the lowest levels of coronary pressure and flow, left ventricular stroke work had decreased to 60 percent of the control value, thus suggesting that approximately 40 percent of the total left ventricular function in control conditions was lost by reducing to almost zero the flow to a segment of the myocardium.

Discussion

Myocardial segment function examined by pressure-length loop: In this study, segment function was measured in a myocardial region during controlled coronary perfusion in the distal left anterior descending coronary artery. Any changes in coronary flow or regional function that may have occurred outside the region of controlled perfusion were not measured. Segment function was analyzed by means of the pressure-length loop method, a technique developed in this laboratory.[7,8]

The pressure-length loop provides a sensitive means of examining the synchrony of contraction of a given segment with respect to the total left ventricle. Left ventricular pressure reflects the time course of contraction in the mass of normal myocardium, whereas regional segment length reflects the time course of contraction of the ischemic segment interacting with adjacent normal myocardium. Interestingly, the progression of segment length changes during stepwise reduction of coronary perfusion in

	75% stenosis	90% stenosis
CPP	55 mmHg	55
CBF	40 ml/min.	40
Required P_{Ao}	59 mmHg	98
Pressure drop	4·3 mmHg	43
Resistance (r)	1·37 units	1·37

FIGURE 7. Schematic illustration of the effect of proximal coronary arterial stenosis on the aortic perfusion pressure (P_{Ao}) required to maintain a distal coronary perfusion pressure (CPP) of 55 mm Hg and coronary blood flow (CBF) of 40 ml/min per 100 g for two stenoses of 75 and 90 percent. (See text.) ΔP = change in pressure.

this study (Fig. 2) closely resembles the time course of changes in segment length in an ischemic region after coronary occlusion, as described in a previous study from this laboratory.[7] The segment length first began to lengthen late in systole; this lengthening occurred progressively earlier until there was little or no shortening during systole. These changes represent a progressive decrease in capacity of the ischemic muscle segment to shorten during systole against the stress developed by normal segments of the left ventricle.

The area enclosed by the pressure-length loop, inscribed over the entire course of one cardiac cycle, tends to reflect the net mechanical work of the myocardial segment during that cycle.[7,8] A segment that contracts during systole produces a positive loop area; one whose contraction is negated by expansion produces a zero loop area; and one that shortens at a lesser pressure than that at which it lengthens produces a negative loop area. Thus, the relative magnitude of energy that the heart loses with an expanding ischemic segment is represented by the area of the clockwise (that is, negative) pressure-length loop. In this manner, regional myocardial function is evaluated during stepwise reduction of coronary perfusion.

Coronary perfusion pressure and flow and regional myocardial function: Our study indicates that the effect of a given reduction in regional coronary perfusion pressure and flow upon regional myocardial function is critically dependent upon the preexisting levels of pressure and flow. Thus, substantial reductions in perfusion pressure, from 100 to approximately 55 mm Hg, were accompanied by a small reduction in regional function, whereas reduction in pressure below the narrow range of 65 to 50 mm Hg resulted in substantial reduction in the function of the ischemic segment. In addition, our study demonstrates that the reduction in regional function is translated into comparable reductions of lesser magnitude in left ventricular performance.

Our results are in agreement with those obtained by other investigators[11–15] who found that cardiac contractile performance varies directly but minimally with coronary perfusion pressure in the normal physiologic range. Our data suggest that the approximate lower limits of the so-called normal physiologic range for coronary flow and pressure are approximately 55 to 25 ml/min per 100 g and 65 to 50 mm Hg, respectively. Below these levels, regional myocardial function deteriorated three to five times more sharply than at the higher, more physiologic levels of pressure and flow. Changes in left ventricular stroke work paralleled those of regional myocardial function but were smaller. These data are in close agreement with those of Lekven et al.,[5] who found that total cardiac function was impaired when perfusion pressure in the main left coronary artery was less than 50 to 60 mm Hg.

Subendocardial vs. epicardial segmental function: Since the subendocardium is more vulnerable than the epicardium to ischemia,[16] it is possible that the relation of function in the subendocardium to coronary perfusion may be different from the relation found in our study between epicardial segment function and coronary perfusion (especially the critical levels of flow and perfusion). Lekven et al.[5] used ultrasonic micrometer measurements to evaluate changes in left ventricular subendocardial end-diastolic segment length. Although their studies did not quantitate regional systolic performance in the manner described in this investigation, replotting of their instantaneous subendocardial segment length and

left ventricular pressure data from a single experiment reveals that at coronary perfusion pressures of less than 55 mm Hg, subendocardial segment function decreased markedly. These data suggest that the same critical levels of coronary perfusion pressure found in our study for epicardial segment function are applicable to subendocardial segmental function.

High oxygen concentrations and regional myocardial ischemic function: Our study demonstrates that administration of high oxygen concentrations has little effect on regional ischemic myocardial function. Although oxygen administration increases arterial oxygen tension from 100 to 300 mm Hg, oxygen delivery is not increased much because almost complete saturation of hemoglobin normally occurs at an oxygen tension of 100 mm Hg. It is possible that the gradient for oxygen transfer is improved by high levels of arterial oxygen tension. However, at the lowest levels of coronary perfusion pressure, mean segment function was significantly lower ($P < 0.02$) in the experiments with 95 percent oxygen saturation, and retrograde flow was most often observed in the experiments with 21 percent oxygen saturation. At the lowest levels of coronary perfusion pressure, the mean loop area was approximately zero for the experiments with 21 percent oxygen, indicating that no effective work was produced in the ischemic region; in the experiments with 95 percent oxygen saturation the mean loop area was approximately −35 percent of the control value, indicating a dissipation of energy into the dyskinetic ischemic segment. Although these observations may have been the result of individual variations in collateral circulation, it is also possible that 95 percent oxygen concentrations may reduce flow through collateral vessels to the ischemic region and thus reduce contraction in these regions.

Applications to clinical coronary artery disease: The following example demonstrates the clinical usefulness of the combined data from this study and another study performed in this laboratory.[17] The critical levels of regional coronary perfusion pressure and flow, 50 to 65 mm Hg and 25 to 55 ml/min per 100 g, respectively, are analogous to the critical pressure and flow levels distal to a coronary stenosis in a patient with coronary artery disease. If the size of the stenosis is known, the aortic diastolic pressure necessary to maintain regional myocardial function can be calculated as schematically illustrated in Figure 7. The decrease in pressure across stenotic fresh postmortem human coronary arteries was measured at various flow rates and perfusion pressures.[17] Two hemodynamically significant stenoses, 75 and 90 percent, are represented. The coronary flow and pressure distal to both stenoses were identical, that is, in the range of the minimal pressure and flow necessary to maintain regional myocardial function, as determined in this study (coronary perfusion pressure = 55 mm Hg and coronary blood flow = 40 ml/min for 100 g of perfused tissue). At a coronary blood flow rate of 40 ml/min, the measured reductions in pressure across the two stenoses were found to be 4.3 mm Hg for the 75 percent stenosis and 43 mm Hg for the 90 percent stenosis. Thus, to maintain coronary perfusion pressure at 55 mm Hg distal to a 75 percent stenosis, an aortic diastolic pressure of 59.3 mm Hg would be required whereas, if a 90 percent stenosis were present, the required aortic diastolic pressure would be 98 mm Hg. In the latter situation, maintenance of aortic pressure at high levels would be critical for maintenance of useful function in myocardium beyond the coronary stenosis.

The missing links in the clinical application of this knowledge are the capabilities for determining the precise degree of coronary stenosis and the mass of myocardium perfused by the affected vessel. Once these capabilities are obtained, determination of the critical level of aortic diastolic pressure necessary to maintain regional myocardial function will be possible in patients with coronary disease. This will be an important step in the clinical management of such patients, especially since the use of agents that decrease arterial blood pressure is becoming more widespread.

From these data, therefore, two hypotheses may be proposed for the relation between regional blood flow, pressure and function in clinical coronary artery disease. First, the magnitude of deterioration in regional function that accompanies a reduction in regional blood supply is probably curvilinear in nature; only a small decrease in function occurs until a critical flow level is reached, after which a substantial reduction in function accompanies a minimal reduction in flow. Second, although the administration of oxygen may be justified in an attempt to reduce infarct size, it may have little effect upon the relation between regional flow and function.

Diastolic Compliance of the Left Ventricle in Man

WILLIAM H. GAASCH, MD, FACC
MIGUEL A. QUINONES, MD*
EFRAIN WAISSER, MD
HANS G. THIEL, MD*
JAMES K. ALEXANDER, MD, FACC

Houston, Texas

Two coordinates of left ventricular end-diastolic pressure (P) and volume (V) were provided by the infusion of angiotensin in 22 patients. The slope (k) of the ln P-V relation, coupled with knowledge of the operating (end-diastolic) pressure allows determination of end-diastolic volume compliance (dV/VdP). Estimates of end-diastolic compliance from a single coordinate of pressure and volume compared well (r = 0.90) with the two coordinate method, whereas values for specific compliance ($\Delta V/V_i \Delta P$) appeared to be misleading in cases of idiopathic hypertrophic subaortic stenosis and congestive cardiomyopathy. Since volume compliance is determined in part by the operating pressure, compliance may be reduced in small, normal or enlarged ventricles.

Left ventricular linear compliance was derived from volume compliance and was normalized for left ventricular wall thickness. The product of linear compliance and end-diastolic stress provides an index of myocardial strain, termed "muscle fiber stretch," which may be related to systolic performance and thus allow comparison of length-performance relations in ventricles with normal and abnormal compliance.

Meaningful interpretation of left ventricular end-diastolic pressure in the analysis of ventricular function can be made only when the relation between filling pressure and end-diastolic volume is known. Several investigators using different methods and assumptions have determined diastolic pressure-volume relations in man and have estimated diastolic compliance. These measurements have been utilized to aid in interpreting standard ventricular function curves,[1] gain prognostic information,[2] investigate the increase in ventricular filling pressure observed during angina pectoris[3] and estimate relative sarcomere length at end-diastole in diseased ventricles.[4] In this study, serial heterometric changes were produced (using infusion of angiotensin) to provide two coordinates of left ventricular end-diastolic pressure and volume, and these two coordinates were plotted as the natural logarithm of pressure (ln P) vs. volume. The slope of this (ln P-V) relation and knowledge of the operating (end-diastolic) pressure allow estimation of left ventricular end-diastolic compliance, which in turn may be related to (1) increased pulmonary venous pressure and consequent dyspnea, or (2) abnormal utilization of the Starling mechanism with consequent alterations in systolic performance, or (3) both.

Methods

Patients

Hemodynamic studies were performed in 22 patients undergoing diagnostic cardiac catheterization. Five patients, studied to evaluate a cardiac

murmur or chest pain, had normal hemodynamic and angiographic findings. Eight patients had coronary artery disease with angina pectoris and various degrees of left ventricular asynergy. Five patients with normal coronary arteriograms had the essential clinical and hemodynamic manifestations of congestive cardiomyopathy as described by Goodwin.[5] A fourth group consisted of four patients with marked left ventricular hypertrophy, two with severe valvular aortic stenosis and two with the typical clinical, hemodynamic and angiographic findings of idiopathic hypertrophic subaortic stenosis. All 22 patients had normal sinus rhythm and only 1 (Case 21) had mild mitral regurgitation.

Hemodynamic Studies

All patients underwent cardiac catheterization in the fasting state after premedication with diazepam, 10 mg intramuscularly. Pressures were measured with no. 8F catheters connected to Statham P23Db pressure transducers from a zero reference point at mid-chest level. An Electronics for Medicine photographic recorder was utilized. The left ventricular end-diastolic pressure was taken as the junction of the downslope of the *A* wave with the upstroke of the ventricular pressure wave; the end-diastolic and end-systolic volumes were determined using single plane cineangiography and the area-length method. Wall thickness was determined as the average thickness of the middle third of the left ventricular free wall as visualized cineangiographically (right anterior oblique projection).[6] The systolic ejection fraction was derived as the angiographic stroke volume divided by the end-diastolic volume. Ventricular premature contractions and the beats following the premature beats were excluded from analysis. All cineangiographic measurements were corrected for magnification and all volumes expressed in cubic centimeters per square meter of body surface area.

In each case, resting hemodynamic measurements and a left ventricular cineangiogram (right anterior oblique projection) were obtained before infusion of angiotensin. Angiotensin was infused (0.5 mg/250 cc of 5 percent dextrose in water) at a rate sufficient to produce a distinct pressor response and an increase in end-diastolic pressure. Five to 6 minutes after achievement of a steady state, left ventricular pressure was measured and a second ventriculogram was obtained and analyzed in the manner outlined. No patient complained of angina or dyspnea during angiotensin infusion.

Diastolic Properties of Left Ventricle

The diastolic properties of the left ventricle were evaluated by a method similar to that employed in animals by McCullagh et al.[7]; in their studies, several coordinates of end-diastolic pressure and end-diastolic dimension were obtained over a range of end-diastolic pressures produced by volume expansion or controlled hemorrhage. Pressures were plotted against dimensions and the pressure-dimension relation was defined by employing a linear analysis of the data.

In this study, two coordinates of left ventricular end-diastolic pressure (P) and volume (V) were obtained (control period and angiotensin infusion) and, assuming an exponential relation between end-diastolic pressure and volume, a modulus or coefficient of volume compliance was derived as the slope (k′) of the ln P-V relation (ln P = natural logarithm of the end-diastolic pressure). The slope (k′) was calculated as:

$$k' = (\ln Pa - \ln Pc)/(Va - Vc) \quad (1)$$

where Pa and Va = end-diastolic pressure (mm Hg) and end-diastolic volume (cc/m^2) during infusion of angiotensin, and Pc and Vc = end-diastolic pressure (mm Hg) and end-diastolic volume (cc/m^2) during the control period. Additionally, the pressure intercept (b′) at zero volume was obtained in every case by linear extrapolation of a line joining the two coordinates of ln P and V. Although extensive data in man are lacking, isolated cardiac muscle length-tension relations[8] and canine pressure-volume relations[9] are easily fit by an exponential function, and thus we elected to analyze our data on the basis of exponential relation between pressure and volume at end-diastole. Preliminary studies in our laboratory suggest that although dynamic components of the in vivo human diastolic pressure-volume relation produce minimal deviations from the elastic (exponential) curve, pressure and volume can be fit by an exponential function.[10] Visual inspection of these curves, in fact, suggests that the data are better fit by a curvilinear than by a linear equation.

An index of end-diastolic volume distensibility (dV/dP), defined as the inverse slope of a tangent to the pressure-volume curve at end-diastole, may be calculated as:

$$(dV/dP)_{ed'} = 1/k'P \quad (2)$$

and end-diastolic volume compliance, likewise may be calculated as (dV/dP)ed′ normalized for end-diastolic volume:

$$(dV/VdP)_{ed'} = 1/k'P \cdot 1/V \quad (3)$$

where P = control end-diastolic pressure, V = control end-diastolic volume and k′ = the slope of the ln P-V relation as defined in equation 1.

A similar, but simplified, method of evaluating left ventricular diastolic volume compliance was also employed. This method, which utilizes a single coordinate of end-diastolic pressure and volume and a constant pressure intercept (b) of 0.43 mm Hg, assumes that the end-diastolic pressure-volume relation can be represented as:

$$P = be^{kV} \quad (4)$$

where e = the base of the natural logarithm. This equation can be rearranged and rewritten as:

$$k = (\ln P - \ln 0.43)/V \quad (5)$$

Thus, left ventricular (dV/dP)ed and (dV/VdP)ed may be calculated as 1/kP and 1/kP·1/V, respectively. Note that k (equation 5) is derived from a single measured coordinate of pressure and volume, whereas k′ (equation 1) is derived from two measured coordinates of pressure and volume. The theory and derivations of these formulas have previously been outlined in detail,[4,11] and the basic assumptions have been utilized in clinical studies.[3,12,13]

"Specific compliance" was determined by relating the total diastolic increase in volume to the diastolic increase in pressure, and the value was normalized by initial volume as described by Smith et al.[14] This method of estimating diastolic compliance describes an average relation between pressure and volume throughout diastole and is calculated as:

$$SC = \Delta V/\Delta P \cdot 1/V_i \quad (6)$$

where ΔV = average stroke volume (cc/m^2), ΔP = the difference between left ventricular end-diastolic pressure and the lowest pressure recorded in early diastole (mm Hg) and V_i = end-systolic volume (cc/m^2). The units of specific compliance (l/mm Hg) are the same as the units of (dV/VdP)ed.

Left ventricular end-diastolic stress and peak systolic stress were estimated utilizing a method previously described in detail.[4] The basic calculations were made using the formula of Sandler and Dodge[15]; the stresses derived represent mean circumferential wall stresses and are expressed in 10^3 dynes cm^2. Peak developed systolic stress was determined as the peak systolic stress minus end-diastolic stress. A work index of the ventricle was provided by the product of peak developed stress and stroke index and is expressed in units of 10^5 dyne/cm.

Determinants of left ventricular end-diastolic fiber strain include not only the force acting to lengthen the fiber (end-diastolic stress), but also the passive resistance to stretch (parallel elasticity or linear compliance). Thus an index of end-diastolic fiber strain is provided by the product of end-diastolic stress and end-diastolic compliance.[4] End-diastolic volume compliance (equation 3) was obtained from volume data, and an estimate of linear muscle compliance, corrected for wall thickness (h), was derived as:

$$\text{Linear compliance (cm/mm Hg)} = 1/3 \cdot dV/VdP \cdot h \quad (7)$$

This estimate is made assuming a spherical left ventricle and results in an under-estimation of linear compliance (which is of greater magnitude in idiopathic hypertrophic subaortic stenosis than in congestive cardiomyopathy). More precise determination of linear compliance at the minor axis (b) of the ventricle would be provided by the approach of Battle et al.,[16] which defines db/bdP using a prolate spheroid as a model. Linear muscle fiber stretch (LMFS) is calculated as:

$$\text{LMFS} = \text{Linear compliance} \cdot \text{LVED stress} \quad (8)$$

where LVED = left ventricular end-diastolic.

Muscle fiber stretch, an index of muscle strain, is expressed in arbitrary units, and results are expressed as averages ± 1 standard error of the mean.

Results

Left ventricular end-diastolic pressure-volume relations: Hemodynamic and angiographic data on all 22 patients are presented in Table I. During the control period, the average left ventricular end-diastolic volume of the patients with coronary artery disease (86 ± 9 cc/m^2) did not differ significantly from the average for the normal group (75 ± 8 cc/m^2). The patients with cardiomyopathy had an average end-diastolic volume (101 ± 13 cc/m^2) that was significantly greater ($P = 0.05$) than normal. Although the average end-diastolic volume in the group with hypertrophy (55 ± 11 cc/m^2) was less than normal, the difference did not achieve statistical significance.

The average end-diastolic pressure during the control period of the group with coronary artery disease (14.9 ± 1.8 mm Hg) was greater ($P < 0.02$) than the average of the normal group (8.2 ± 1.2 mm Hg). The average end-diastolic pressure of the group with hypertrophy (15 ± 2.5 mm Hg) was significantly greater ($P < 0.05$) than normal, whereas the average of the group with cardiomyopathy (10.7 ± 2.6 mm Hg) did not differ significantly from normal. The low level of filling pressures in these patients with cardiomyopathy was undoubtedly secondary to the aggressive use of potent parenterally administered diuretic agents; all of these patients had previously presented to the hospital with pulmonary congestion and dyspnea.

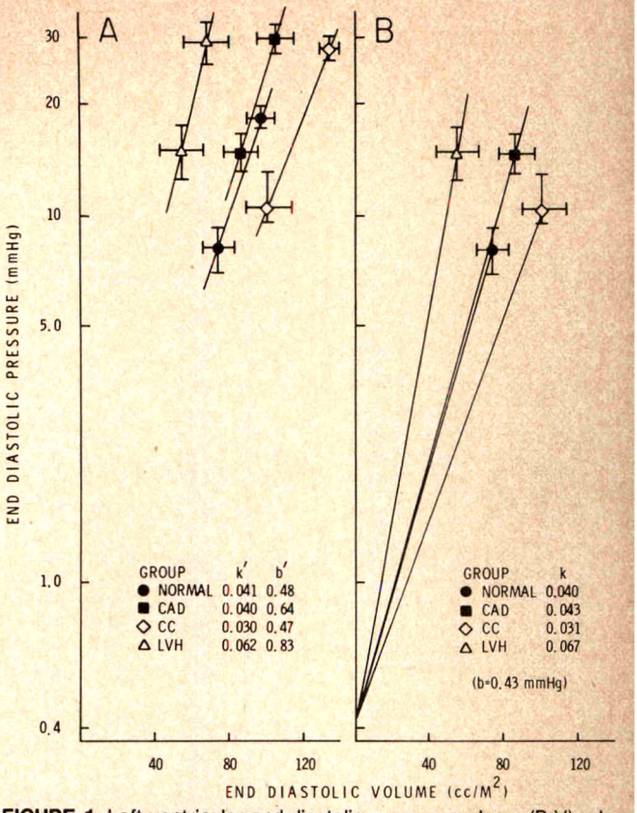

FIGURE 1. Left ventricular end-diastolic pressure-volume (P-V) relations in 22 patients. **A,** the average end-diastolic P-V coordinates (control period and angiotensin infusion) are plotted for each of the four groups. The slope (k′) of the ln P-V relation and the pressure intercept (b′) were determined from the two coordinates of P and V. **B,** the average end-diastolic P-V coordinates (control) are plotted; the slope (k) of the ln P-V relation was determined from a constant pressure intercept (b) of 0.43 mm Hg (animal data). CAD = coronary artery disease; CC = congestive cardiomyopathy; LVH = left ventricular hypertrophy.

After infusion of angiotensin, as described under Methods, a second coordinate of end-diastolic pressure and volume was obtained. The slope (k′) of the ln P-V relation obtained from two end-diastolic pressure-volume coordinates (control period and after angiotensin infusion) was calculated for each patient (Table I), and the average k′ for each group is represented graphically in Figure 1A by a line connecting the two coordinates. In the group with hypertrophy the ln P-V relation is to the left and k′ is greater than normal; in the group with cardiomyopathy, the ln P-V relation is to the right and k′ is less than normal. Although the average end-diastolic pressure of the group with coronary artery disease is significantly greater ($P < 0.02$) and the average end-diastolic volume is only slightly greater (P = not significant) than normal, the ln P-V slopes for these two groups are similar.

A pressure intercept (b′) at zero volume was obtained for each patient from the two coordinates of end-diastolic pressure and volume. The mean value of b′ for the groups with hypertrophy, coronary ar-

EDS = end-diastolic stress; LMFS = linear muscle fiber stretch (see Methods); PDS = peak developed stress; SV = stroke volume.

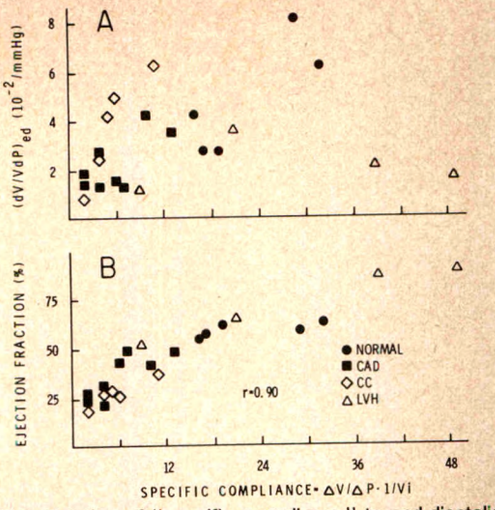

FIGURE 2. Relation of "specific compliance" to end-diastolic compliance [(dV/VdP)ed] and systolic ejection fraction. **A,** although there is agreement between (dV/VdP)ed and specific compliance in normal patients and those with coronary artery disease, discrepancies exist when patients with congestive cardiomyopathy and left ventricular hypertrophy are considered. **B,** specific compliance correlates well (r = 0.90) with the systolic ejection fraction.

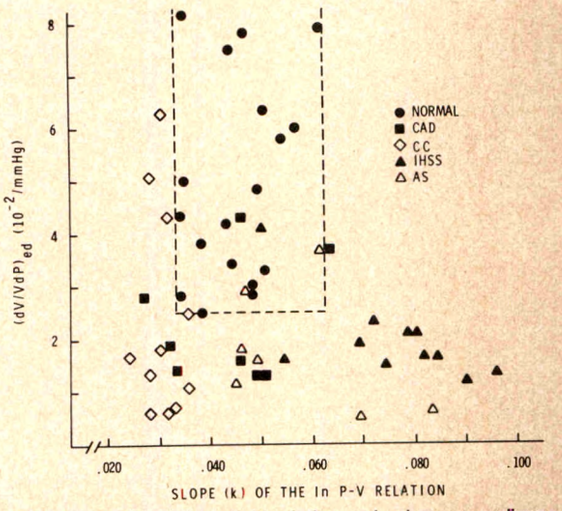

FIGURE 3. Slope (k) of the ln P-V relation and volume compliance at end-diastole in 55 patients. In congestive cardiomyopathy, the value for k is low but (dV/VdP)ed may be normal or depressed. In ventricular hypertrophy, k is high or normal but (dV/VdP)ed is generally reduced. In coronary artery disease, k varies widely, but (dV/VdP)ed tends to be depressed. The range of normal is outlined by the **broken line.** AS = aortic stenosis; IHSS = idiopathic hypertrophic subaortic stenosis.

tery disease, normal findings and cardiomyopathy was 0.83 ± 0.28, 0.64 ± 0.14, 0.48 ± 0.13, and 0.47 ± 0.12 mm Hg, respectively. The range for the entire group of 22 patients (0.14 to 1.49 mm Hg) was wide. Although the average b′ value tended to be higher in patients with a high k value and lower in patients with a low k value, the differences (in b′) between these groups were nonsignificant at the 0.05 level.

A value for the slope (k) of the ln P-V relation was calculated for each patient utilizing a single coordinate of end-diastolic pressure and volume (control) and a constant pressure intercept (b) of 0.43 mm Hg (Table I). The average value for k for each group is presented graphically in Figure 1B by a line between the average end-diastolic coordinate of pressure and volume, and b = 0.43 mm Hg. Again, the ln P-V relation is to the left in the group with hypertrophy, to the right in the group with cardiomyopathy and similar to normal in the group with coronary artery disease. When the slope was calculated from two coordinates, the result was similar to that obtained from a single coordinate of end-diastolic pressure and volume (see Fig. 1).

Left ventricular end-diastolic compliance: Since the values for the slope of the ln P-V relation were similar by the single and double coordinate methods, it follows that estimates of end-diastolic compliance would likewise be little changed if the simplified (single pressure-volume coordinate) method of obtaining (dV/VdP)ed were used in place of the multiple coordinate approach. In fact, the correlation between (dV/VdP)ed and (dV/VdP)ed′ was excellent (r = 0.90). For this reason, end-diastolic compliance and derived parameters are calculated and reported using the single coordinate method (Tables I and II, Fig. 2 to 4). This approach allows comparison among the average values for groups, but may be of limited value in the examination of individual patients.

The average end-diastolic compliance [(dV/VdP)ed] of the group with coronary artery disease ($2.3 \pm 0.4 \times 10^{-2}$ mm Hg^{-1}) was less ($P < 0.05$) than normal ($4.9 \pm 1.1 \times 10^{-2}$ mm Hg^{-1}). The value for this normal group is similar to that of a different

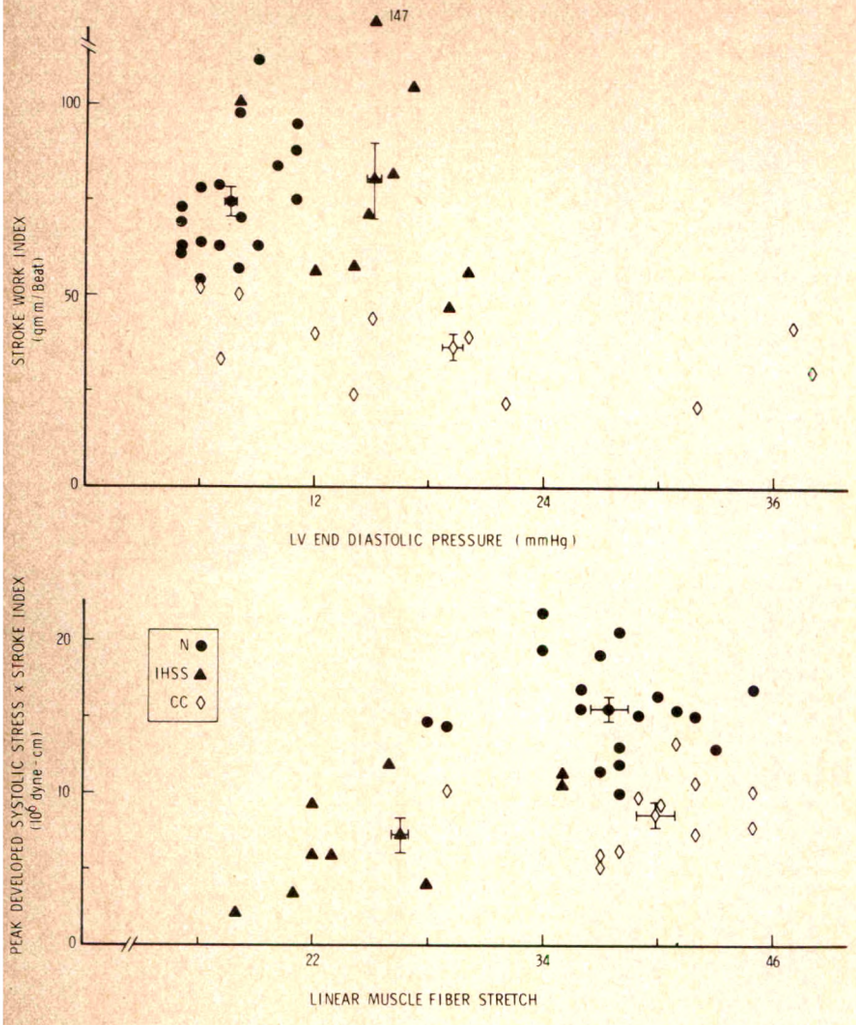

FIGURE 4. Left ventricular function curves. A conventional plot **(above)** of left ventricular stroke work against end-diastolic pressure suggests that systolic performance in idiopathic hypertrophic subaortic stenosis is achieved through increased end-diastolic fiber length; although performance is depressed in congestive cardiomyopathy, end-diastolic pressure varies widely. In contrast, when "linear muscle fiber stretch" is plotted against the product of peak developed systolic stress and stroke index (below), it appears that both systolic performance and fiber stretch are reduced in idiopathic hypertrophic subaortic stenosis; in congestive cardiomyopathy, systolic performance is reduced but fiber stretch is slightly greater than normal.

group of normal subjects previously described.[4] Compliance at end-diastole was less than normal ($P < 0.05$) in the group with hypertrophy ($2.2 \pm 0.5 \times 10^{-2}$ mm Hg^{-1}). Although the average end-diastolic compliance in the group with cardiomyopathy ($3.9 \pm 0.9 \times 10^{-2}$ mm Hg^{-1}) was lower than normal, the difference was nonsignificant at the 0.05 level.

Specific compliance ($\Delta V/\Delta P \cdot 1/V_i$): The average value for left ventricular specific compliance in the group with coronary artery disease ($6 \pm 1.4 \times 10^{-2}$ mm Hg^{-1}) was significantly lower ($P < 0.001$) than the average value for the normal group ($23 \pm 3.3 \times 10^{-2}$ mm Hg^{-1}). Specific compliance in the group with cardiomyopathy ($5.6 \pm 1.5 \times 10^{-2}$ mm Hg^{-1}) was likewise significantly less ($P < 0.01$) than normal, whereas the average value for the group with hypertrophy (29.5 ± 8.9) did not differ significantly from normal. The lowest values for specific compliance were obtained in patients with the hemodynamic findings of congestive cardiomyopathy and the highest values in patients with idiopathic hypertrophic subaortic stenosis. In Figure 2A (dV/VdP)ed is plotted against specific compliance. The value for specific compliance is very high and that for (dV/VdP)ed is low in patients with idiopathic hypertrophic subaortic stenosis, whereas patients with congestive cardiomyopathy have low values for specific compliance and low to normal values for (dV/VdP)ed. Thus, a positive correlation exists between these two methods of estimating diastolic compliance in normal subjects and those with coronary artery disease, but a lack of correlation is seen when patients with congestive cardiomyopathy and idiopathic hypertrophic subaortic stenosis are considered.

In Figure 2B, specific compliance is plotted against the systolic ejection fraction. A high correlation ($r = 0.90$) exists between these two variables; patients with cardiomyopathy had the lowest values for specific compliance and ejection fraction, whereas patients with idiopathic hypertrophic subaortic stenosis had the highest values for specific compliance and exhibited extreme degrees of systolic emptying. In contrast, there was no direct relation between (dV/VdP)ed and ejection fraction in any of the four groups studied.

Left ventricular function curves: To assess the active length-tension relations of these hearts, a work index (peak developed systolic stress × stroke vol-

ume index) of the left ventricle was plotted against end-diastolic linear muscle fiber stretch. The work index gives a ventricle credit for both force generation and fiber shortening, whereas fiber stretch is derived from end-diastolic stress and linear compliance corrected for wall thickness. This analysis was made for the patients in our study with a normal left ventricle, idiopathic hypertrophic subaortic stenosis or congestive cardiomyopathy (Table II); data from three groups of similar patients, previously described,[4] are combined with those from patients reported herein and left ventricular function curves are constructed in Figure 4. This analysis suggests that end-diastolic fiber stretch is reduced in idiopathic hypertrophic subaortic stenosis (average fiber stretch was 28 percent less than the average for the normal group), and that the reduced systolic performance seen in this group may be in part related to inefficient utilization of the Starling mechanism. Depressed systolic performance is apparent in the group with congestive cardiomyopathy; in this group, end-diastolic fiber stretch is slightly greater than normal (average fiber stretch was 8 percent greater than the average for the normal group). Conventional ventricular function curves (stroke work vs. end-diastolic pressure) are shown for comparison.

Discussion

Because several indexes have been used to define the diastolic properties of the left ventricle in man, it is important to define carefully the methods and assumptions in any clinical evaluation of ventricular compliance.[17] First, it should be reemphasized that the left ventricular diastolic stress-strain relation is nonlinear and that the exponential nature of the diastolic pressure-volume relation results in progressive reduction of end-diastolic compliance as the filling pressure increases. Thus, the level of end-diastolic compliance is abnormally low in any ventricle that is filled sufficiently. Second, the assumption regarding an exponential pressure-volume relation is made in this study only for end-diastolic pressure and volume and no attempt has been made to fit a simple exponential to data obtained throughout diastole. Restricting the analysis to end-diastole attenuates the effects of incomplete ventricular relaxation, which may be a major determinant of the diastolic pressure-volume relation especially in early diastole.[18] Importantly, since the Starling mechanism is adjusted at end-diastole, end-diastolic compliance (or resistance to stretch) becomes a critical determinant of end-diastolic fiber stretch and, thus, of systolic performance.

Diastolic Pressure-Volume Relations and Compliance

Pressure-volume relations: In this study the average slope (k′) of the ln P-V relation determined from *two* end-diastolic pressure-volume coordinates was similar to the average slope (k) determined from a *single* coordinate of end-diastolic pressure and volume and a pressure intercept (b) of 0.43 mm Hg. Evidence that the pressure intercept (b) varies little in the presence of reduced diastolic compliance (as in experimental myocardial infarction) has previously been reported,[4,19] and the pressure intercept has been found to be similar in patients with a normal left ventricle and in those with aortic stenosis.[4,20] By contrast, when changes in b were measured by Barry et al.[3] during pacing-induced angina pectoris, the value for b increased from an average of 1.05 mm Hg during the control period to an average of 2.25 mm Hg during angina. The range of b in our study was 0.14 to 1.49 mm Hg and, although the average b value for the group with cardiomyopathy was lower than the average for the group with hypertrophy, there was no consistent difference between patients with a large dilated heart and those with a small hypertrophic heart. Methodologic differences may be somewhat responsible for the variation in results, but acute changes in the diastolic properties of the left ventricle during angina must be considerably different from those observed during the chronic development of hypertrophy, dilation or scar formation. Since the average k values (and the average b values) for each group were similar by the single and double coordinate methods, we elected to utilize the simplified single coordinate approach to describe end-diastolic compliance and derived functions (linear compliance and muscle fiber stretch). In this study similarities and differences among groups are emphasized, but since k (and b) variability exist within groups, the single coordinate analysis may have limitations in the examination of individual patients. Accurate definition of diastolic pressure-volume or stress-strain relations await methods that employ frequent sampling of simultaneously measured pressure and volume.[10]

End-diastolic compliance: In agreement with previous reports,[1,4,14,21] end-diastolic compliance was found to be reduced in patients with left ventricular hypertrophy and in some with coronary artery disease. Since end-diastolic compliance may be reduced in ventricles that are smaller than normal (idiopathic hypertrophic subaortic stenosis), have a normal end-diastolic volume (coronary artery disease) or are larger than normal (congestive cardiomyopathy), it is proper to consider both k and (dV/VdP)ed in assessing the diastolic properties of diseased ventricles. The k value describes the overall relation between end-diastolic pressure and volume, whereas (dV/dP)ed and (dV/VdP)ed are determined by the operating pressure. Thus, a ventricle with a given value for k might be more or less compliant at end-diastole depending on the operating end-diastolic pressure. For these reasons, diuretic agents may reduce the operating pressure and thus increase end-diastolic distensibility or compliance, but k should not be affected. Likewise, a positive inotropic intervention, although not affecting the basic passive elastic properties of the muscle (no effect on k), could improve the systolic ejection fraction and thus reduce heart size; accordingly, end-diastolic compliance would increase.

In Figure 3, the relation between k and (dV/VdP)ed is illustrated for a total of 55 patients (the 22 patients in this study and 33 previously reported on[4]). In congestive cardiomyopathy, the value for k is low and (dV/VdP)ed ranges from low to normal; in hypertrophy, k is high or normal and (dV/VdP)ed is reduced; in coronary artery disease, k varies widely and (dV/VdP)ed is low. This analysis allows characterization of relative differences in pressure-volume relations as well as definition of compliance at end-diastole in ventricles with various types of disease.

Specific compliance: Some have attempted to define the diastolic pressure-volume relation and diastolic compliance by relating the total increase in diastolic volume (ΔV) to the increase in pressure that occurs throughout diastole (ΔP). Smith et al.[2,14] have calculated $\Delta V/\Delta P$ and have normalized this value for initial volume. Specific compliance ($\Delta V/\Delta P \cdot 1/V_i$) was calculated for each patient in our study and, although there was agreement between specific compliance and end-diastolic compliance [(dV/VdP)ed] in the normal subjects and those with coronary artery diseases, certain important discrepancies occurred when patients with congestive cardiomyopathy and idiopathic hypertrophic subaortic stenosis were considered (Fig. 2A). In idiopathic hypertrophic subaortic stenosis, the value for specific compliance was very high whereas that for end-diastolic compliance was very low; in cardiomyopathy, the value for specific compliance was low whereas that for end-diastolic compliance ranged from low to normal. The high values for specific compliance in idiopathic hypertrophic subaortic stenosis and reduced values in congestive cardiomyopathy parallel the values for systolic ejection fraction (Fig. 2B) and are at variance with general concepts of ventricular compliance in these two forms of heart disease. The good correlation between specific compliance and ejection fraction does not imply a causal relation between these two variables, but suggests that the former should be interpreted with caution in appraising certain clinical problems. For example, values for specific compliance have been found to be of some prognostic value in acute myocardial infarction,[2] but it is possible that this finding may be, in part, a reflection of the ejection fraction.

Left Ventricular Function Curves

An assessment of left ventricular active length-tension relations is provided by plotting the product of peak developed systolic stress and stroke volume (work index) against end-diastolic linear muscle fiber stretch (strain index). The concept of end-diastolic muscle fiber stretch is especially important because the ultrastructural basis of the Starling mechanism is not the absolute length of a muscle fiber but the degree to which the fiber is stretched. The work index utilized in this type of ventricular function curve credits the ventricle both for the development of force (stress) and for myocardial shortening. Figure 4 demonstrates that the normal ventricles and those with idiopathic hypertrophic subaortic stenosis define a work-length curve in which the patients differ in the degree of heterometric recruitment to determine systolic performance. In spite of normal preload, hearts with idiopathic hypertrophic subaortic stenosis recruit subnormal end-diastolic fiber stretch (and perform subnormally), which suggests that reduced compliance prevents efficient utilization of the Starling mechanism. Those with congestive cardiomyopathy operate on a depressed ventricular function curve with fiber stretch that is only slightly greater than normal.

Linear muscle fiber stretch: Despite markedly increased preload (end-diastolic stress), the average linear muscle fiber stretch in patients with congestive cardiomyopathy was only 8 percent greater than the average for the normal group. These data are consistent with the observations of Ross et al.,[22] who studied the effects of chronic dilatation on left ventricular end-diastolic sarcomere lengths; the average sarcomere length in these large dilated hearts was only 5 percent greater than normal. In contrast, the average muscle fiber stretch in idiopathic hypertrophic subaortic stenosis was 28 percent less than normal, in spite of normal preload. Sarcomere lengths are extremely variable in idiopathic hypertrophic subaortic stenosis, with both overstretched and short sarcomeres present within a given cell; large groups of sarcomeres measure less than 1.5 μ.[23] Decreased sarcomere lengths have also been demonstrated in right ventricular hypertrophy secondary to pulmonary arterial banding.[24] If the average end-diastolic sarcomere length in idiopathic hypertrophic subaortic stenosis is less than normal, then reduced systolic performance (Fig. 4) may be explained at least in part on this basis.

Clinical Implications

Many forms of heart disease produce symptoms more as a result of abnormal left ventricular diastolic compliance than of depressed contractility or reduced systolic performance. The most common symptom of idiopathic hypertrophic subaortic stenosis is said to be dyspnea,[25] whereas evidence for reduced systolic pump function is meager. Some patients with coronary artery disease may be restricted by symptoms of pulmonary congestion secondary to the "paradox of the stiff heart."[26] Symptoms in chronic constrictive pericarditis may be more related to abnormal ventricular compliance than to reduced cardiac contractility.[27] In contrast to these examples of fixed reduction in left ventricular compliance, transient abnormalities of volume compliance have been observed to occur during angina pectoris.[3,28] The importance of right ventricular distensibility as a determinant of the degree of intracardiac shunting in atrial septal defect is well known. The pattern of flow from the right ventricle to the pulmonary artery during ventricular diastole has been described in carcinoid heart disease and is said to be due to the combined effects of increased right atrial pressure, de-

creased right ventricular compliance and normal pulmonary arterial pressure.[29] The mechanisms and potential reversibility of these and other abnormalities of left ventricular compliance require further study. Although passive volume compliance of the left ventricle can be estimated by several methods, frequent sampling of simultaneously measured pressure and volume will be necessary to define optimally the continually changing relation between these variables during diastole.

Dobutamine, a derivative of dopamine, was infused at a rate of 10 μg/kg per min in 15 patients with severe congestive heart failure. Cardiac output increased from an average of 3.1 to 5.6 liters/min ($P < 0.001$) with no change in mean arterial pressure (93.3 to 98.2 mm Hg) and only a slight increase in heart rate (98.5 to 105.2 beats/min) ($P < 0.02$). Pulmonary wedge pressure was decreased from an average of 27.4 to 21.1 mm Hg ($P < 0.001$). In seven patients a dose of 5 μg/kg per min also produced a significant increase in cardiac output but the effect was less than with the 10 μg/kg per min dose. No side effects were observed during the infusion. Dobutamine therefore is a potent inotropic drug with limited chronotropic and peripheral vascular effects and deserves therapeutic trial in the short-term management of low output heart failure.

Although sympathomimetic amines are the most potent known agents for augmenting myocardial contractility, their clinical application for this purpose has been limited because of their chronotropic and peripheral vascular actions. Isoproterenol, for example, induces a marked increase in cardiac output but at the expense of a decrease in arterial diastolic pressure, tachycardia and increased myocardial irritability.[1–3] Norepinephrine, on the other hand, produces systemic vasoconstriction, which increases diastolic arterial pressure and thus may limit the increase in cardiac output and result in a reduction of regional perfusion.[4–6] Dopamine has been introduced as a sympathomimetic inotropic agent with less chronotropic and vasoconstrictive effect[7,8]; however, it has considerable vasoconstrictive properties in large doses, the cardiac output response is variable and arrhythmias have been reported.[9–11]

A derivative of dopamine, dobutamine ([±] -4-[2-] [3-(p-hydroxphenyl)-1-methyl propyl] amino] ethyl] pyrocatechol hydrochloride), has recently been synthesized by Tuttle and Mills[12] and has been demonstrated in early animal studies to have a relatively selective inotropic effect.[13] In this study we examined the acute hemodynamic response to dobutamine in patients with severe left ventricular failure. Our results indicate that this drug has potent cardiac stimulating properties with little effect on heart rate or blood pressure and therefore may prove to be a useful agent for the management of severe heart failure.

Methods

Studies were performed in 15 patients with severe chronic class III or class IV (New York Heart Association criteria) heart failure (primary myocardial, rheumatic or ischemic heart disease). Pertinent clinical data are summarized in Table I. All patients were male; their ages ranged from 39 to 76 (average 51) years. All were receiving maintenance doses of digitalis and had been treated with diuretic agents. The digitalis and diuretic agents were withheld for 24 hours before the study.

BSA = body surface area (m^2); C = control; CM = cardiomyopathy; CO = cardiac output (liters/min); D = dobutamine infusion; HR = heart rate (beats/min); IHD = ischemic heart disease; MAP = mean arterial pressure (mm Hg); NS = not significant; *P* = probability; PAP = mean pulmonary arterial pressure (mm Hg); PCW = pulmonary wedge pressure (mm Hg); PVR = pulmonary vascular resistance (dynes sec cm^{-5}); RHD = rheumatic heart disease; SE = standard error; SVR = systemic vascular resistance (dynes sec cm^{-5}).

Right heart catheterization was performed using a Swan-Ganz flow-directed balloon-tipped catheter inserted percutaneously by way of an antecubital vein. In 12 patients the pulmonary artery was successfully entered, but in 3 the catheter could not be advanced beyond the right atrium. The brachial artery was cannulated with a Teflon® needle. Arterial, pulmonary arterial and pulmonary capillary wedge (occluded) pressures were recorded using Statham P23 Db strain gauge transducers and a Hewlett-Packard recorder. Cardiac output in liters per minute was determined by the indicator-dilution technique using indocyanine green dye injected into the pulmonary artery and sampled from the brachial artery through a Gilford cuvette densitometer. Systemic vascular resistance in dynes sec cm^{-5} was calculated from the formula: (MAP − RAP) × 80/CO, where MAP is the mean arterial pressure in mm Hg, RAP is the mean right atrial pressure in mm Hg and CO is the cardiac output in liters/min. Pulmonary vascular resistance was calculated from the formula: (MPAP − PCW) × 80/CO, where MPAP is the mean pulmonary arterial pressure in mm Hg and PCW is the mean pulmonary capillary wedge pressure in mm Hg. Stroke work in g-m was calculated from the formula: (MAP − PCW) (SV) (0.0136) where SV is the stroke volume in ml.

After control hemodynamic measurements were obtained dobutamine (200 mg in 500 ml of dextrose in water) was administered intravenously as a continuous infusion at a rate of 10 μg/kg per min. In seven patients dobutamine was given at two dose levels, 5 and 10 μg/kg per min. Hemodynamic measurements were repeated after at least 15 minutes of constant infusion of the drug at each dose level.

Results

Hemodynamic data at rest and during infusion of 10 μg/kg per min of dobutamine in the 15 patients

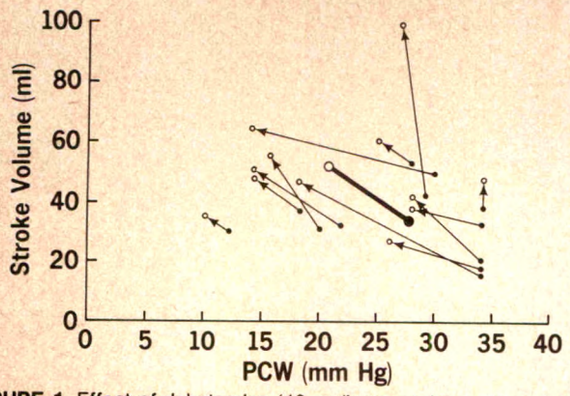

FIGURE 1. Effect of dobutamine (10 μg/kg per min) on the relation between stroke volume and pulmonary capillary wedge pressure (PCW). **Closed circles** represent control observations, **open circles** observations during dobutamine infusion. **Heavy line** represents the average values for all patients studied.

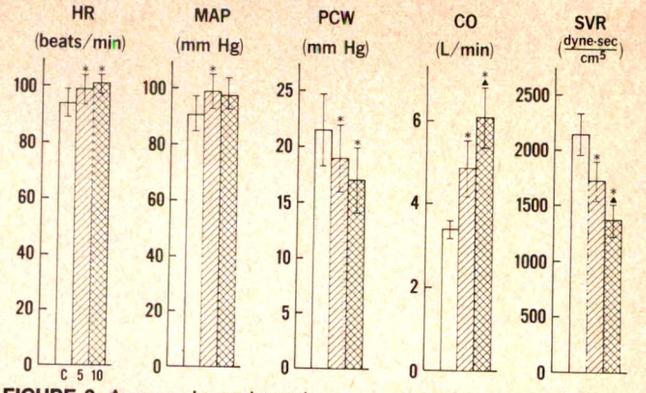

FIGURE 2. Average hemodynamic measurements in seven patients during control period **(open bar)** and infusions of 5 μg/kg per min **(middle bar)** and 10 μg/kg per min of dobutamine **(right bar).** Asterisk indicates significant difference from control ($P < 0.05$); triangle indicates significant difference from values during 5 μg/kg per min infusion ($P < 0.05$). CO = cardiac output; HR = heart rate; L = liters; MAP = mean arterial pressure; PCW = pulmonary wedge pressure; SVR = systemic vascular resistance.

studied are shown in Table I. Cardiac output increased in every patient ($P < 0.001$), from an average of 3.1 to 5.6 liters/min (81.8 percent), whereas heart rate changed only slightly (average 98.5 to 105.2 beats/min, $P < 0.02$), indicating that the increase in cardiac output was due mainly to the alteration in stroke volume, which increased by an average of 65.8 percent. The cardiac index was less than 2.5 liters/min per m^2 in all subjects during the control period and was restored to the normal range in 10 (67 percent) of the patients during dobutamine infusion. Mean pulmonary capillary wedge pressure in 12 patients decreased from 27.4 to 21.1 mm Hg during infusion of the drug ($P < 0.001$) (Fig. 1).

Mean arterial pressure was not significantly altered (93.3 to 98.2 mm Hg) during infusion of dobutamine, but systolic pressure increased from an average of 120 ± 5.5 (standard error) to 136 ± 5.5 mm Hg ($P < 0.05$) whereas diastolic pressure was unaltered (79 ± 3.5 to 82 ± 3.2 mm Hg). Cardiac work almost doubled as indicated by an increase in mean stroke work from 28.3 to 57.5 g-m ($P < 0.01$). The values for both systemic and pulmonary vascular resistance decreased during the drug infusion, from an average of 2,237 to 1,418 dynes sec cm^{-5} ($P < 0.001$) and from 281 to 162 dynes sec cm^{-5} ($P < 0.001$), respectively.

The 10 μg/kg per min infusion produced a greater hemodynamic effect than the 5 μg/kg per min infusion in the seven patients who were studied at both dose levels (Fig. 2). No arrhythmias or untoward side effects were observed in any patients during dobutamine infusion.

Discussion

Our data indicate that dobutamine possesses pharmacologic properties that make it an ideal sympathomimetic agent for producing a selective improvement in myocardial function. In the doses employed in these patients with severe congestive heart failure, cardiac output was restored to normal levels, pulmonary capillary wedge pressure was reduced, heart rate was only slightly increased whereas mean arterial pressure was unchanged.

Since myocardial oxygen consumption is directly related to aortic pressure and heart rate as well as to the contractile state of the myocardium,[14] sympathomimetic amines that increase heart rate (isoproterenol) or systemic vascular resistance (norepinephrine) may have a deleterious effect on the ischemic left ventricle.[3,15,16] Use of dobutamine in this clinical setting may be advantageous because this drug does not have prominent chronotropic or peripheral vascular effects but retains a potent inotropic effect. The reduction in peripheral vascular resistance during dobutamine infusion is consistent with either a direct vasodilating effect of the drug or a reflex relaxation of vascular tone.

Clinical implications: The incremental circulatory effect demonstrated when the dose was increased from 5 to 10 μg/kg per min indicates that within this dose range the hemodynamic response is linearly related to dose. Because of the prompt response to the drug, its reliability in restoring cardiac output to normal levels and the absence of side effects during these short-term infusions, further evaluation of the use of dobutamine in the treatment of low output syndromes is indicated. Since most of the patients in our series were less than 50 years old and had cardiomyopathy, additional data are needed on the responses in older patients with ischemic heart disease.

Effects of Isosorbide Dinitrate on the Response to Atrial Pacing in Coronary Heart Disease

ROBERT J. STEELE, MD*
GARY W. BURGGRAF, MD*
JOHN O. PARKER, MD, FACC

Kingston, Ontario, Canada

To study the efficacy of isosorbide dinitrate in prevention of myocardial ischemia, 20 patients with angiographically proved coronary artery disease underwent atrial pacing (mean rate 138/min) before (P_1), 10 minutes after (P_2) and 65 minutes after (P_3) sublingual administration of 5 mg of isosorbide dinitrate. The symptomatic, hemodynamic and metabolic responses were evaluated at rest and during each pacing period. Angina occurred in all subjects during P_1. Angina did not recur or was less severe in 17 of 19 patients during P_2 and in 19 of 20 patients during P_3. Resting left ventricular end-diastolic pressure for the group was normal at 11 ± 4 mm Hg (mean ± standard deviation). On interruption of pacing at 4.5 minutes during P_1, average end-diastolic pressure during sinus rhythm was abnormal (18 ± 6 mm Hg). After administration of isosorbide dinitrate mean left ventricular end-diastolic pressure was significantly decreased at rest and remained normal when pacing was interrupted during P_2 and P_3. Brachial arterial pressure, cardiac index, tension-time index, left ventricular stroke work index and maximal rate of rise of left ventricular pressure were all diminished at rest before and during P_2 and P_3. S-T segment depression was less during P_2 and P_3 than during P_1. Before isosorbide dinitrate was given, resting myocardial lactate extraction was 15 ± 11 percent; during P_1 lactate extraction decreased to −2 ± 25 percent. Lactate extraction was significantly greater during P_2 and P_3 than during P_1.

This study demonstrates that sublingual administration of 5 mg of isosorbide dinitrate has a significant protective effect against pacing-induced myocardial ischemia at 10 and 65 minutes after administration.

Isosorbide dinitrate is one of the most widely used of the so-called long-acting nitrates in the management of angina pectoris. It has been given both orally and sublingually, either alone or in combination with propranolol.[1–3] Although most reports have suggested that it achieves better control of angina when administered sublingually, others have claimed that excellent prophylaxis can be achieved by administering daily oral doses of up to 360 mg.[4] Most studies show isosorbide dinitrate is beneficial, although some have found it to be no more effective than placebo.[5]

Both the mechanism and the duration of action of isosorbide dinitrate are unknown. The drug probably acts through alterations in the balance between myocardial oxygen demand and supply by decreasing left ventricular oxygen requirements. It may also change total coronary blood flow and distribution, but there have been no definitive studies of its effect on the coronary circulation. Investigations into the drug's duration of action have shown beneficial effects on hemodynamics and exercise tolerance ranging from less than 1 to at least 2 hours.[6–10] The different exercise protocols employed may account in part for the variable results reported in these studies.[11]

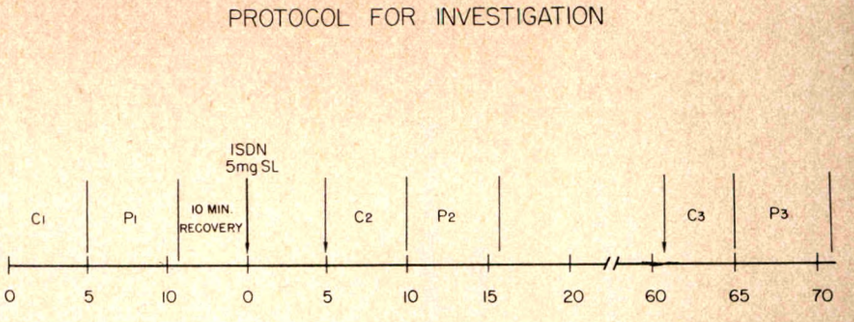

FIGURE 1. Protocol for sequential pacing studies. C_1, C_2, C_3 = first, second and third control periods before, 5 minutes after and 60 minutes, respectively, after drug administration; ISDN = isosorbide dinitrate; P_1, P_2, P_3 indicate, respectively, pacing periods before and 10 and 65 minutes after drug administration.

Previous investigations of the antianginal effects of isosorbide dinitrate have determined the response to exercise before and after drug administration.[1–3,5–10] Atrial pacing is well documented as a valid and reproducible stress test in patients with coronary artery disease and has been utilized to study the effect of nitroglycerin on the clinical, hemodynamic and metabolic concomitants of myocardial ischemia.[12–15] However, no information is available regarding the effect of sublingually administered isosorbide dinitrate on the response to atrial pacing in patients with symptomatic coronary artery disease. Accordingly, this study examines the early and late clinical, hemodynamic and metabolic effects of sublingually administered isosorbide dinitrate using atrial pacing as a stress.

Methods

Twenty patients with angina pectoris who were subsequently shown to have significant coronary artery disease were studied. Each patient was a potential candidate for saphenous vein coronary bypass surgery. Informed consent was obtained and there were no complications related to the investigation. Sodium Nembutal® (100 mg) was given orally 1 hour before the procedure. A single electrocardiographic lead (modified lead II) was monitored to evaluate S-T segment depression. Under local anesthesia, the brachial artery and two veins were isolated in the right antecubital fossa. A no. 8 Gorlin catheter was positioned in the mid-portion of the coronary sinus for pacing and blood sampling, a no. 8 Goodale-Lubin catheter was advanced to the pulmonary artery and a no. 8 Eppendorf catheter was passed to the left ventricle from the right brachial artery. With use of the Seldinger technique, a Teflon® cannula was inserted into the left brachial artery for blood sampling and arterial pressure monitoring. Pressures from the brachial artery, pulmonary artery and left ventricle were measured with P_{23}DB Statham strain gauges 5 cm below the angle of Louis and were recorded on a photographic recorder (Electronics for Medicine DR12). Mean brachial arterial and pulmonary arterial pressures and maximal systolic rate of rise of left ventricular pressure (dP/dt) were obtained electronically. Each measurement was averaged over at least two respiratory cycles.

Protocol (Fig. 1)

Control pressures and cardiac output determinations in duplicate were obtained by the dye-dilution technique. Blood samples were obtained simultaneously from the coronary sinus and brachial artery for subsequent analysis of lactate concentration (C_1). Each patient then underwent pacing from the coronary sinus at a rate of 120 to 150 beats/min (P_1). The rate was preselected with the aim of inducing angina within 3 to 4 minutes of the onset of pacing. Pacing was continued for 7 minutes with three 15 second periods of interruption at 1, 3 and 4.5 minutes, respectively, to measure left ventricular end-diastolic pressure during sinus rhythm. Cardiac output was determined and blood samples were taken between 5 and 7 minutes of pacing. After a 10 minute recovery period, 5 mg of isosorbide dinitrate was given sublingually. After 5 minutes (C_2) and 60 minutes (C_3), during sinus rhythm, pressures and cardiac output were recorded and blood samples obtained. After C_2 and C_3, pacing was repeated at the same rate for each patient starting at 10 minutes (P_2) and 65 minutes (P_3) after administration of isosorbide dinitrate. During P_2 and P_3 hemodynamic and metabolic data were obtained as during P_1.

After the hemodynamic study, selective coronary arteriography with use of the Sones technique and left ventriculography were performed. All patients had significant obstructive coronary disease with 75 percent or greater obstruction in at least one major coronary artery.

Calculations

Left ventricular end-diastolic pressure was measured at the nadir of the atrial deflection (*A*) in the left ventricular pressure tracing. In the tracings in which the *A* wave could not be clearly defined, end-diastolic pressure was measured at a point corresponding to the peak of the R wave of the electrocardiogram or where an abrupt rise in the pressure curve was visible.

Tension-time index (TTI) in millimeters of mercury × 10^{-1} was calculated according to the formula TTI = BA systolic × HR × 10^{-1} where BA = brachial arterial pressure in millimeters of mercury and HR = heart rate in beats per minute. Left ventricular stroke work index (LVSWI) in gram-meters per square meter was calculated according to the formula: LVSWI = [SI × (BAm − LVEDP) × 13.6]/1000 where SI = stroke index in milliliters per square meter, BAm = mean brachial arterial pressure in millimeters of mercury and LVEDP = left ventricular end-diastolic pressure in millimeters of mercury.

Blood samples for determination of lactate concentration were collected in glass tubes with no additive and immediately spun and frozen at −5° C for later analysis. Lactate concentration, determined by the automated enzymatic method of Apstein et al.,[16] was expressed as milligrams per 100 ml of plasma and the percentage of myocardial extraction of lactate was calculated as the ratio of the arteriovenous difference to the arterial level (a-v/a) × 100.

Statistical analyses were performed using Student's paired *t* test.

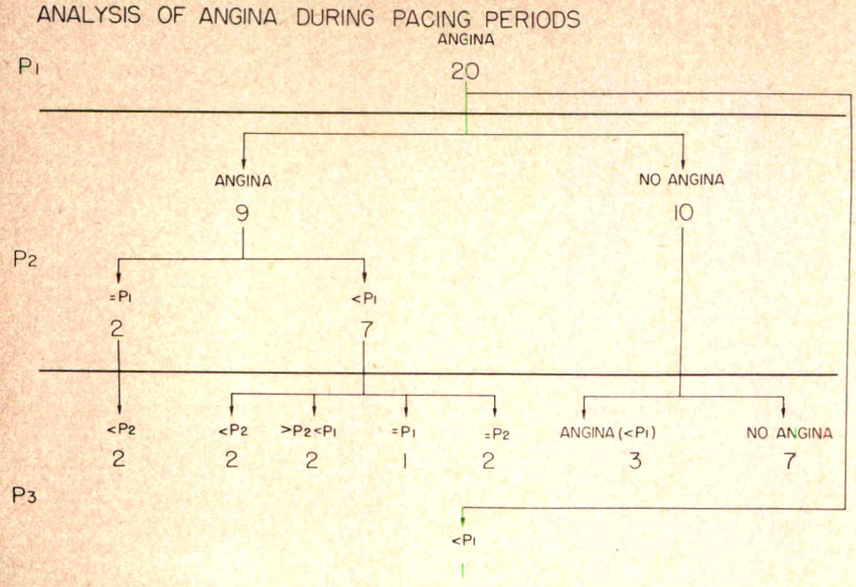

FIGURE 2. Analysis of angina during pacing periods. Abbreviations as in Figure 1.

Results

Angina during pacing: Figure 2 shows an analysis of the occurrence of chest pain during the three pacing periods. Angina developed in each of the 20 patients during the first pacing period (P_1). During P_2 (10 minutes after drug administration) only nine patients had angina; the pain was less severe than during P_1 in seven patients and equally severe in two. P_3 (65 minutes after drug administration) produced angina in 13 patients that was less severe than that during P_1 in all but 1 patient. The patient who did not undergo pacing during P_2 had less severe angina during P_3 than during P_1. Thus, angina did not recur or was less marked in 17 of 19 patients during P_2 and in 19 of 20 patients during P_3.

Hemodynamics during pacing: The hemodynamic and metabolic data are summarized in Table I, and statistical comparisons are shown in Table II. At the 4.5 minute interruptions of pacing and during the immediate post-pacing periods, heart rate returned to control values. The heart rate during sinus rhythm was similar during each control period. Left ventricular end-diastolic pressure was abnormal (more than 12 mm Hg) in six patients during the initial control period (C_1), but the average value was normal. During the initial pacing period (P_1) left ventricular end-diastolic pressure decreased from 11 ± 4 (mean ± standard deviation) to 8 ± 4 mm Hg ($P < 0.015$). During interruption of pacing at 4.5 minutes left ventricular end-diastolic pressure was 15 mm Hg or more in 14 patients and averaged 18 ± 6 mm Hg. This was a significant increase from the value obtained during C_1 ($P < 0.001$). These hemodynamic observations are commonly documented during myocardial ischemia induced by atrial pacing.[12–14] During all subsequent pacing and at periods of interruption the average left ventricular end-diastolic pressure remained normal. During the early pacing period after isosorbide dinitrate administration (P_2), none of the patients had abnormal end-diastolic pressure during interruption of pacing although nine had chest pain. During P_3 end-diastolic pressure on interruption was abnormal in only three of the patients who experienced angina and the mean value was normal (10 ± 4 mm Hg).

Cardiac index averaged 3.3 ± 0.5 liters/min per m^2 during C_1 and fell significantly 5 minutes (C_2) and 60 minutes (C_3) after drug administration ($P < 0.001$). Cardiac index during both P_2 and P_3 was significantly lower than during P_1.

Mean brachial arterial pressure did not change significantly 5 minutes after drug administration (C_2), but the decrease at 60 minutes (C_3) was significant ($P < 0.001$). There was a significant increase in brachial arterial pressure during P_1 but not during P_2 and P_3. The level of brachial arterial pressure during P_2 and P_3 was significantly lower than during the initial pacing period. Changes in tension-time index paralleled those of brachial arterial pressure.

Left ventricular stroke work index decreased after administration of isosorbide dinitrate from 54 ± 10 g-m/m^2 during C_1 to 44 ± 10 during C_2 and 37 ± 7 during C_3 ($P < 0.001$). During P_1 stroke work index decreased significantly as a result of the increased heart rate and hence decreased stroke index; the values during P_2 and P_3 were still lower than during P_1 ($P < 0.001$). During each pacing period left ventricular dP/dt increased. After administration of isosorbide dinitrate dP/dt decreased during both C_2 ($P < 0.015$) and C_3 ($P < 0.005$) and was also significantly reduced during pacing.

S-T segment depression was measured only during sinus rhythm because of the distortion introduced by coronary sinus pacing. During the control periods before and after drug administration S-T segments were isoelectric. After interruption of pacing before administration of isosorbide dinitrate the average S-T segment depression was 1.3 mm; after administration of isosorbide dinitrate it was significantly less during the two periods of pacing ($P < 0.001$).

Metabolic data: Lactate extraction averaged 15 percent during C_1. During P_1 there was a shift to lactate production for the group as a whole that averaged 2 percent. Among the 17 patients in whom metabolic sampling was performed lactate production occurred in 8. In the other nine patients the coronary sinus concentration tended to increase, resulting in a smaller arteriovenous difference. During C_2 three patients continued to show evidence of lactate production but for the group as a whole lactate extraction averaged 12 percent. During P_2 only four patients produced lactate; for the group, lactate extraction averaged 10 percent. During C_3 no patients showed evidence of lactate production. During P_3 five patients showed evidence of lactate production; for the group, lactate extraction averaged 9 percent.

Discussion

We have shown that administration of 5 mg of isosorbide dinitrate sublingually exerts a protective effect on the response to atrial pacing in patients with coronary artery disease. The subjective response of each patient with regard to lessening of chest pain is supported by objective hemodynamic and metabolic data showing an effect lasting at least 70 minutes in the majority of patients. Similar conclusions regarding the long-term effects of isosorbide dinitrate on hemodynamics at rest and during exercise have been reached by other investigators.[7–9]

During bicycle or treadmill exercise, angina occurs at a relatively constant level of myocardial oxygen consumption for each patient.[11] Changes in the determinants of myocardial oxygen consumption and the amount and duration of exercise at which angina occurs can be used to evaluate the efficacy of antianginal drugs. However, differences in exercise protocols employed may affect the ability to detect changes in exercise performance.[11] Use of right atrial pacing to precipitate angina provides an easily standardized, reproducible stress that is particularly suitable in the assessment of response to drug therapy.

Isosorbide dinitrate and myocardial oxygen consumption: The major determinants of myocardial oxygen consumption are left ventricular wall tension, heart rate and inotropic state.[17] Wall tension varies directly with chamber diameter and developed pressure and inversely with wall thickness. If one assumes that the decrease in left ventricular end-diastolic pressure after administration of isosorbide dinitrate at rest or during pacing is due to a decrease in left ventricular size, then part of the beneficial action

of this drug would be explained. We did not measure chamber size directly, but, in one study of the effects of isosorbide dinitrate total heart size did diminish on plain chest films after administration of the drug.[6] Systemic arterial blood pressure was significantly reduced during sinus rhythm and atrial pacing for at least 1 hour after administration of isosorbide dinitrate. This reduction would result in reduced left ventricular wall tension and, hence, reduced myocardial oxygen consumption. We did not assess contractile state, but it has been shown in animal studies that isosorbide dinitrate exerts a positive inotropic effect on isolated papillary muscle preparations which, in turn, would increase myocardial oxygen consumption.[18] The beneficial effects of isosorbide dinitrate on myocardial ischemia observed in our patients imply that the drug's actions on reducing myocardial oxygen consumption predominate. The role of changes in the coronary circulation induced by isosorbide dinitrate, which might also lead to a more favorable balance between myocardial oxygen supply and demand, is unknown.

Left ventricular end-diastolic pressure: Increase in left ventricular end-diastolic pressure on interruption of atrial pacing has been established as the hallmark of an ischemic response.[14] The relative importance of an increase in heart size or diminished left ventricular compliance during ischemia as determinants of this response is still being debated.[19–22] Whatever the cause, the increase in end-diastolic pressure on interruption of pacing was considerably less even 1 hour after isosorbide dinitrate was administered. An unexpected finding was the normalization of the end-diastolic pressure response to pacing even in patients who experienced angina during the second and third pacing periods. Previous investigations[12–14] have shown that pacing-induced angina is usually accompanied by an abnormal hemodynamic response. Apparently isosorbide dinitrate reduced heart size and, hence, left ventricular end-diastolic pressure in these patients, but this effect was not always sufficient to prevent myocardial ischemia during pacing.

Lactate metabolism: The metabolic data in this study also provide objective confirmation that isosorbide dinitrate exerts a beneficial effect on myocardial ischemia for as long as 70 minutes after its administration. Myocardial ischemia causes a shift from aerobic to anaerobic metabolism with lactate production.[23,24] Previous investigations[25] have shown that atrial pacing is a sensitive method for assessing lactate production by ischemic myocardium because there is no change in arterial lactate concentration as there is with exercise. When the arterial lactate level is constant, changes in coronary sinus lactate concentration are an accurate reflection of the metabolic state of the myocardium. Although individual variations in lactate metabolism were wide, the group as a whole tended to produce lactate during the first pacing period. At 15 and 70 minutes after administration of isosorbide dinitrate, metabolic status was improved, as shown by a return to lactate extraction.

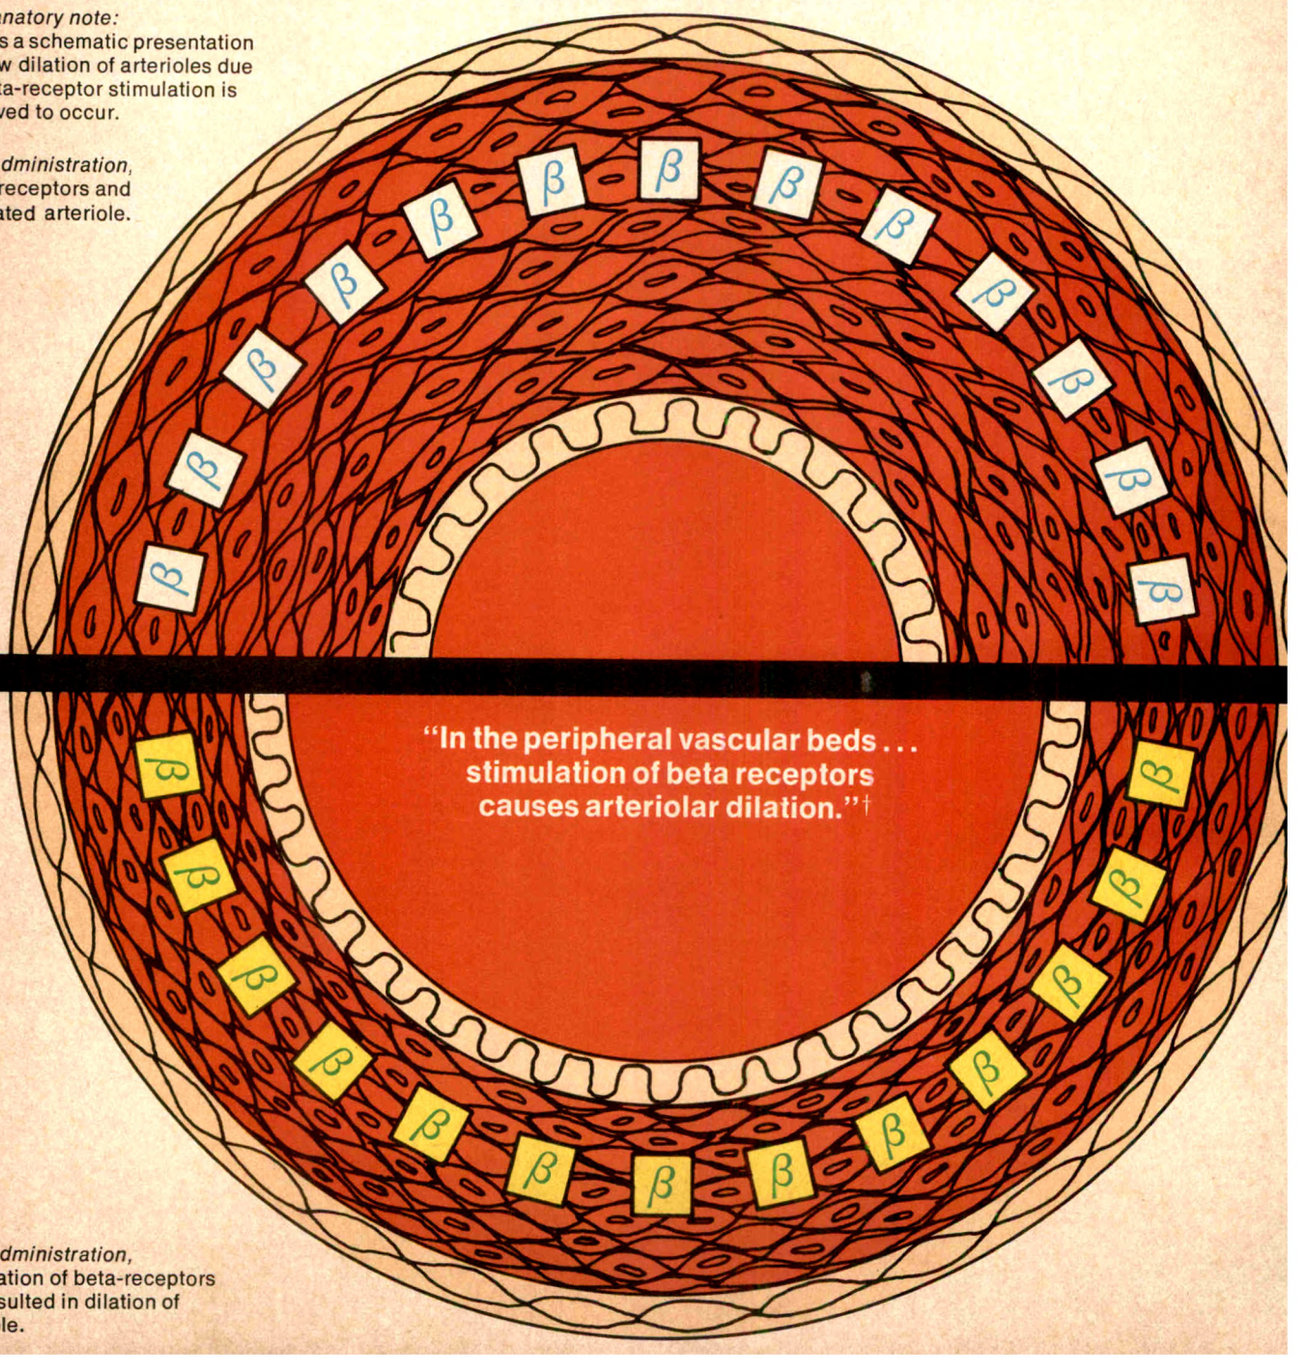
What chronic vascular disorder do these photos and symptoms describe?

1. Characteristic symptoms due do malnourishment of the skin may include atrophic changes, scaly appearance and dryness. Hair is sparse on toes and dorsa of the feet.

2. Impaired blood supply leads to characteristic nail changes: irregular growth, changes in shape and form and—commonly observed—slow growth.

Explanatory note:
This is a schematic presentation of how dilation of arterioles due to beta-receptor stimulation is believed to occur.

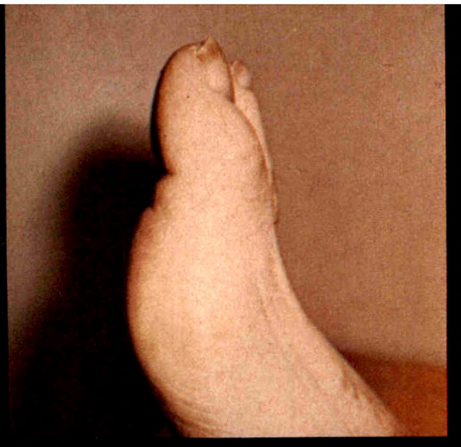
Pre-administration,
beta-receptors and undilated arteriole.



"In the peripheral vascular beds . . . stimulation of beta receptors causes arteriolar dilation."†

Post-administration,
stimulation of beta-receptors has resulted in dilation of arteriole.

Dependent rubor (a cyanotic redness) usually more intense in distal parts of e extremities, most often distal to wrists nd ank



4. Pallor of the skin on elevation of the affected extremities is caused by impaired circulation inadequate to overcome the effect of gravity.

Answer: Arteriosclerosis obliterans. These early changes suggest the need for instituting peripheral vasodilation therapy.

DILATES ARTERIOLES IN SKELETAL MUSCLES

- to help increase blood supply to ischemic areas*
- to help relieve leg cramps, tingling, numbness, cold hands and feet*

*ndications**

- arteriosclerosis obliterans
- thromboangiitis obliterans (Buerger's disease)
- diabetic vascular disease
- night leg cramps
- ischemic ulcer
- Raynaud's phenomenon and disease

Miller, R.R. et al.: The pharmacologic basis for clinical use of beta-adrenergic blocking drugs, lation. Drug Ther. 8:2, April 1974.

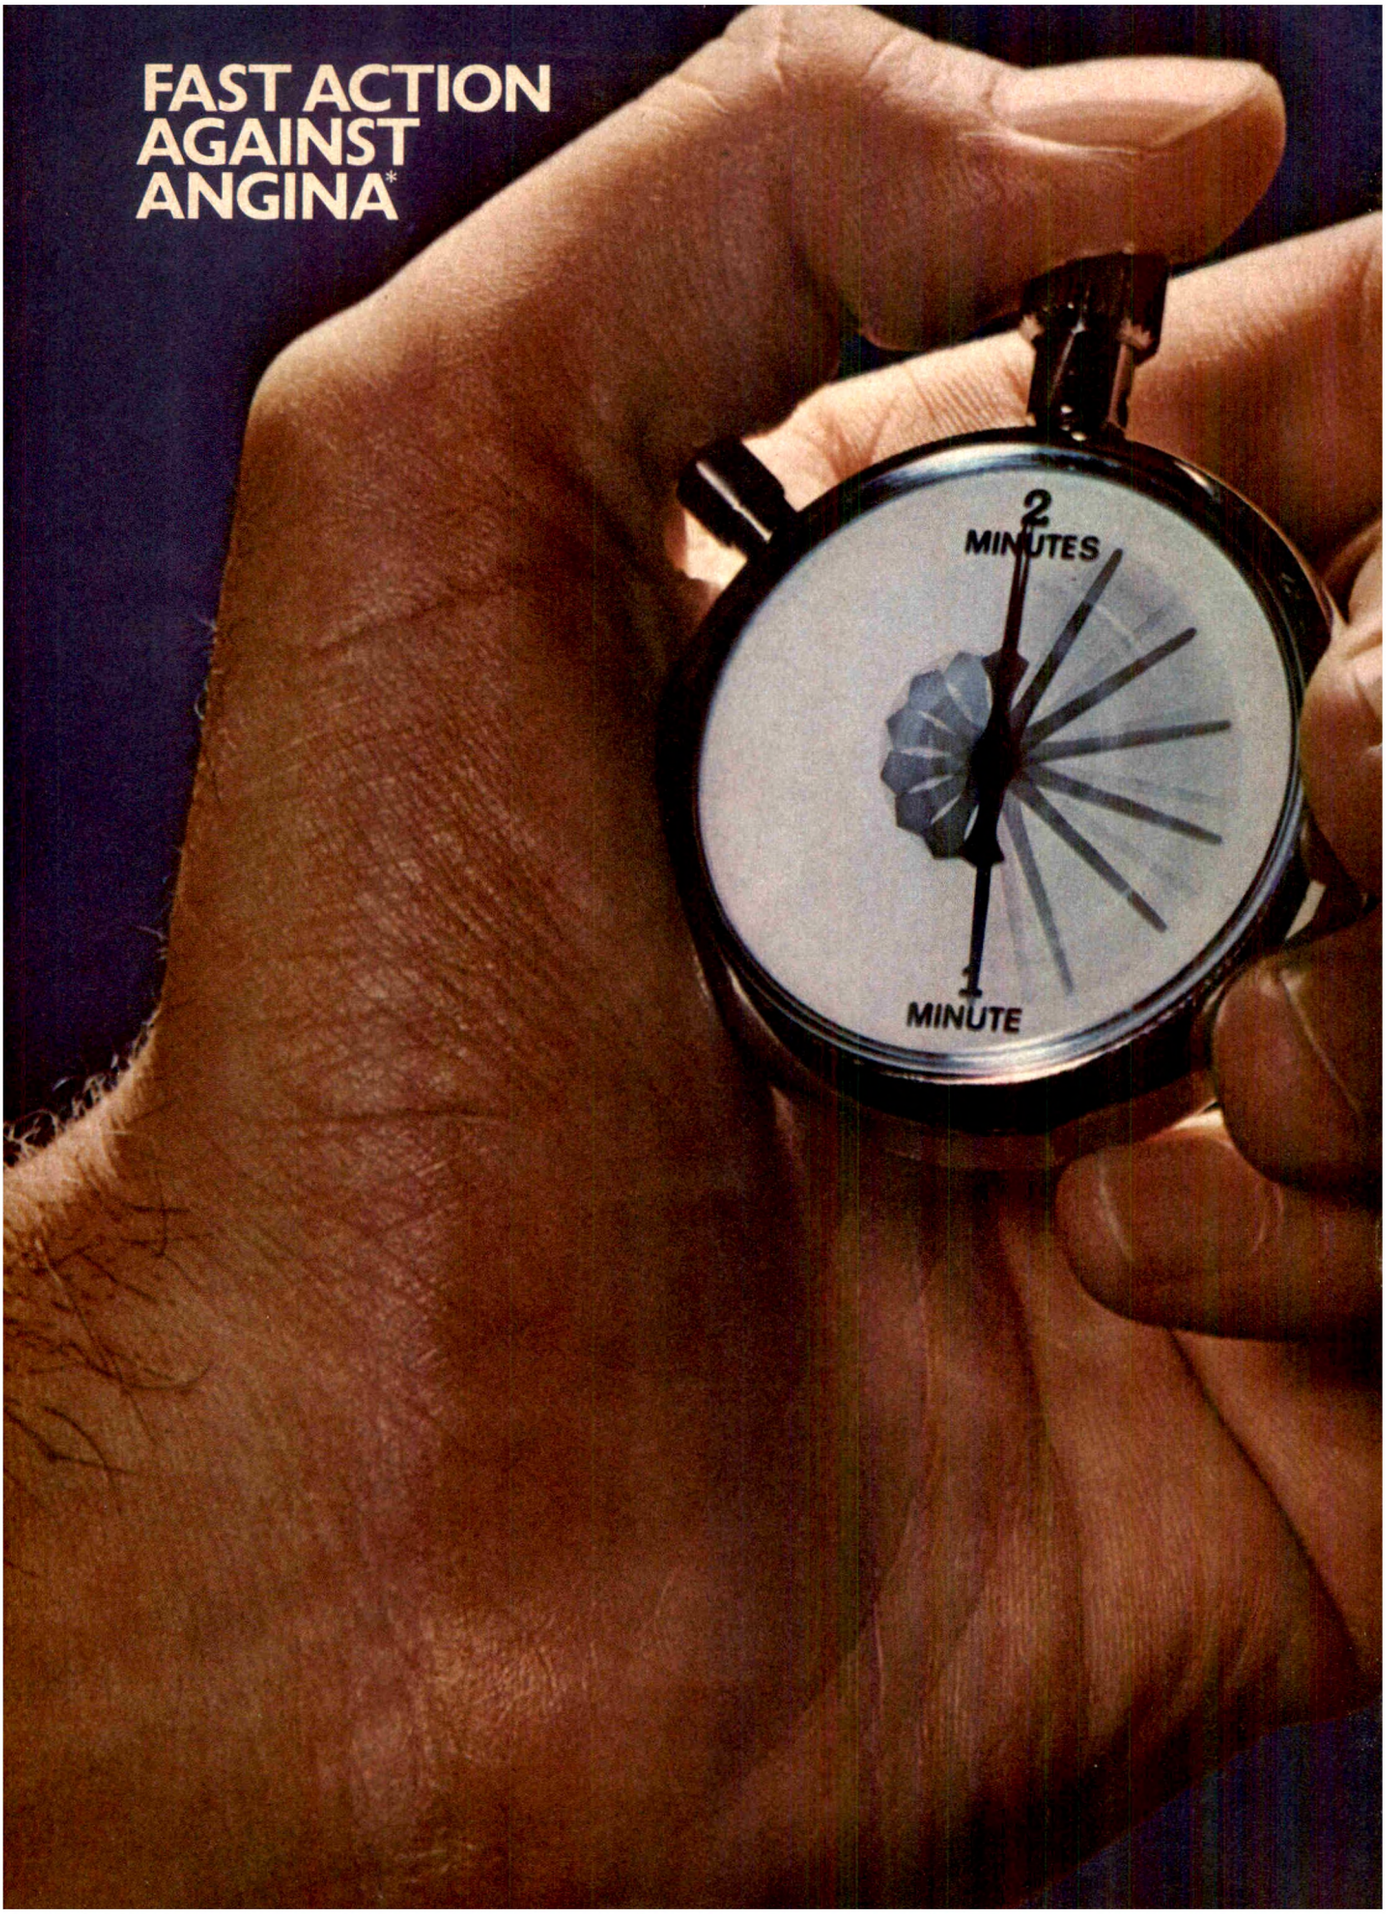
ARLIDIN® (nylidrin HCl)

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified this drug as "possibly" effective for peripheral vascular disease and circulatory disturbances of the inner ear. Final classification of the less-than-effective indications requires further investigation.

Contraindications: Acute myocardial infarction, paroxysmal tachycardia, progressive angina pectoris and thyrotoxicosis. **Warnings:** In patients with cardiac disease such as tachyarrhythmias and uncompensated congestive heart failure, the benefit/risk ratio should be weighed prior to therapy and reconsidered at intervals during treatment. **Adverse Reactions:** Trembling, nervousness, weakness, dizziness (not associated with labyrinthine artery insufficiency), palpitations, nausea and vomiting may occur. Postural hypotension, while not reported, may also occur. **Dosage:** Orally, 3 to 12 mg. three or four times a day. **How Supplied:** White, scored tablets, 6 mg. and 12 mg. Bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV PHARMACEUTICALS

USV PHARMACEUTICAL CORP.
Tuckahoe, N.Y. 10707



FAST ACTION
AGAINST
ANGINA*
2
MINUTES
1
MINUTE

...AS FAST AS SUBLINGUAL

CHEWABLE SORBITRATE® 5MG.

ISOSORBIDE DINITRATE

Offers all the benefits you've come to expect of sublingual ISDN:

- ☐ acts just as fast for therapeutic use...within 2 minutes
- ☐ acts just as long for prophylaxis...up to 2 hours
- ☐ just as stable in air

(Can be stored or carried with no significant loss of potency.)

Offers these unique advantages over the sublingual form:

Natural chewing action stimulates saliva secretion...

- ☐ helps dissolve medication more easily
- ☐ helps distribute nitrate over a larger mucosal area
- ☐ helps avoid "dry-mouth" problems

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

* **Indications:** Based on a review of this drug by The National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: Sublingual and chewable dosage forms of SORBITRATE are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and chewable tablets.

Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE.

Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

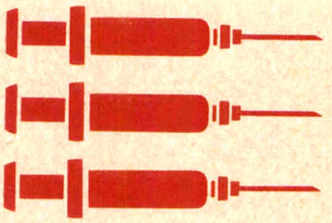
Effectiveness...

I.V. Administration Guidelines for Premature Ventricular Contractions and Tachycardia

1. Preparation of drug: Dilute before I.V. use.
2. Usual dosage range: 200-1000 mg.
3. Infusion rate: Not to exceed 25-50 mg. per minute. Total I.V. dose not to exceed 1000 mg.
4. Precautionary measures:
   a. Keep patient in supine position.
   b. Monitor electrocardiographically and discontinue if myocardial toxicity is evidenced.
   c. Measure blood pressure almost continuously and temporarily discontinue infusion if blood pressure falls more than 15 mm. Hg.

When therapeutic blood levels are required quickly, I.V. Injections

100 mg. every 5 minutes until arrhythmia suppressed (up to a maximum dose of 1 gram).



For ventricular arrhythmias

SQUIBB® 'The Priceless Ingredient of every product is the honor and integrity of its maker.'™

by a variety of routes

I.V. Infusion

2-6 mg. per minute[1].
(42.8 μg./min./kg.)[2]

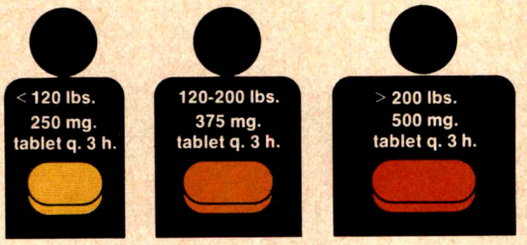
1. Wyman MG, Hammersmith L: Am J Cardiol 33:661-667, 1974
2. Bigger JT, Jr., Giardina EV: MCV Quart 9 (1): 65-76, 1973

Terminate I.V. infusion *4 hours before* oral regimen begun.

Oral Administration Guidelines to Provide 50 mg./kg./day* for Ventricular Arrhythmias

Ventricular Tachycardia
(give priming dose of 1 g. if patient has not received prior infusion)

Premature Ventricular Contractions



*This dosage schedule is for use as a guide for treating the average patient, but all patients must be considered on an individual basis.

Pronestyl®
(Procainamide Hydrochloride)
through the entire therapeutic course

See next page for brief summary.

PRONESTYL® TABLETS
(Procainamide Hydrochloride Tablets)

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate considerations of alternative anti-arrhythmic therapy.

Pronestyl Tablets (Procainamide Hydrochloride Tablets) are veneer-coated tablets providing 250 mg., 375 mg., and 500 mg. procainamide hydrochloride.

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; bear in mind cross sensitivity to procaine and related drugs. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of second degree and third degree A-V block unless an electrical pacemaker is operative.

Administration: Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous if myocardial damage exists.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with severe organic heart disease and ventricular tachycardia that complete heart block, which may be difficult to diagnose, may be present. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related to continued procainamide therapy (see boxed Warning). Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see Precautions). Reactions consisting of fever and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever or any symptoms of upper respiratory tract infection. If any of these symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions and for full prescribing information.

How Supplied: Pronestyl Tablets (Procainamide Hydrochloride Tablets) providing 250 mg., 375 mg., and 500 mg. are available in bottles of 100.

PRONESTYL® INJECTION
(Procainamide Hydrochloride Injection U.S.P.)

Description: Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) is a sterile aqueous solution providing 100 mg. or 500 mg. procainamide hydrochloride per ml. The 100 mg./ml. potency contains 0.9% (w/v) benzyl alcohol and 0.09% sodium bisulfite as preservatives. The 500 mg./ml. potency contains 0.1% methylparaben and not more than 0.2% sodium bisulfite as preservatives.

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; cross sensitivity to procaine and related drugs must be borne in mind. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage, procainamide may produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Because procainamide is a peripheral vasodilator, I.V. administration may produce transient but at times severe hypotension particularly in conscious patients. I.M. injection is less likely to cause serious falls in blood pressure. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

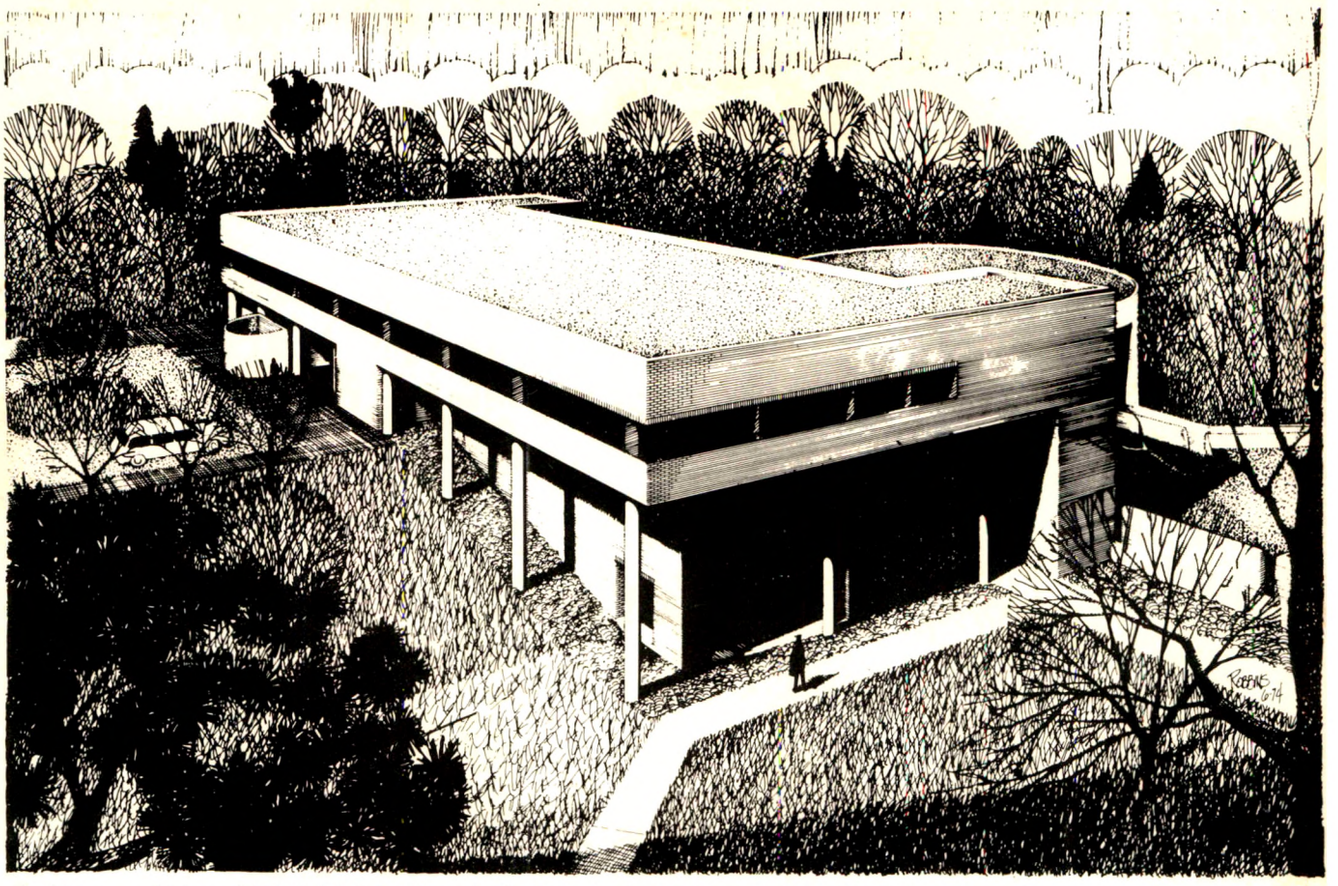
A syndrome resembling lupus erythematosus has been reported. Reactions consisting of fever and chills including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in SGOT following single doses of the drug have been reported. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred; therefore, routine blood counts are advisable during maintenance therapy. If soreness of mouth, throat or gums, unexplained fever or any symptoms of upper respiratory tract infection should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Administration: Oral administration is preferred. When parenteral therapy is necessary, intramuscular administration is the method of choice. *Intravenous use should be limited to extreme emergencies,* **the drug should be administered as a dilute infusion,** and the patient should be monitored electrocardiographically. The intravenous dose should not exceed 1 gram. Administer at a rate not exceeding 25 to 50 mg. per minute.

Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

The package insert should be read carefully to become familiar with the recommended dosage for the indicated conditions.

How Supplied: Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) is available in 10 ml. vials providing 100 mg./ml. and in 2 ml. vials providing 500 mg./ml. © 1974 E. R. SQUIBB & SONS, INC. 444-009



Architect rendering of HEART HOUSE to be built in Bethesda, Maryland by the American College of Cardiology

America's heartland is still being built.

You will know it as **Heart House**. Soon to rise above nine acres of hard work and hope in the Bethesda countryside, it will be the national continuing education center dedicated to the diagnosis, treatment and eventual prevention of cardiovascular disease.

Heart House is for you, Doctor.

As it is for both those who will follow and those who depend upon your professional progress. As an incomparable learning laboratory for physicians, and as the national headquarters of the American College of Cardiology, Heart House will frontier the development of all types of educational materials and circulate them throughout the world.

Help build and equip Heart House through either a 36-month Pledge or a tax-deductible enclosure now.

AJC-8

I would like to help build and equip HEART HOUSE. ☐ Please find my gift or pledge enclosed. ☐ Please send me additional information on HEART HOUSE, including memorial and honorary gift opportunities.

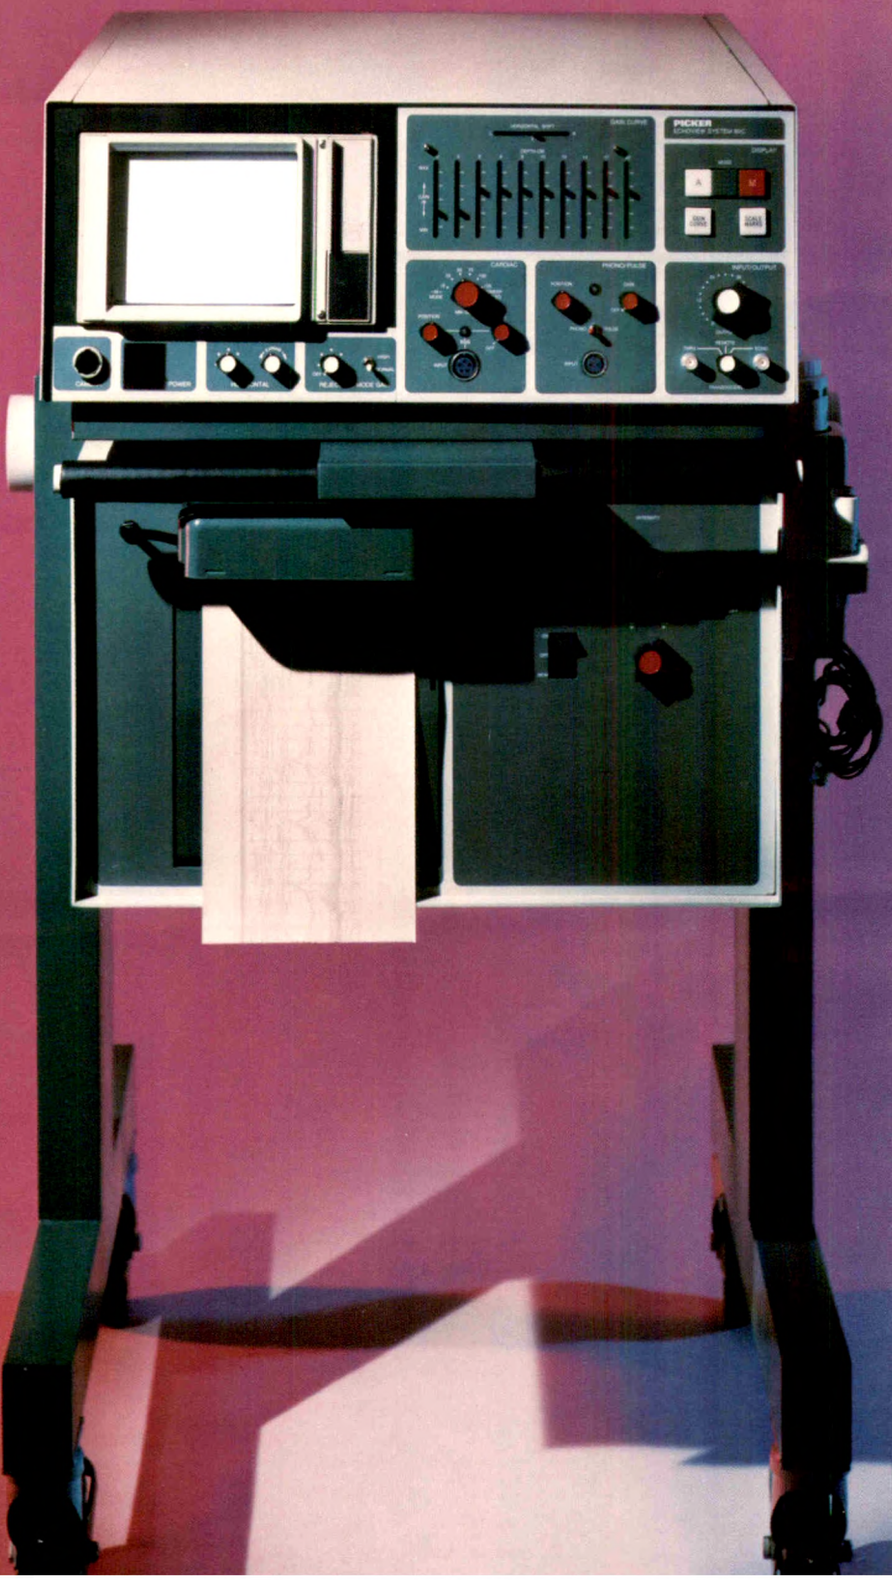
HEART HOUSE

DSA* gives echocardiography a new dimension.



Echoview™ System 80C Echocardiograph

The latest advance in echocardiography has just advanced again with *Depth Selective Amplification — the heart of the new Echoview System 80C.

DSA allows you to select optimum gain for every position of the cardiac structure. Echoes — from anterior wall, interventricular septum, mitral valve or posterior wall — can be selectively increased or decreased in order to define these structures with the greatest clarity. Picker Echoview System 80C with exclusive DSA gives your tracings more clinical data and a higher percentage of interpretable results.

But DSA is only part of the story. Logically grouped controls simplify operation. Lightweight cart allows you to take the Echoview System 80C to the patient's bedside. And our strip chart recorder provides excellent grey scale representation of weak and strong echoes so that all structures are clearly delineated.

The clinical data tell the story. Contact your Picker representative or Picker Corporation, 12 Clinton-ville Road, Northford, CT 06472, Telephone 203-484-2711, Ext. 371.

The Yorke Book Shelf is Growing

For years the Yorke Medical Publishing Group has been serving the Medical Profession with four outstanding journals. In fact, you are reading one of them now. In 1974 Yorke expanded its publishing services to include Medical Books—informative, timely, and incisive medical books. To date the response from the profession has been very encouraging—Here's why . . .

Congestive Heart Failure:

Mechanisms, Evaluation and Treatment

Edited by Dean T. Mason, M.D. Approximately 500 pages double column, including 200 illustrations. This integrated and comprehensive text provides thorough and up-to-date coverage of the subject by many of the world's foremost authorities on congestive heart failure. Ready Late 1975 *$35.00*

Hypertension Manual:

Mechanisms, Methods and Management

Edited by John H. Laragh, M.D., founder of the Columbia-Presbyterian Hypertension Center. 970 pages, 150 illustrations. This book, published February 1974, has already become a *classic* reference work on hypertension. *$37.00*

Also available: Selections in paperback: Hypertension-Mechanisms. 488 pages, 127 illustrations. $12.50. Hypertension-Methods. 120 pages, 17 illustrations. $7.50. Hypertension-Renin Systems, Drug Therapy & Diet. 100 pages, 12 illustrations. *$7.50*

The Practitioners' Dermatology

By Richard L. Sutton, Jr., M.D., and Morris Waisman, M.D. 530 pages with over 600 illustrations. Written uniquely with the busy internist, general practitioner, and dermatologist in mind, this book is organized for one-stop dermatologic referencing with emphasis on procedures that *work*. *$30.00*

Modern Drug Encyclopedia

A valuable independent drug information service for today's referencing needs, the Encyclopedia is organized generically with three comprehensive indexes. Over 3,000 ethical drugs are described. Purchase includes a free two-year updating service, *Modern Drugs*. *$33.00*

Yorke Medical Books/666 Fifth Avenue, New York, New York 10019 AJC-8

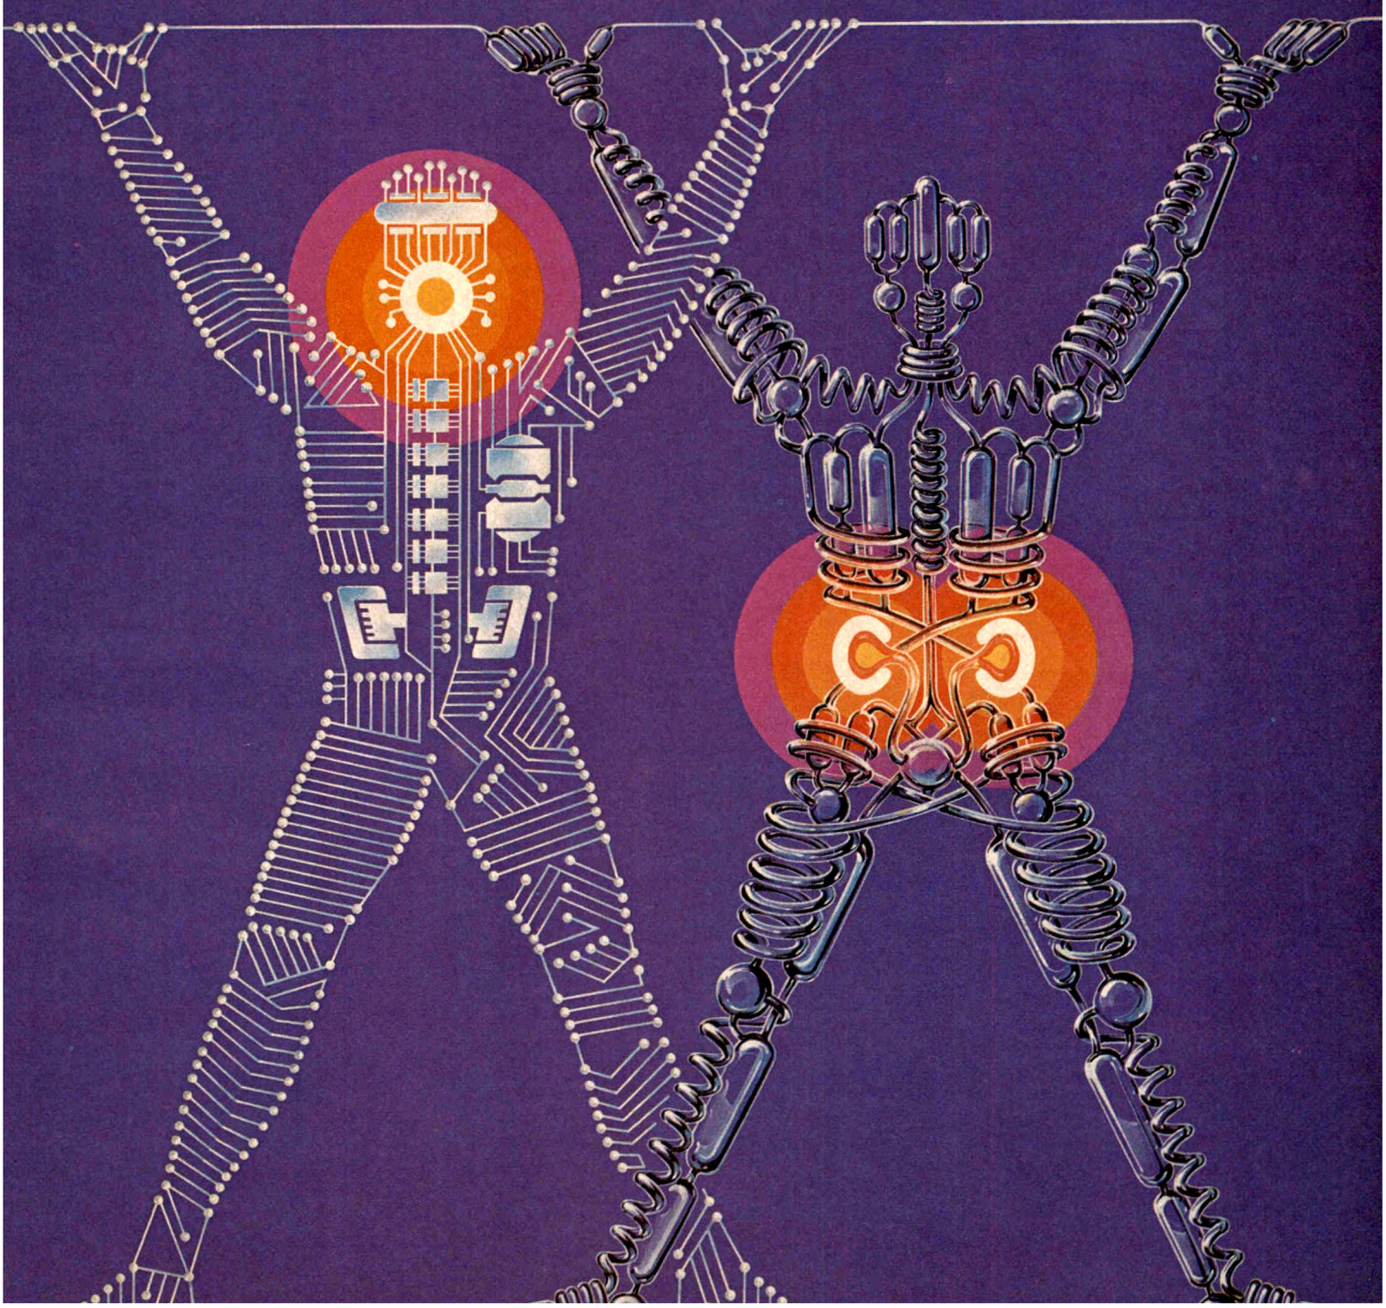
Announcing nonreserpine Combipres®

Each tablet contains: Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

The only major new combination antihypertensive in a decade

Please see last page of advertisement for a brief summary of the prescribing information including precautions, warnings, and adverse reactions.

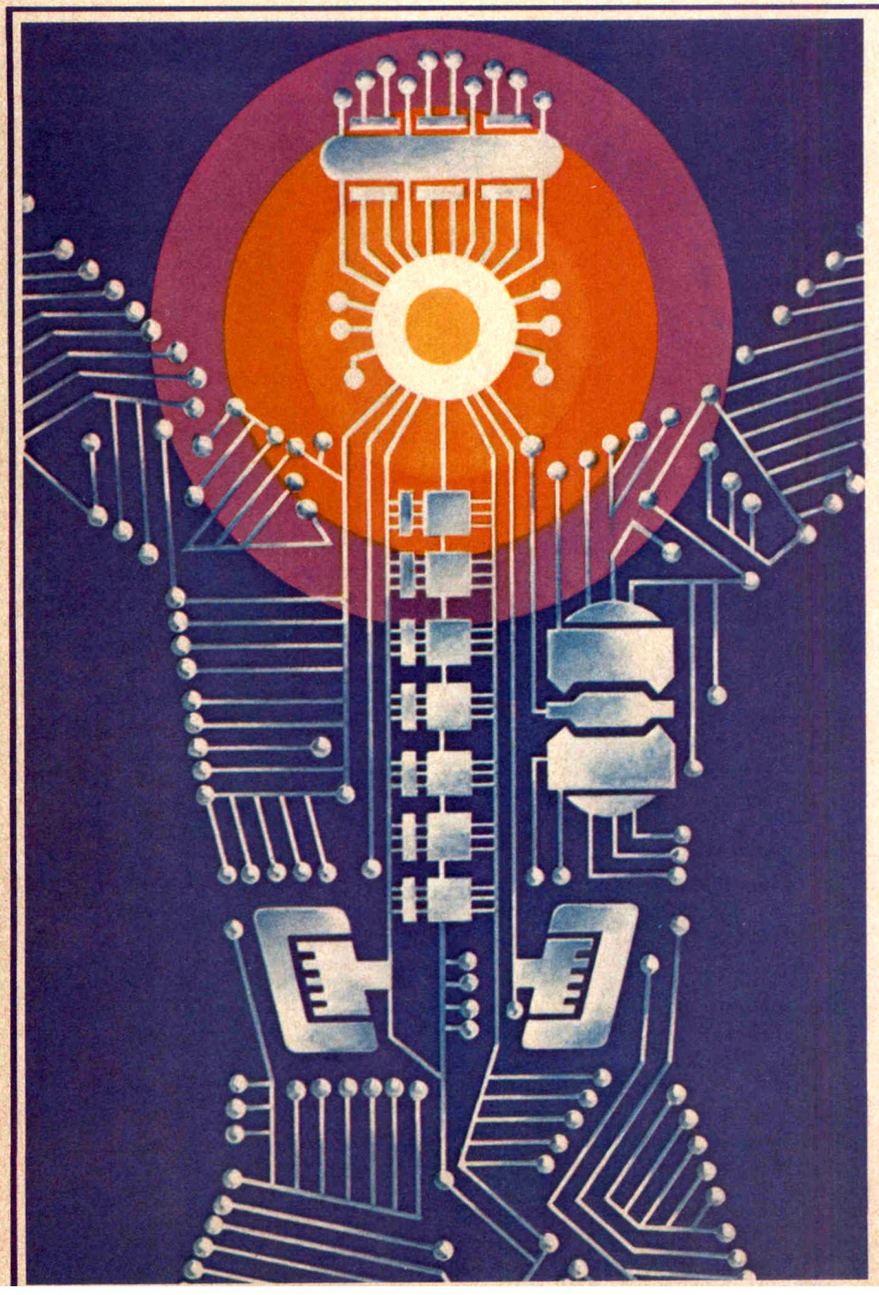


nonreserpine

new Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride,
0.1 or 0.2 mg and chlorthalidone, 15 mg

.1 and .2



Catapres®
(clonidine hydrochloride)
contributes:

Action at the vasomotor centers, as shown in animal studies—not a rauwolfia derivative or a sympathetic blocker or a "false transmitter"

Maximal blood pressure lowering without the weeks of delay common with the rauwolfia class of antihypertensives

Significant blood pressure reduction without alteration of normal hemodynamic responses to exercise

Mild and infrequent orthostatic hypotension

Little or no change in renal blood flow and glomerular filtration rate

Reduced plasma renin activity and excretion of aldosterone and catecholamines (see Actions section)

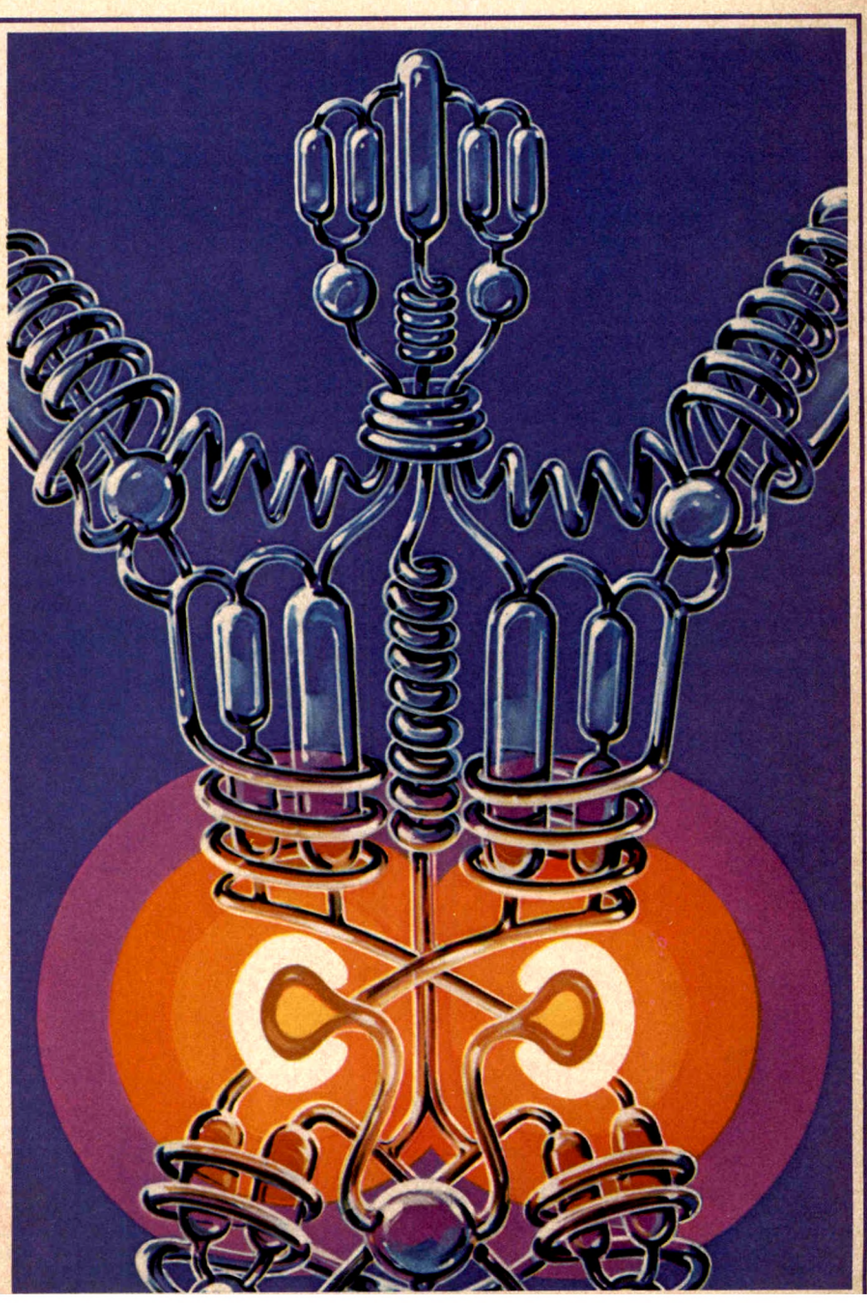
Combines Catapres (clonidine hydrochloride) with a diuretic—the only major new combination antihypertensive in a decade

Chlorthalidone contributes:

Pharmacologic action similar to the thiazides

Smooth, extended diuretic/antihypertensive effect

Additive or potentiating effect on adjunctive antihypertensive agents



The most common adverse reactions with Combipres are dry mouth, drowsiness, and sedation. As with thiazide-containing combination antihypertensives, hypokalemia, hyperuricemia, and decreased glucose tolerance may occur. Combipres is contraindicated in patients with known sensitivity to chlorthalidone and in those with severe renal or hepatic disease.

Please see last page of advertisement for a brief summary of the prescribing information including precautions, warnings, and adverse reactions.

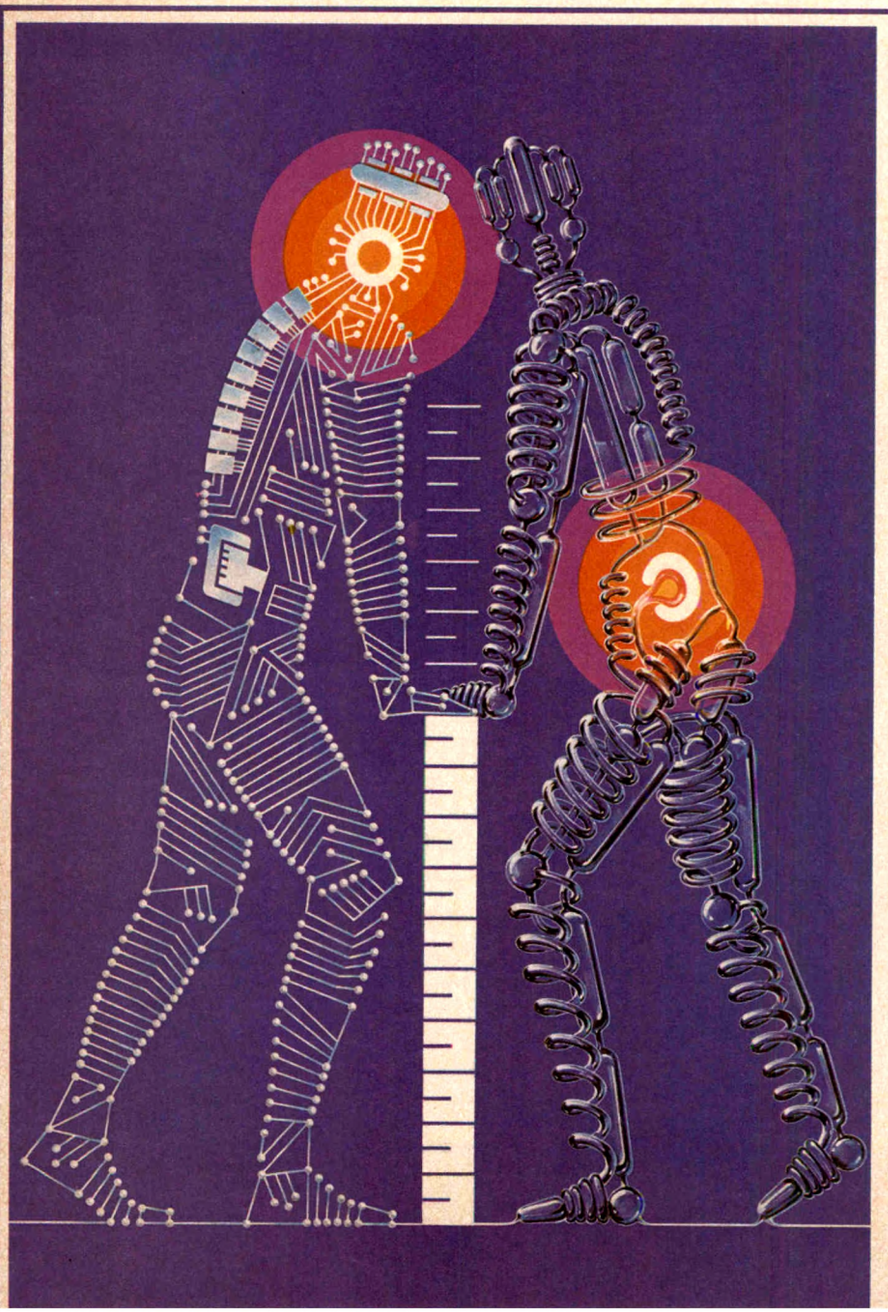
See box Warning on next page concerning the appropriate use of Combipres.

nonreserpine

new Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride,
0.1 or 0.2 mg and chlorthalidone, 15 mg

.1 and .2



Works harder

Usually exerts a more pronounced antihypertensive effect than either component alone in equivalent doses*

Works broadly

Wide therapeutic range—mild to severe hypertension

Works conveniently

Simplifies therapy for the hypertensive patient who needs more than one drug*

Works for less

Costs less than two separate prescriptions*

Works and works and works

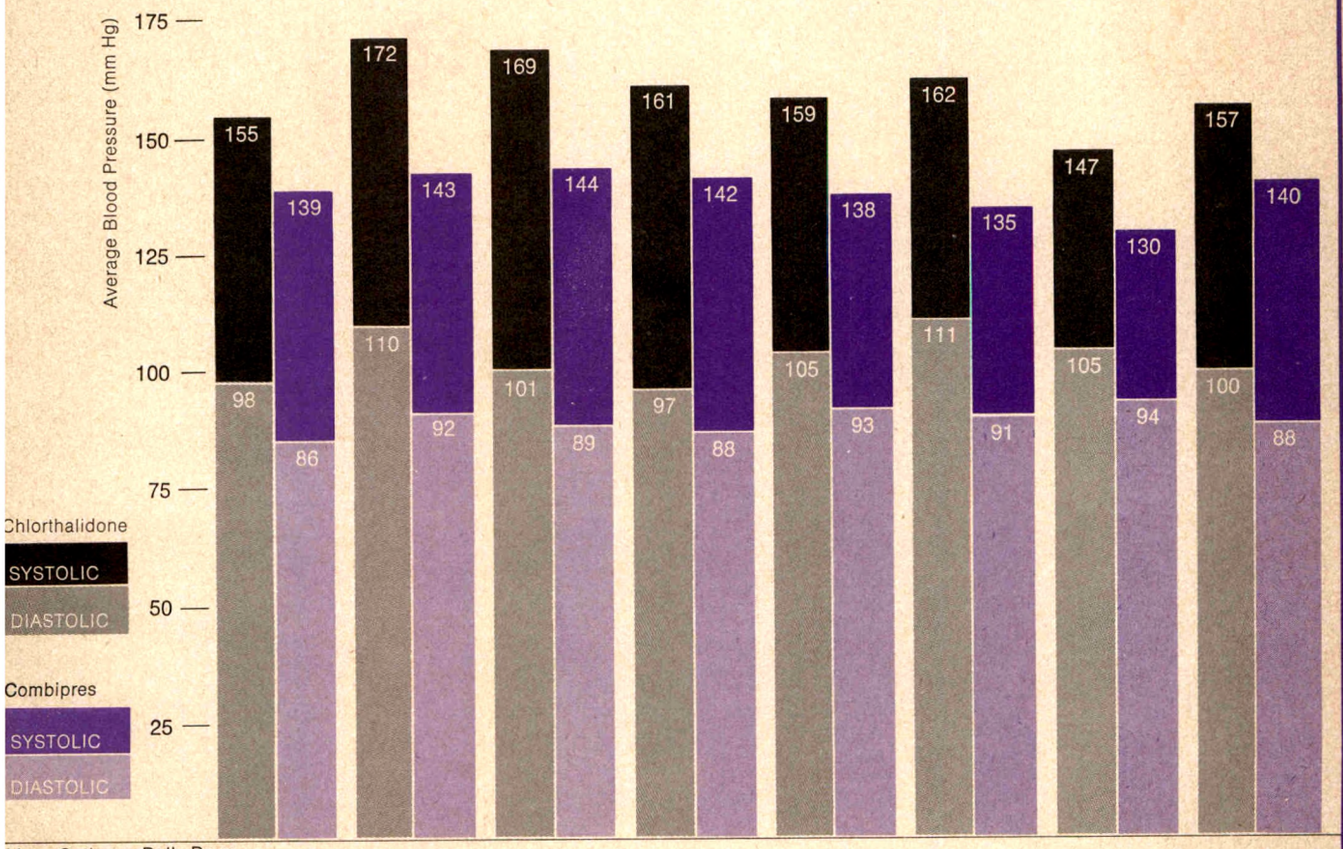
Convenience and economy encourage patients to stay on medication, help assure continued blood pressure control over the long course of therapy*

*__WARNING__ Combipres is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

The only major new combination antihypertensive in a decade

Works in the majority of hypertensive patients

Chlorthalidone vs Combipres
A Comparison of Standing Blood Pressure Response in 8 Studies



Mean Optimum Daily Dose Chlorthalidone (mg)	50	50	47.7	50	50	50	71	50

nonreserpine

new Combipres®

Each tablet contains: Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

Guidelines for Titrating Catapres and Chlorthalidone Dosages:

Initial doses: Catapres—one 0.1 mg tablet twice daily. Chlorthalidone—50 mg daily.

Dosage increments: While daily chlorthalidone doses remain at 50 mg, further increments of Catapres of 0.1 mg or 0.2 mg per day can be made at intervals of 2 to 14 days depending on severity of hypertension. The usual daily dose of Catapres ranges between 0.2 and 0.8 mg. Studies indicate that 2.4 mg is the maximum effective daily dose, but doses as high as this have rarely been used.

Combipres®

Each tablet contains:
Catapres®, brand of clonidine hydrochloride, 0.1 or 0.2 mg and chlorthalidone, 15 mg

WARNING: This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Actions: Catapres (clonidine hydrochloride): The mechanism of action appears to be central alpha-adrenergic stimulation as demonstrated in animal studies. This results in inhibition of bulbar sympathetic cardioaccelerator and sympathetic outflow from the brain. Other studies in humans have provided evidence of a reduction in plasma renin activity and the excretion of aldosterone and catecholamines. The exact relationship between these pharmacologic actions of Catapres (clonidine hydrochloride) in humans and its antihypertensive effect has not been fully elucidated at this time.

Chlorthalidone: The diuretic action of chlorthalidone is thought to be due to inhibition of sodium and chloride reabsorption in the proximal tubule.

Indication: The drug is indicated in the treatment of hypertension (see box warning).

Contraindications: Patients with known hypersensitivity to chlorthalidone and patients with severe renal or hepatic diseases.

Warnings: Tolerance may develop in some instances necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxicity findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefit outweighs the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Combipres in children.

Precautions: When discontinuing Combipres, reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been suggested that a withdrawal syndrome may be responsible for the hypertensive episodes. Symptoms of withdrawal hypertension, such as nervousness, agitation, headache, tremor, palpitation, nausea, vomiting, and occasionally hypertensive encephalopathy and cerebral hemorrhage with coma and convulsions have been reported. Withdrawal hypertension, if severe, should be treated promptly with appropriate antihypertensive therapy. Mild withdrawal hypertension may be controlled with sedation alone. Increased blood pressure, should it occur, can be reversed by resumption of Combipres therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect of the clonidine hydrochloride component. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other antihypertensive agent, Combipres should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Combipres should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmological findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Patients predisposed toward or affected by diabetes should be tested periodically while receiving Combipres, because of the hyperglycemic effect of chlorthalidone.

Because of the possibility of progression of renal failure, periodic determination of the BUN is indicated. If, in the physician's opinion, a rising BUN is significant, the drug should be stopped.

The chlorthalidone component of Combipres may lead to sodium and/or potassium depletion. Muscular weakness, muscle cramps, anorexia, nausea, vomiting, constipation, lethargy or mental confusion may occur. Severe dietary salt restriction is not recommended in patients receiving Combipres.

Periodic determinations of the serum potassium level will aid the physician in the detection of hypokalemia. Extra care should be given to detection of hypokalemia in patients receiving adrenal corticosteroids, ACTH or digitalis. Hypochloremic alkalosis often precedes other evidence of severe potassium deficiency. Frequently, therefore, more sensitive indicators than the potassium serum level are the serum bicarbonate and chloride concentrations. Also indicative of potassium depletion can be electrocardiographic alterations such as changes in conduction time, reduction in amplitude of the T wave; ST segment depression; prominent U wave. These abnormalities may appear with potassium depletion before the serum level of potassium decreases. To lessen the possibility of potassium deficiency, the diet, in addition to meat and vegetables, should include potassium-rich foods such as citrus fruits and bananas. If significant potassium depletion should occur during therapy, oral potassium supplements in the form of potassium chloride (3 to 4.5 gm/day), fruit juice and bananas should be given.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy.

Clonidine hydrochloride: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one case of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash; impotence, urinary retention; increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as

Chlorthalidone: Symptoms such as nausea, gastric irritation, anorexia, constipation and cramping, weakness, dizziness, transient myopia and restlessness are occasionally observed. Headache and impotence or dysuria may occur rarely. Orthostatic hypotension has been reported and may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics. Skin rashes, urticaria and purpura have been reported in a few instances.

A decreased glucose tolerance evidenced by hyperglycemia and glycosuria may develop inconsistently. This condition, usually reversible on discontinuation of therapy, responds to control with antidiabetic treatment. Diabetics and those predisposed should be checked regularly.

As with other diuretic agents hypokalemia may occur (see Precautions). Hyperuricemia may be observed on occasion and acute attacks of gout have been precipitated. In cases where prolonged and significant elevation of blood uric acid concentration is considered potentially deleterious, concomitant use of a uricosuric agent is effective in reversing hyperuricemia without loss of diuretic and/or antihypertensive activity.

Idiosyncratic drug reactions such as aplastic anemia, thrombocytopenia, leukopenia, agranulocytosis, and necrotizing angiitis have occurred, but are rare.

The remote possibility of pancreatitis should be considered when epigastric pain or unexplained gastrointestinal symptoms develop after prolonged administration.

Other adverse reactions which have been reported with this general class of compounds include: jaundice, xanthopsia, paresthesia and photosensitization.

Overdosage: *Catapres (clonidine hydrochloride):* Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals abolishes all effects of Catapres overdosage.

Chlorthalidone: Symptoms of overdosage include nausea, weakness, dizziness, and disturbances of electrolyte balance. There is no specific antidote, but gastric lavage is recommended, followed by supportive treatment. Where necessary, this may include intravenous dextrose and saline with potassium administered with caution.

How Supplied: Combipres® 0.1 (Each tablet contains clonidine hydrochloride, 0.1 mg + chlorthalidone, 15 mg). It is available as pink, oval, single-scored compressed tablets in bottles of 100.

Combipres® 0.2 (Each tablet contains clonidine hydrochloride, 0.2 mg + chlorthalidone, 15 mg). It is available as blue, oval, single-scored compressed tablets in bottles of 100.

For complete details, please see full prescribing information.

SYMPOSIUM
Reperfusion During Acute Myocardial Infarction. Part I

Samuel Meerbaum, PhD, FACC and Eliot Corday, MD, FACC, *Guest Editors*

Introduction

SAMUEL MEERBAUM, PhD, FACC
ELIOT CORDAY, MD, FACC

Los Angeles, California

This Symposium appears at a time when there is substantial disagreement relative to the potential benefits or hazards of reperfusion after acute coronary occlusion. The basic question to be answered is: How does reperfusion affect jeopardized ischemic myocardium? The decision as to whether or how long after onset of an evolving acute infarction revascularization should be instituted needs to be based on applicable pathophysiologic data. It is our hope that the investigations reported on in this Symposium will provide information that will help develop criteria for applications of reperfusion.

There is increasing evidence that even after relatively brief periods of acute coronary occlusion the ischemic tissue is not capable of fully utilizing the blood reflow of reperfusion. Among possible mechanisms implicated in the reperfusion "no reflow" phenomenon are myocardial cell swelling, cell membrane dysfunction, interstitial edema and derangements of the coronary microcirculation. The degree of such reperfusion derangements and their consequences for global cardiac function depend on the preceding duration of ischemia. Studies quoted in this Symposium demonstrate that within 1 to 3 hours of acute coronary occlusion dysfunction in the ischemic myocardium is profound and may not be reversed by short periods of reperfusion. In fact, despite reestablishment of the patency of major coronary arteries, cardiac mechanical and metabolic function may not return for several hours, and hemorrhagic infarction may supervene. Thus, the early period of reperfusion is often associated with a state of hazardous metabolic, electrophysiologic and mechanical dysfunction, which might explain observed failures of surgical revascularization after acute myocardial infarction. On the other hand, current experimental studies indicate that 1 to 2 weeks of reperfusion, even after 3 to 4 hours of coronary occlusion, can lead to a substantial return of cardiac function and significant saving of myocardium.

Clinical results of revascularization performed during acute infarction are extremely difficult to interpret, in part because of a lack of control subjects and generally unsatisfactory classification of a complex patient population into subsets suitable for data analysis. The rationale of applying bypass surgery is based on the expectation of saving jeopardized but still viable ischemic myocardium by correcting a severe imbalance between regional myocardial oxygen demands and supply. Histologic studies in man have indicated that a substantial portion of the acutely ischemic zone becomes necrotic if it remains untreated for 24 to 48 hours. Experimental studies have revealed even earlier resolution of the fate of the jeopardized ischemic myocardium. Depending on the mode and degree of coronary obstruction, the extent of preexisting collateral vessels and prevalent myocardial stress, irreversible damage to the subendocardial layer of the ventricular wall is often noted with coronary occlusion of 40 minutes or longer. Necrosis of as much as 60 percent of the regionally ischemic left ventricle may be expected in 3 to 4 hours of occlusion, and 80 to 90 percent is lost after 24 hours of occlusion. Thus, if therapy is to lead to significant salvage of myocardium, it must be initiated between 40 minutes and 4 hours after the onset of acute infarction. This short period of myocardial viability presents a formidable clinical deadline to revascularization treatment of acute infarction. Temporary pharmacologic or mechanical modes of treatment might be instituted to buy time and avoid serious myocardial damage until the surgical team can be mobilized.

The validity of transferring information from animal experiments to the clinical setting may be questioned. However, such data have often been useful in elucidating related pathophysiologic mechanisms and providing guidelines for applying interventions.

Address for reprints: Eliot Corday, MD, Cedars-Sinai Medical Center, 4833 Fountain Ave., Los Angeles, Calif. 90029.

There is no shortage of research studies on reperfusion, but these have been plagued by a dearth of end points required to characterize explicitly and unequivocably the processes of ischemia and infarction and interventions. Inadequate markers hinder the definition of effectiveness of reperfusion, which otherwise might serve as an ultimate control in comparative evaluations of other modes of treatment. The heterogeneity of contributions to this Symposium reflects the current patchy knowledge and variety of questions surrounding reperfusion. Although this Symposium may not resolve the central issues of criteria for revascularization and optimal markers for its assessment, the contributors share a common objective of providing new insights and clarifications.

Summary of Symposium Papers

The Symposium begins with a brief paper by Krug, who has previously reported on coronary reperfusion in cats. Utilizing hydrogen ion concentration in ischemic zone tissue as an end point, he presents indirect observations of myocardial viability after acute occlusion of the proximal left anterior descending coronary artery. Reperfusion after 30 minutes of occlusion resulted in full return to normal pH values. After coronary occlusion exceeding 45 minutes, an "acid reaction" during the first minutes of reperfusion indicated persisting ischemia, presumably due to the "no reflow" phenomenon. After 90 minutes of reperfusion the reperfused region exhibited an "alkaline reaction" (pH ~7.4), particularly in the subendocardium, that correlated with enzymatic and histologic alterations characteristic of myocardial necrosis. After 180 minutes of coronary occlusion, the alkaline reaction was limited to a small border zone.

The nature of the metabolic changes during the first 2 hours of reperfusion was examined by Kane et al. in a series of pigs with 15 to 180 minutes of occlusion of the mid-left anterior descending coronary artery. Markers of myocardial viability included mitochondrial function, oxygen extraction, epicardial electrocardiographic S-T segments and distribution of tritiated digoxin. Within the first minutes of reperfusion after 1 or more hours of coronary occlusion, there were signs of hyperemia and improved regional kinesis, but soon thereafter (15 minutes or more) the ischemic zone became akinetic and noncompliant. After 2 hours of reperfusion following 1 hour of occlusion, regional mitochondrial function was severely impaired, myocardial oxygen extraction significantly reduced and tritiated digoxin stratified. Kane et al. noted that the S-T segments rose steeply after occlusion, but tended to return to control levels over 3 hours of coronary occlusion. Generally, epicardial S-T segment elevations in the ischemic zone diminished markedly with reperfusion, but after temporary occlusion in excess of 1 hour, the electrocardiogram exhibited a distinct loss of R waves and significant Q waves.

The problem of electrocardiographic and enzyme markers of myocardial ischemia or infarction is dealt with by Blumenthal et al., who performed open chest studies in dogs with 1 to 3 hours of occlusion of the left anterior descending coronary artery followed by 2 hours of reperfusion. A correlation was established between the appearance of Q waves and a sharp rise in coronary sinus serum enzymes, creatine phosphokinase (CPK) and glutamic oxaloacetic transaminase (GOT) after reperfusion. The usual delay in appearance of elevated enzyme levels and new Q waves after acute infarction does not necessarily indicate delayed necrosis; rather, it may simply reflect limited blood circulation within the ischemic region. Epicardial S-T segments most often returned to control levels after reperfusion, but in some instances decreased significantly during the preceding occlusion. Hence, the potential use of S-T segment elevation as a marker remains unclear. Two other experimental markers, namely, regional contraction force and reactive hyperemia, proved useful in assessing the effectiveness of reperfusion after periods of coronary occlusion. Blumenthal et al. conclude that myocardial viability may be limited to less than 2 hours of occlusion.

Sharma et al. provided ultrastructural evidence of myocardial derangements in the early phase of reperfusion after coronary occlusion. Histochemical study of specially prepared tissue samples revealed that 1 hour of reperfusion after 60 to 90 minutes of occlusion failed to return creatine phosphate toward control levels, while adenosine triphosphate and total nucleotide concentrations decreased further. Electron microscopic analysis indicated that the reperfusion resulted in swelling of sarcoplasmic reticulum, mitochondrial damage and gross contraction of myofibrils. Impairment of myocardial cell membranes was inferred from significant increases in coronary sinus blood enzyme levels noted immediately after reperfusion.

Measurement of regional mechanics was employed by Puri in a study addressed to the important question of late versus early reperfusion after various periods of coronary occlusion. Utilizing a strain gauge-tipped catheter probe that measures myocardial fiber shortening, Puri attempted to map the central and border zones of ischemia. He found that whenever myocardial blood flow was returned to the ischemic zone within 45 minutes, there was full and prompt resumption of contraction. With coronary occlusions lasting 1 hour, contraction returned gradually but completely after 2 weeks. With 2 or 3 hours of occlusion, only 60 to 75 percent of the reperfused zone was contracting after prolonged reperfusion. After 4 to 5 hours of occlusion, even extended reperfusion failed to restore partial contraction.

The effectiveness of reperfusion was studied in the intact conscious dog by Mathur et al. An implanted balloon cuff provided coronary occlusion for up to 5 hours, and subsequent reperfusion was maintained for up to 7 days. Occlusion of the proximal left anterior descending coronary artery led to expected hemodynamic and metabolic derangements. Immediately after reperfusion, following coronary occlusion

of more than 2 to 3 hours' duration, Mathur et al. noted striking and persistent arrhythmias, Q waves, hemodynamic dysfunction, regional left ventricular dyskinesia and diminished oxygen extraction. Infarct size was assessed and appeared to correlate with the duration of the occlusion. It was concluded that a reperfusion period of 1 week after more than 2 hours of occlusion in conscious dogs fails to prevent functional deterioration and is associated with a higher mortality rate.

In a similar study performed by Costantini et al. an intracoronary occlusion-reperfusion model in anesthetized dogs was used to investigate regional myocardial metabolism and detailed histopathology to provide insights into the effects of early and prolonged (7 days) reperfusion. The early phase of reperfusion following 3 hours of occlusion of the proximal left anterior descending coronary artery was characterized by persisting dysfunction, measured in terms of left ventricular ejection fraction, as well as by regional ischemic zone balances of oxygen, lactate and potassium. However, when compared with the persisting dysfunction and large infarcts observed in a control series with 7 days of permanent occlusion, there was an average 50 percent reduction in infarct size and return of cardiac function in animals undergoing 7 days of reperfusion. However, Costantini et al. emphasize that one third of the reperfused hearts showed no reduction in infarct size.

Corday et al. present evidence of functional and morphologic alterations in zones of the myocardium that are remote from an acutely ischemic region and are therefore often considered to be uninvolved. A 3 hour occlusion of the left anterior descending coronary artery was found to be associated with metabolic derangements as well as microinfarction in the remote myocardium. Reperfusion did not seem to reduce the number of microinfarcts. Since these remote segments of the heart are vital to global cardiac performance during infarction and revascularization, it is suggested that these zones should also be considered jeopardized.

Bolooki et al. address themselves to clinical evidence and supplement their study of patients with selected dog experiments. Utilizing left ventriculography for determination of left ventricular volume and ejection fraction, along with hemodynamic measurements and assessment of infarct size, they studied in dogs occlusion of the left anterior descending artery lasting up to 4 hours followed by 7 days of reperfusion. Only hearts with coronary occlusion of less than 2 hours' duration benefited from reperfusion. Reperfusion after 3 to 4 hours of occlusion resulted in infarcts and left ventricular dyskinesia equal to or greater than those measured after a 7 day permanent occlusion. The patient population was subdivided into groups receiving revascularization within less than 4 or within 8 hours from the onset of acute myocardial infarction. Analysis of data was difficult, but it appeared to Bolooki et al. that after 4 hours from the onset of an acute myocardial infarction, reperfusion may no longer provide benefits and may even precipitate hazardous derangements.

The quantitative differences in the reported reperfusion data are not surprising in view of differences in species and preparations (for example, open versus closed chest) and the normally encountered variability in experimental studies of coronary occlusion. One may conclude that in the dog derangements of the myocardium will appear early during reperfusion after 1 hour of occlusion, and that substantial irreversible damage must be expected when reperfusing after 2 to 3 hours of occlusion. The first few hours of reperfusion are clearly critical since there is a limited reflow, and severe derangements in mechanical and metabolic function persist, together with ominous arrhythmias. Nonetheless, 1 to 2 weeks of reperfusion after occlusion of as long as 3 hours can generally normalize function and provide substantial saving of myocardium.

There are several clinical implications. The observed myocardial derangements of reperfusion after coronary occlusion may account for the variability of results when clinical revascularization is applied during an evolving infarction. If such revascularization is to be effective, it must be started within a few hours of the onset of acute infarction. This raises practical questions relative to rapid mobilization of the angiographic-surgical team for earliest possible intervention. The studies of this Symposium indicate that proper monitoring and medical treatment should be available throughout the early period of reperfusion, lest severe arrhythmias and functional derangements escalate to severe hypotension and cardiogenic shock. In applying revascularization to an acute infarction, treatment of viable but jeopardized myocardium becomes a global task. Finally, reliable assessment of infarct size represents a major challenge that must be met to provide conclusions on the effects—and effectiveness—of reperfusion.

Alterations in Myocardial Hydrogen Ion Concentration After Temporary Coronary Occlusion: A Sign of Irreversible Cell Damage

ARNO KRUG, MD, PD

Kiel, West German Federal Republic

Alterations of hydrogen ion (H^+) concentration in the myocardium of 60 cats were determined before release of coronary ligation of 30, 45, 60, 90 or 180 minutes' duration, or 5, 30 and 90 minutes after release of the occlusion, by pressing pH indicator paper on unfixed frozen heart sections. The H^+ concentration had clearly increased (pH <6.0) in a transmural extension in the left ventricle before release of the coronary ligature. This elevated H^+ concentration persisted some time in the subendocardial region despite release of the coronary occlusion, thus proving that the so-called no reflow phenomenon exists in involved myocardium after temporary coronary occlusion. A diminished H^+ concentration (pH 7.4) was found in the border zone between the acid-reacting area and the normal muscle when the coronary occlusion lasted 180 minutes before release of the ligature or 30 minutes after release of the occlusion when the previous period of temporary occlusion had been longer than 30 minutes. Although areas manifesting an acid reaction vanished or diminished in size after release of coronary occlusion, the extent of alkaline-reacting zones showed no reduction in size, and muscle cell necrosis developed in these alkaline-reacting areas. It is assumed therefore that an alkaline reaction of the myocardium is an early sign of irreversible muscle cell damage.

The possibility of surgical treatment of acute myocardial infarction[1] has intensified interest in clarifying questions pertaining to the reversal of ischemic myocardial damage by revascularization. It has long been known that hydrogen ion (H^+) concentration in the myocardium increases immediately after the onset of ischemia[2] and diminishes later in the course of heterolytic processes.[3] In an attempt to answer some unresolved questions concerning these changes, we examined the alterations of H^+ concentration in involved myocardium after temporary coronary occlusion.

Methods

Sixty-three unselected cats, weighing 1.5 to 2.5 kg, were anesthetized with sodium pentobarbital (25 mg/kg body weight). The state of anesthesia was maintained by repeated injections of pentobarbital (10 mg/kg). Rectal temperature was determined by thermometer, and the experimental cats' temperature was maintained by electric blanket. Respiration was maintained through an endotracheal tube attached to a respirator pump. Left thoracotomy and pericardiotomy were performed. In 60 cats the anterior descending branch of the left main coronary artery (together with the accompanying vein) was ligated 2 to 3 mm distal to its origin for a duration of 30, 45, 60, 90 or 180 minutes. In these five groups, the beating heart was excised for study under four conditions: before release of coronary occlusion or 5, 30 or 90 minutes after release of the ligature. Three animals were used in each group.

The excised heart was frozen immediately, and cross sections, 40 μ thick, were cut from the unfixed tissue by cryostat. pH indicator paper (Merck AG, Darmstadt, West German Federal Republic) with pH ranges of 5.4 to 7.0 and 6.8 to 8.0 was pressed onto just-thawing unfixed cryostat sections of the

hearts. In this way, the region of ischemic damage in the myocardium could be demonstrated immediately after the onset of ischemia by different degrees of discoloration of the pH indicator paper.[4,5]

Results

Normal cardiac muscle had a pH value of approximately 6.8. In the three control animals without coronary occlusion there were no zones with a hydrogen ion concentration that deviated from this figure.

H^+ Before Release of Coronary Occlusion (Fig. 1)

The hydrogen ion concentration rose (pH <6.0) in the anterior wall of the left ventricle in a transmural extension when the coronary occlusion lasted 30, 45, 60 or 90 minutes (Fig. 1 and 2A). However, a diminished H^+ concentration (pH 7.4) was found in a small border zone between the acid-reacting area and the normal heart muscle when the coronary occlusion lasted 180 minutes.

H^+ After Release of Coronary Occlusion (Fig. 1)

Occlusion of 30 minutes' duration: No zones with an H^+ concentration that deviated from the normal pH value of 6.8 were found 5, 30 or 90 minutes after release of the ligature (Fig. 1).

Occlusions of 45 and 60 minutes' duration: The acid-reacting region diminished significantly after release of the coronary ligature and a change in H^+ concentration took place in the inner third of the ventricular wall (Fig. 1). Although a continuing acid reaction was found subendocardially 5 minutes after release of the coronary ligature (Fig. 2B), 30 and 90 minutes later, the inner third of the ventricular wall showed an alkaline reaction (pH 7.4, Fig. 2C).

Occlusion of 90 minutes' duration: The acid-reacting region was still diminished after release of the ligature but to a lesser degree than after temporary coronary occlusions of 45 and 60 minutes' duration (Fig. 1). An acid reaction in the center of the anterior wall and a broad alkaline-reacting border zone were found 30 minutes after release of the ligature (Fig. 2D). However, 90 minutes after release of the occlusion the entire inner half of the anterior ventricular wall had a diminished H^+ concentration (pH 7.4).

Occlusion of 180 minutes' duration: The transmural area that showed H^+ alterations did not diminish after release of the coronary ligature (Fig. 1). The H^+ concentration decreased in the entire anterior wall of the left ventricle, but 5 and 30 minutes after release of the ligature there were still acid-reacting areas in the center of the anterior wall. This finding indicates that the alkalization of the previous acid-reacting zones took effect from the periphery to the center. However, 90 minutes after removal of the ligature the entire anterior wall produced an alkaline reaction (Fig. 2E).

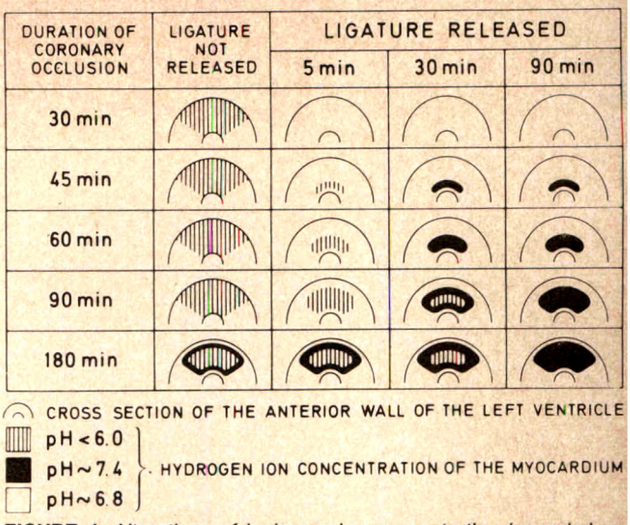

FIGURE 1. Alterations of hydrogen ion concentration (recorded as pH value) in the myocardium of 60 cats after temporary coronary occlusion. Three animals were used in each of the 20 groups shown.

Discussion

As these findings show, alteration of myocardial hydrogen ion concentration by ischemia can be detected by freezing the tissue and pressing a just-thawing tissue section onto pH indicator paper. In this way the intracellular H^+ concentration can be determined because the freezing and thawing process destroys the cells. This procedure makes possible delineation in the heart of early myocardial infarction, which cannot be done by any other available method.[6] The H^+ concentration rose markedly in a transmural extension of the anterior wall of the left ventricle after occlusion of the anterior branch of the left coronary artery. It has long been known that acidification takes place in the myocardium after the onset of ischemia because acid metabolites (predominantly lactic acid) are accumulated during anaerobic glycolysis.[2] The data reported here show further that this acidification of the myocardium is reversible when the blood supply is reestablished by release of the coronary ligature.

The acid-reacting areas vanished completely after release of coronary occlusion of 30 minutes' duration or diminished significantly after release of coronary occlusion of 45 and 60 minutes' duration. But the findings clearly show (Fig. 2B) that an acid-reacting area is still demonstrable subendocardially after release of coronary occlusion of 45 minutes' duration; that is, despite release of the coronary ligature, blood flow is not reestablished in these zones. This conclusion is possible because previous investigations[5,7] have shown that blood flow is heavily disturbed and often nonexistent in myocardial areas with increased H^+ concentration. Therefore, in contrast to the opinion of Jennings et al.,[8] these findings prove the existence of the so-called no reflow phenomenon[9] after temporary myocardial ischemia of only 45 minutes' duration.[7] This no reflow phenomenon indicates that there is persistent ischemia in involved myocardium despite release of the coronary occlusion and that it may be an important cause of cell necrosis. Further

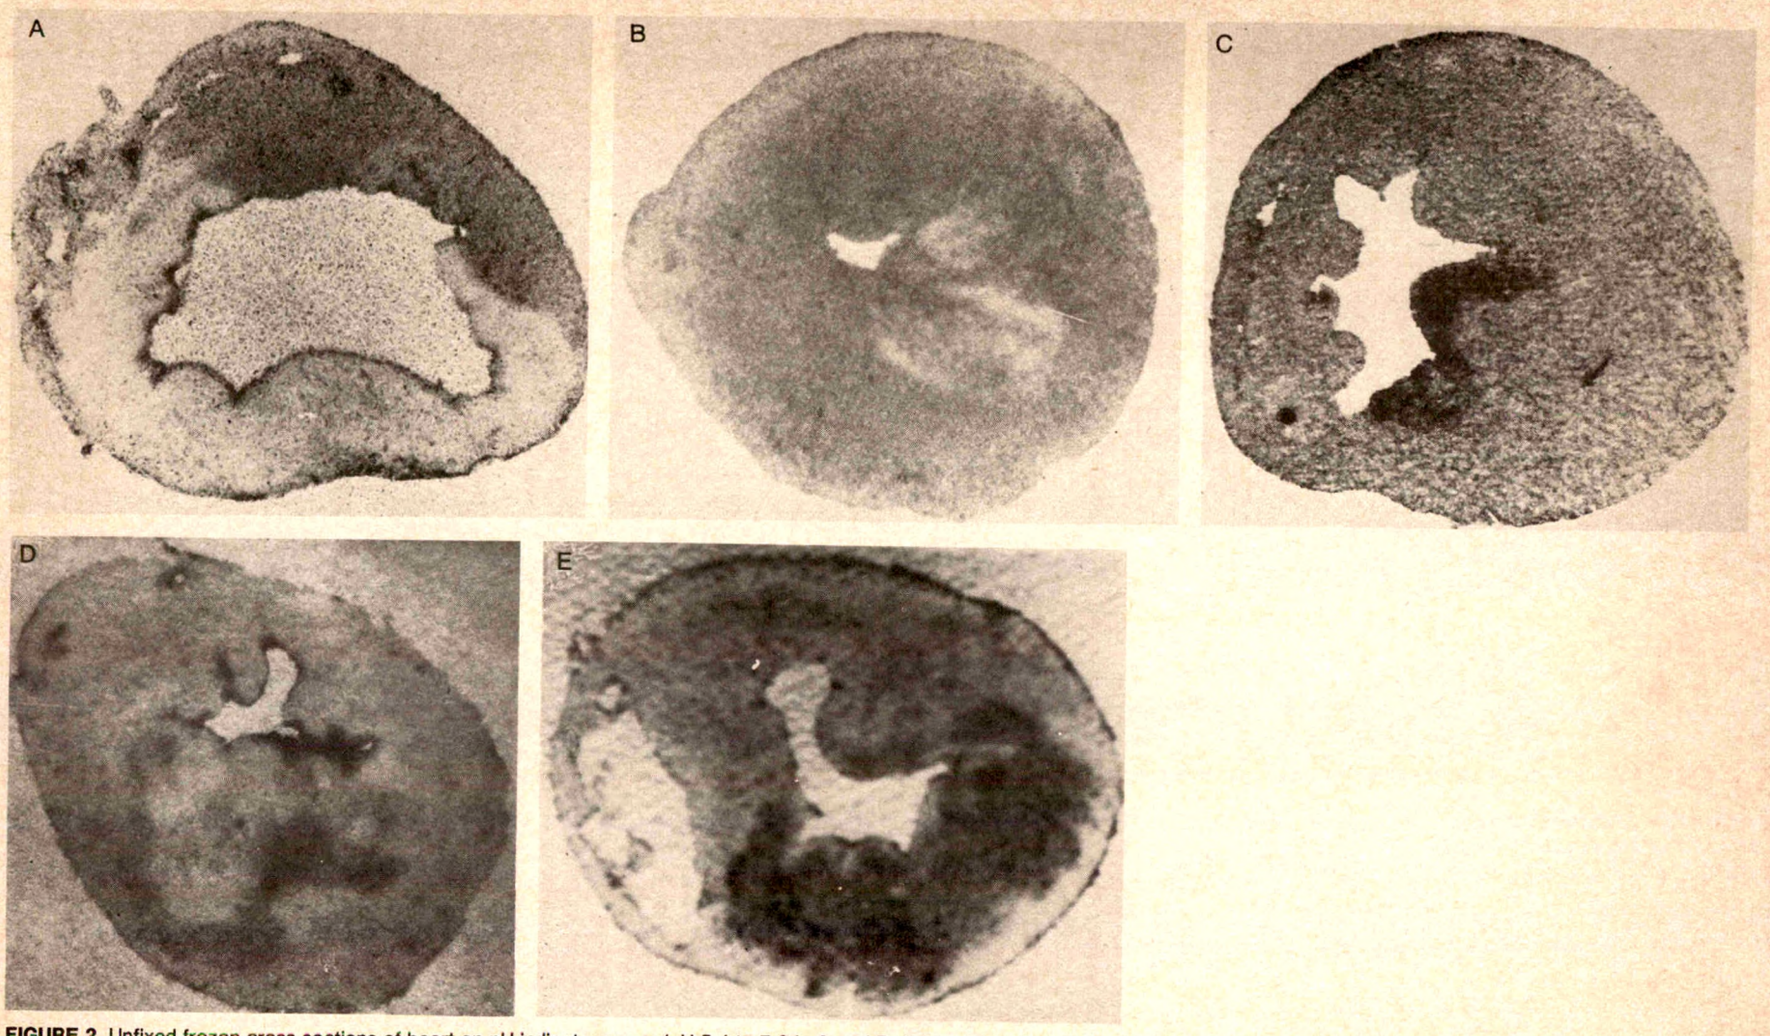

FIGURE 2. Unfixed frozen cross sections of heart on pH indicator paper (pH 5.4 to 7.0 in **A** and **B**, 6.8 to 8.0 in **C** to **E**). **A,** 60 minutes after coronary ligation before release of the ligature. The hydrogen ion (H^+) concentration is elevated (pH <6.0) in a transmural extension of the anterior wall of the left ventricle, as indicated by yellow discoloration of the indicator paper (**light area** in figure). **B,** 5 minutes after release of ligation of 45 minutes' duration. The H^+ concentration is still increased (pH <6.0) in the inner third of the anterior wall of the left ventricle. **C,** 90 minutes after release of ligation of 45 minutes' duration. The H^+ concentration is diminished (pH 7.4) in the inner third of the anterior wall of the left ventricle, as indicated by green discoloration of the indicator paper (**dark area**). **D,** 30 minutes after release of coronary ligation of 90 minutes' duration. A persistent acid-reacting region (**light area**) is shown in the center of the anterior wall; the border zone reveals a diminished H^+ concentration (pH 7.4, **dark area**). **E,** 90 minutes after release of ligation of 180 minutes' duration. The H^+ concentration is diminished in the entire anterior wall of the left ventricle (pH 7.4, **dark area**).

investigations are needed to determine whether this phenomenon is treatable.

Myocardial alkalinity after coronary occlusion and reperfusion: Alkalization of the myocardium was found 180 minutes after coronary occlusion in the border zone between the normal muscle and the area with increased H^+ concentration or 30 and 90 minutes after a temporary occlusion of 45, 60 or 90 minutes' duration. These alkaline-reacting areas did not vanish or diminish. The alkalization of the tissue is caused by penetration of plasma bicarbonate and heterolytic processes.[3,10] It was possible to show by histologic and enzyme histochemical methods that necrosis of the muscle cells occurs very rapidly in those zones that show an alkaline reaction, and myocardial infarctions developing after temporary coronary occlusion of 45, 60 or 90 minutes' duration occurred in the same site in the ventricular wall[11] as the alkaline-reacting areas. From these results, it can be assumed that the presence of an alkaline-reacting area in the myocardium indicates that the heart muscle cells in this region are irreversibly damaged; that is, in an alkaline-reacting area the so-called point of no return for the muscle cells has been reached after the onset of ischemia. In the cats' hearts, this sign of irreversible cell damage was first ascertained 3 hours after permanent coronary occlusion but, after temporary coronary ligation of 45 minutes' duration, alkaline-reacting areas were first seen 30 minutes after release of the ligature.

This study examines the effect of 2 hours of reperfusion on transiently ischemic myocardium in pigs. Indexes of myocardial viability measured were mitochondrial function, oxygen extraction, epicardial S-T segment change and distribution of tritiated digoxin. Results were as follows: (1) Mitochondrial function was markedly impaired in the reperfused area after 60 minutes or more of coronary occlusion. The defect would seem to be a block in electron flow near site I, which can be partially bypassed with succinate. (2) An apparent inability of the reperfused myocardium to extract oxygen did not improve with 2 hours of reperfusion. (3) Epicardial S-T segment mapping suggested that necrosis occurred during reperfusion. (4) There was an altered distribution of tritiated digoxin in the reperfused area. The results show that reperfusion for 2 hours did not improve myocardial viability after 60 minutes or more of ischemia.

Recent reports[1–3] have demonstrated that reperfusion of acutely ischemic myocardium may be associated with deleterious effects. Some studies have demonstrated a "no reflow" phenomenon in transiently ischemic myocardium similar to that observed in the brain and kidneys.[4,5] Although earlier experiments have shown that a coronary artery may be ligated for up to 3 hours before blood flow is restored without development of myocardial necrosis, more recent studies have suggested that reperfusion of an ischemic area alters the metabolism of the ischemic myocardium and may even hasten necrosis.[1,2] Thus, the optimal time for reperfusion of acutely ischemic myocardium and its effect on cardiac metabolism are not well established.

In cardiac muscle the mitochondria, which make up at least 20 percent by dry weight of the cell,[6] consume oxygen to produce adenosine triphosphate (ATP) by oxidative phosphorylation. Adenosine triphosphate is then used by the myocardium as the energy source for contraction and other cellular functions.[7] Previous studies have suggested that mitochondria are very susceptible to hypoxia.[8] Altered mitochondrial function, then, may be the mechanism of irreversible changes that take place in ischemic myocardium.[9] The purpose of this study was to examine mitochondrial function, myocardial oxygen extraction, epicardial S-T segment mapping and distribution of tritiated digoxin in myocardium made transiently ischemic and then reperfused.

Methods

Pigs were chosen as the experimental model because the major coronary distribution, collateral circulation and blood supply to the conduction system

are virtually identical to those of man.[10–12] Forty-six mature farm pigs of either sex, weighing 70 to 120 lb, were fasted for 18 hours and then anesthetized with 6 percent pentobarbital administered intravenously. A tracheostomy was performed and respirations maintained with a Harvard pump using room air supplemented with 100 percent oxygen to maintain the arterial partial pressure of oxygen (PaO_2) over 100 mm Hg. A midline sternal splitting thoracotomy was performed and the heart suspended in a pericardial cradle exposing the distribution of the left anterior descending coronary artery. Central aortic and left ventricular pressures and lead II of the electrocardiogram were continuously monitored.

The left anterior descending coronary artery was reversibly occluded, with use of a nontraumatic rubber ligature, at its midportion after the first or second diagonal branch for intervals of 15 to 180 minutes. Complete occlusion in each case was evidenced by the appearance of a nonpulsatile, nondistended artery distal to the occlusion and nondistended veins draining the ischemic area, and by the immediate appearance of cyanosis and bulging of the ischemic segment. Forty-two animals then had reperfusion of the ischemic zone of the myocardium for an additional 2 hours. Four animals underwent coronary occlusion for 180 minutes without reperfusion. The coronary vein was preserved in each case and not ligated.

Ventricular arrhythmia secondary to coronary occlusion was treated with minimal effective doses of lidocaine or electrical countershock using an American Optical defibrillator set at 30 to 50 watt seconds. Although no attempt was made to heparinize the animals, 1,000 to 2,000 units of heparin was placed in each liter of flush solution for the arterial lines.

Epicardial S-T segment mapping was performed every 30 minutes over three areas of normal left ventricle and five areas of ischemic tissue with use of a soft spring steel electrode with a spherical silver tip. This electrode had a surface area contact of 2 mm and caused minimal pressure artifact. S-T segment elevation and R wave amplitude were quantitated in nine animals.

Blood samples for determining oxygen content and pH were obtained from the large coronary vein draining the ischemic area just before occlusion and then serially during the reperfusion period in nine animals. These were compared with simultaneously obtained samples from the left ventricular chamber.

After release of the ligature, 0.5 mg of tritiated digoxin was injected intravenously to serve as a marker of blood flow and perhaps as a measure of cellular viability in the area of ischemia.[13,14]

At the end of each 2 hour period of reperfusion, 2.5 to 5 cc of 10 percent alphazurine 2G blue dye was injected intravenously in order to identify areas of the myocardium that were not well perfused. This dye stained perfused and presumably viable tissue a vivid blue and was not taken up by ischemic tissue.[15] Immediately after injection of the dye, the heart was removed from the chest and taken to the cold room where samples were excised from normal and reperfused areas of the left ventricle using the surface anatomy and dye staining as guidelines.

The tissue samples were minced and homogenized by methods similar to those previously outlined.[16] Mitochondria were separated and suspended in a medium containing 0.25 molar sucrose; 0.001 molar neutralized ethylenediaminetetraacetic acid (EDTA); 0.01 molar Tris buffer at pH 7.4; 7.5 millimolar potassium phosphate at pH 7.4; and 0.01 molar substrate in a final volume of 3 ml. Either glutamate

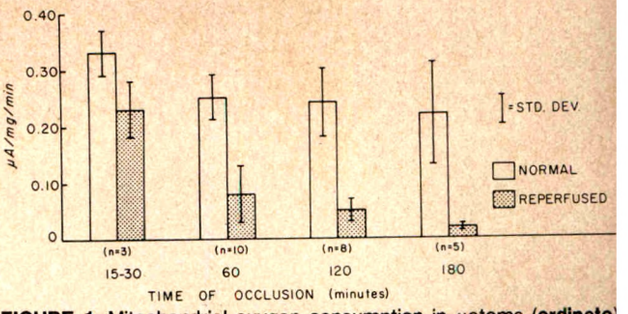

FIGURE 1. Mitochondrial oxygen consumption in μatoms (**ordinate**) using glutamate substrate during state 3 respiration in 26 animals. Mitochondria from normal areas of the left ventricle (**open bars**) are compared with mitochondria from reperfused areas (**dotted bars**). The occlusion period was 15 to 180 minutes. All animals had 120 minutes of reperfusion. n = number of animals; STD. DEV. = standard deviation.

(0.01 molar), succinate (0.01 molar) or a mixture of pyruvic acid (0.005 molar) and L-malic acid (0.005 molar) was used as a substrate (this latter combination being referred to as malate). Oxidative phosphorylation studies were performed in duplicate by a polarographic method[17] and were completed within 90 minutes after the death of the animals. Adenosine diphosphate (ADP) was added to each reaction mixture to give a rapid burst of state 3 respiration. In six animals, dinitrophenol (final concentration 6×10^{-5} molar) was used as an uncoupler of respiration and oligomycin (final concentration 3×10^{-6} molar) added as an inhibitor of phosphorylation. In each experiment, mitochondria from the normal areas of the left ventricle were tested simultaneously with mitochondria from the reperfused area.

Indexes of mitochondrial function obtained were: mitochondrial oxygen consumption in μatoms of oxygen consumed per milligram of mitochondrial protein per minute during state 3 respiration, a measure of the electron transport capability[18]; ADP:O ratio, the ratio of μmoles of adenosine diphosphate phosphorylated to atoms of oxygen consumed, a measure of efficiency of adenosine triphosphate production[19]; and respiratory control ratio, the ratio of oxygen consumed in the presence of adenosine diphosphate to oxygen consumed after complete phosphorylation of the adenosine diphosphate, a measure of tightness of coupling.[19] Mitochondrial protein content was determined by a standard method[20] with attempts being made to achieve 2 mg/ml of mitochondrial protein. Adenosine diphosphate assays were determined spectrophotometrically.[21] Tissue and serum tritiated digoxin levels were measured as previously described.[22]

Results

General observations: After coronary occlusion myocardium supplied by the left anterior descending coronary artery ceased contracting, became cyanotic and bulged within seconds. These changes persisted throughout the occlusion. Arterial blood pressure, heart rate and left ventricular end-diastolic pressure were not significantly different from control values.

After release of the ligature and reperfusion, the distal left anterior descending coronary artery became distended. The reperfused epicardium lost its cyanotic appearance within 30 seconds to 1 minute o

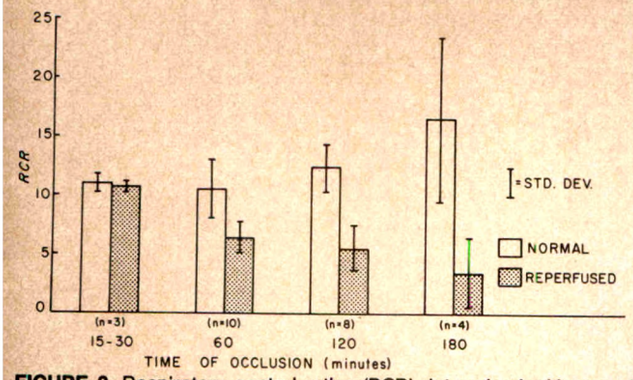

FIGURE 2. Respiratory control ratios (RCR) determined with use of glutamate substrate in 25 animals. Mitochondria from normal areas of the left ventricle (**open bars**) are compared with mitochondria from reperfused areas (**dotted bars**). The occlusion period was 15 to 180 minutes. All animals had 120 minutes of reperfusion.

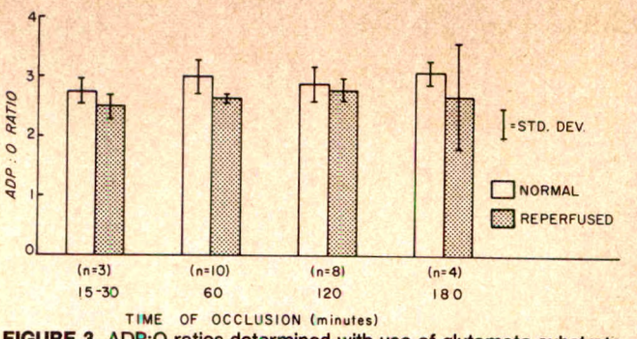

FIGURE 3. ADP:O ratios determined with use of glutamate substrate in 25 animals. Mitochondria from normal areas of the left ventricle (**open bars**) are compared with mitochondria from reperfused areas (**dotted bars**). The occlusion period was 15 to 180 minutes. All animals had 120 minutes of reperfusion.

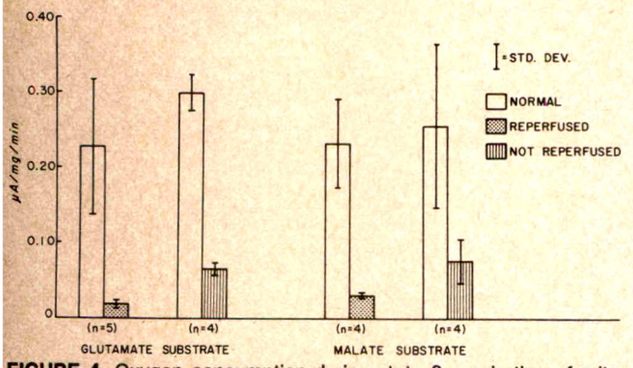

FIGURE 4. Oxygen consumption during state 3 respiration of mitochondria from normal areas of the left ventricle (**open bars**), and areas of the left ventricle with 180 minutes of occlusion and 120 minutes of reperfusion (**dotted bars**) is compared with that of mitochondria from animals that had 180 minutes of occlusion but no reperfusion (**striped bars**). Determinations were made with use of glutamate and malate substrates.

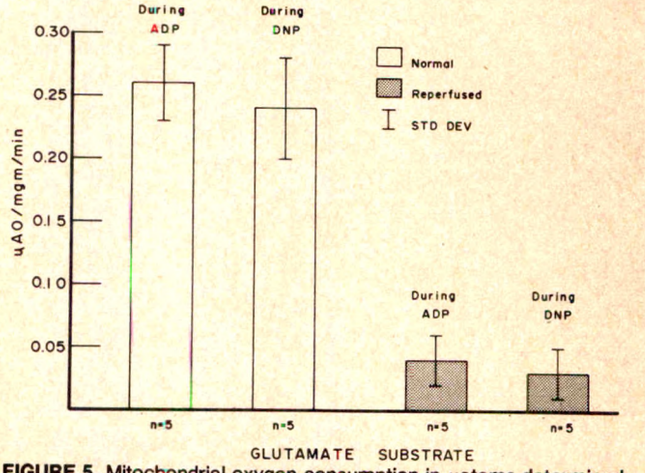

FIGURE 5. Mitochondrial oxygen consumption in μatoms determined with use of glutamate substrate during phosphorylation (addition of adenosine diphosphate [ADP]) and uncoupling (addition of dinitrophenol [DNP]) in normal and reperfused preparations. Rates are similar with adenosine diphosphate and dinitrophenol in normal and in reperfused mitochondria.

release of occlusion and became hyperemic when compared with normal areas of the left ventricle. Bulging of the involved segment likewise diminished within 30 seconds to 1 minute; however, over a period of 5 to 15 minutes the muscle became akinetic and firm rather than regaining contractile function. Reperfusion for 2 hours did little to change the gross appearance.

After removal of the heart, the reperfused area could be recognized by its firm texture as opposed to the soft and pliable texture of normal myocardium or myocardium from hearts with 180 minutes of occlusion and no reperfusion.

Mitochondrial function: Figure 1 shows the effect of different periods of occlusion on mitochondrial oxygen consumption by mitochondria from normal and reperfused areas of the left ventricle, as determined with use of glutamate substrate in 26 animals. After 15 to 30 minutes of occlusion, there was a slight decrease in oxygen consumption in the reperfused mitochondria ($P < 0.05$) (Student's t test). By 60 minutes the difference was highly significant ($P < 0.001$). Further impairment was evident with longer periods of occlusion. Studies with malate substrate gave similar results. Figure 2 shows the results of different periods of occlusion on the respiratory control ratio again with use of glutamate substrate. Although there was little difference after 15 to 30 minutes of occlusion, occlusion periods longer than 60 minutes resulted in a significant decrease in the respiratory control ratio ($P < 0.001$). ADP:O ratios, a measure of efficiency of adenosine triphosphate production, were not significantly different even with occlusion of up to 3 hours (Fig. 3). That reperfusion itself may have contributed to an inhibition of oxidative phosphorylation is shown in Figure 4, which compares oxygen consumption of mitochondria from normal and reperfused tissue with that of mitochondria from animals that had identical periods of occlusion (180 minutes) but did not undergo reperfusion. When

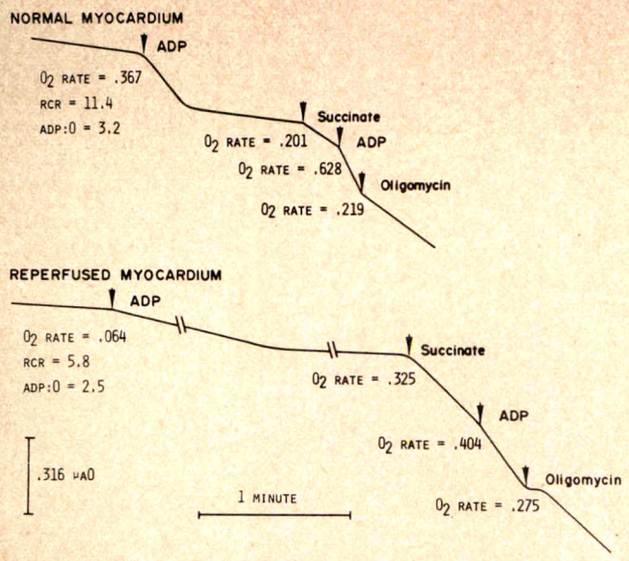

FIGURE 6. Simultaneous oxygen electrode tracings showing oxygen consumption by mitochondria from normal and reperfused myocardium in glutamate substrate. The occlusion period was 120 minutes. Addition of succinate markedly increased oxygen consumption in both normal and reperfused preparations. Oligomycin was added in a final concentration of 3×10^{-6} molar as an inhibitor of phosphorylation. ADP = adenosine diphosphate; ADP:O = ratio of micromoles of adenosine diphosphate phosphorylated to atoms of oxygen consumed; RCR = respiratory control ratio.

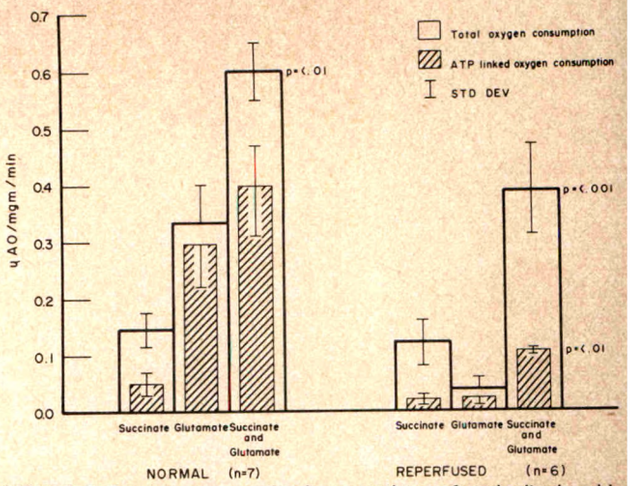

FIGURE 7. Oxygen consumption by normal reperfused mitochondria after addition of adenosine diphosphate (ADP) is compared using succinate and glutamate alone or in combinations as substrates. Adenosine triphosphate (ATP)-linked oxygen consumption is indicated by the **hatched bars.** Although total oxygen consumption is increased in both preparations by the addition of succinate, adenosine triphosphate-linked oxygen consumption was significantly greater with a combination of substrates in reperfused mitochondria.

studied with either glutamate or malate substrate, mitochondrial function was worse in the reperfused tissue ($P < 0.005$).

In six animals dinitrophenol (final concentration 6×10^{-5} molar) was used as an uncoupler of respiration (Fig. 5). The rate of oxygen consumption was the same during phosphorylation (addition of adenosine diphosphate) or uncoupling (addition of dinitrophenol) in the normal mitochondria. Oxygen consumption was much less in the reperfused mitochondria but the rates were the same during phosphorylation or uncoupling. Results were similar in studies with malate substrate.

The diminished mitochondrial oxygen consumption and results with dinitrophenol as an uncoupler of respiration suggested that mitochondrial dysfunction was caused by a block in electron flow. Based on the theory that the block might be located at site I, succinate was used as a substrate either singly or in combination with glutamate and malate to attempt to bypass the electron transport chain block. Figure 6 illustrates the results obtained when succinate was used as a substrate in combination with glutamate. Figure 7 shows the oxygen consumption of mitochondria in seven such experiments together with data for succinate and glutamate used alone. The combination of glutamate and succinate resulted in a total oxygen consumption that significantly exceeded the sum of that produced individually by these substrates in mitochondria from normal ($P < 0.01$) or reperfused ($P < 0.001$) myocardium. Of particular interest is that the combination of substrates yielded more adenosine triphosphate-linked oxygen consumption* than was obtained, in sum, by the two substrates individually in mitochondria from reperfused myocardium ($P < 0.01$). In the mitochondria prepared from normal myocardium, the sum of adenosine triphosphate-linked oxygen consumption with the individual substrates is the same as that produced by the combination of succinate plus glutamate. The enhancement of total oxygen consumption and adenosine triphosphate-linked oxygen consump-

tion was not seen in experiments using succinate in combination with malate.

Myocardial oxygen extraction: There was a highly significant rise in oxygen tension in the coronary vein draining the reperfused area with a reduction in arteriovenous oxygen difference (Table I). Grossly, the veins draining the reperfused area became red 5 to 10 minutes after reperfusion indicating that they were carrying arterialized blood. These findings persisted throughout the 2 hour period of reperfusion.

Epicardial S-T segment mapping: S-T segments were elevated in the ischemic area within minutes of occlusion but drifted toward control values later during the occlusion period (Fig. 8). Within 30 minutes of reperfusion, S-T segments returned to normal but there was a striking loss in R waves over the reperfused area with formation of significant Q waves. Results for nine animals are presented in Table II. There were no significant differences in results obtained from epicardial leads monitored at the marginal area of reperfusion.

Tritiated digoxin distribution: There were marked abnormalities in tritiated digoxin uptake in the reperfused area (Fig. 9) compatible with a failure of the reperfused myocardium to bind tritiated digoxin that was distributed to the area of decreased blood flow after reperfusion. Although there was little difference in the 15 to 30 minute occlusion group, in the groups with 60 minutes or more of coronary occlusion there was a highly significant decrease in tritiated digoxin concentration in the reperfused tissue ($P < 0.001$). Poor uptake of alphazurine dye also occurred in the reperfused area in animals with 60 minutes or more of coronary occlusion.

Discussion

Our results show that a severe metabolic derangement occurs in myocardium made ischemic for more than 60 minutes and then reperfused for 2 hours. There was marked functional impairment of mitochondria isolated from the reperfused area as compared with mitochondria from normal left ventricular tissue. Occlusion times greater than 60 minutes appeared to result in irreversible changes. The near normal ADP:O ratios with a decreased oxygen consumption are compatible with inhibition of phosphorylation rather than uncoupling and suggest a block in electron flow. The use of an uncoupler, dinitrophenol, confirmed that there was a block in electron flow. In mitochondria from reperfused myocardium a significant increase in total and adenosine triphosphate-linked oxygen consumption occurred with either succinate or succinate and glutamate substrates together, suggesting the block can be partially bypassed with succinate. The site of the block would thus seem to be near site I of the electron transport chain.

The increase in coronary venous oxygen tension and reduction in arteriovenous difference in the coro-

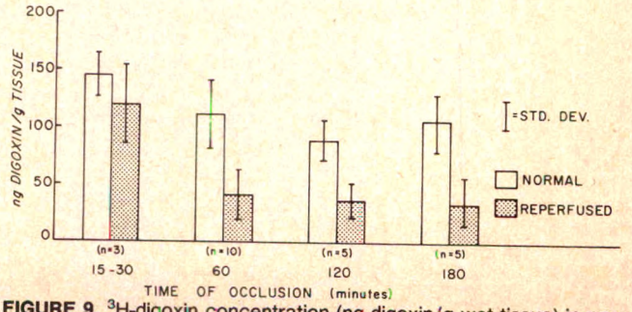

FIGURE 9. ^{3}H-digoxin concentration (ng digoxin/g wet tissue) in normal (**open bars**) and reperfused (**dotted bars**) myocardium is compared in 23 animals with 15 to 180 minutes of coronary occlusion and 120 minutes of reperfusion.

nary vein draining the reperfused area is compatible with arteriovenous shunting or, more likely, failure of the reperfused area of the left ventricle to extract oxygen. These findings correlated well with impaired mitochondrial function from this same area.

The results of epicardial S-T segment mapping show the reperfusion of ischemic myocardium was associated with a return of elevated S-T segments to control levels. However, formation of significant Q waves and impaired mitochondrial function in the reperfused area suggest the persistence of severe damage. Measurement of epicardial S-T segment changes alone did not indicate the true status of the myocardium after reperfusion. Formation of Q waves during reperfusion also suggests that accelerated damage may have occurred during the reperfusion period.

The failure of reperfused tissue to accumulate tritiated digoxin or vital dye may simply indicate a failure to restore blood to the area, or may be a further reflection of cellular damage. Impairment of mitochondrial function correlated with the altered distribution of tritiated digoxin and poor uptake of alphazurine 2G blue dye. Other investigators[13] have also reported a marked alteration in distribution of ^{3}H-digoxin or radioactive microspheres[23] by an infarcted and ischemic left ventricle and have suggested that ^{3}H-digoxin is a marker of blood flow. Although our study did not attempt to measure ^{3}H-digoxin concentration in the inner and outer layers of the left ventricular wall, it was evident from staining by the alphazurine dye that there was a marked defect in regional blood supply to the middle layers of myocardium, with the epicardium and endocardium generally staining evenly after reperfusion. These findings indicate a disturbance in circulation, especially to the innermost layers of the left ventricular wall, that persists after reperfusion. The abnormal mitochondrial function demonstrated in this area is therefore most likely the result of inadequate tissue perfusion with persisting ischemia.

These results agree with those reported by other observers. Krug,[24] using cats in reperfusion experiments, found that there were ischemic areas in the inner layer of the heart that could not be reperfused after coronary ligation of 30 to 45 minutes. Copeland et al.[7] showed that there were morphologic changes in dog heart mitochondria after 45 minutes of anoxia and that these changes were not reversed by up to 7 hours of reperfusion. Jennings et al.[25] likewise noted ultrastructural change and marked functional abnormalities in mitochondria isolated from ischemic dog papillary muscle after 60 minutes of coronary occlusion. Recently Lang et al.[1] reported profound changes in hemodynamics, metabolic function and morphologic structure in dog hearts after 3 hours of coronary occlusion followed by 5 hours of reperfusion. They concluded that reperfusion may not reverse hemodynamic and metabolic disorders induced by 3 hours of occlusion and that reperfusion may even have a detrimental effect, resulting in accelerated necrosis and deterioration of function. Banka et al.[26] demonstrated accentuation of contractile abnormalities after 2 hours of occlusion that appeared irreversible with reperfusion.

In summary, this study shows by a number of different measurements that reperfusion of transiently ischemic myocardium for 2 hours does not restore significant myocardial viability in that area. Mitochondrial function was markedly impaired after 60 minutes of coronary occlusion. The defect would seem to be a block in electron flow near site I that can be partially bypassed with use of succinate. There was an apparent inability of the reperfused myocardium to extract oxygen as evidenced by an increase in coronary venous oxygen tension and a decrease in arteriovenous oxygen difference. Epicardial S-T segment mapping provided evidence of necrosis during reperfusion, and there was a markedly altered distribution of tritiated digoxin and vital dye in the reperfused area compatible with a disturbance in blood flow or cellular integrity.

Clinical implication: If these results are applicable to the acutely infarcted myocardium in man, they suggest that revascularization for 2 hours or more will not salvage ischemic myocardium. Thus, the results of early surgical intervention as treatment for acute ischemia must be critically evaluated.

Experimental Coronary Arterial Occlusion and Release

Effects on Enzymes, Electrocardiograms, Myocardial Contractility and Reactive Hyperemia

MARVIN RICHARD BLUMENTHAL, MD
HSUEH-HWA WANG, MD
LETTY MEI PANG LIU, MD

New York, New York

After less than 1 hour of coronary arterial occlusion, the myocardium suffers irreversible changes as revealed by electron microscopy. Yet, the earliest clinical laboratory indexes of myocardial infarction—elevated serum enzyme levels and significant Q waves on the electrocardiogram—are not detected until at least 6 hours after coronary occlusion. To study the early period after coronary occlusion in the dog, occlusion of the left anterior descending coronary artery for 1 to 3 hours was followed by release, and coronary sinus and venous enzyme levels, the electrocardiogram and myocardial contractility from the infarcted area, and reactive hyperemia were monitored. Coronary sinus enzyme levels rose within 15 minutes after release of occlusion in half of the experiments with 1 to 1 1/2 hours and in all of those with 2 to 3 hours of occlusion, and this rise preceded the rise in venous levels by only 10 to 20 minutes. Significant Q waves appeared 15 to 30 minutes after release of occlusion as the serum enzymes were increasing. Thus, clinically, the delayed appearance of increased serum enzymes and significant electrocardiographic Q waves is probably largely due to a lack of circulation in the infarcted area rather than to prolonged survival time. Also, the venous enzyme level reflects the coronary sinus level minutes later. The presence of viable myocardium in the infarcted area was suggested by elevation of the S-T segment upon reclamping, and by residual myocardial contractility and retained capacity for reactive hyperemia. These findings occurred in some experiments even in the presence of a significant Q wave.

Coronary artery bypass surgery is still seeking its proper position in relation to traditional medical management of coronary artery disease. One area of current discussion is the applicability of this procedure to acute myocardial infarction.[1] After experimental coronary occlusion, the myocardium has been shown by electron microscopy to be irreversibly damaged in 1 hour or less.[2] Yet the accepted clinical laboratory criteria—elevation of serum enzyme levels and appearance of significant electrocardiographic Q waves—do not appear for many hours after coronary occlusion. Clearly, more knowledge of the genesis of these indexes is required.

Previous studies of acute experimental coronary occlusion have confirmed the delay in appearance of elevated serum enzyme levels and electrocardiographic Q waves. The loss of enzymes from the myocardium after coronary arterial occlusion has been monitored in three ways: (1) Serum levels have been measured in *delayed occlusion* experiments, in which a loop is placed around a coronary artery and closed 1 week later after the surgically induced increase in serum enzymes has subsided. (2) Serum levels have been determined after *bead embolization* of a coronary artery in closed chest dogs, thus avoiding any rise in enzyme levels due to operation; and (3) *myocardial enzyme content* has been determined at different intervals after

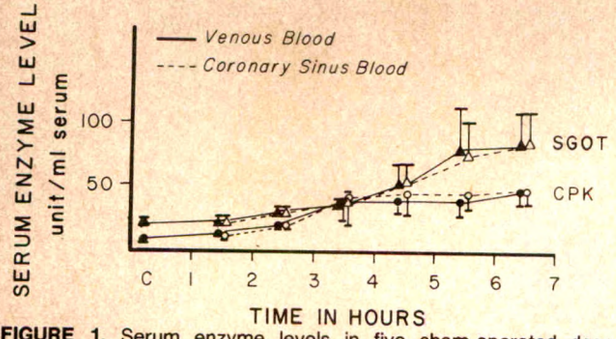

FIGURE 1. Serum enzyme levels in five sham-operated dogs. Values are expressed as mean ± standard error of the mean. Serum glutamic oxaloacetic transaminase (SGOT) in international units and serum creatine phosphokinase (CPK) in Sigma units are plotted against time from start of operation (C).

coronary occlusion. In *delayed occlusion,* serum glutamic oxaloacetic transaminase (GOT) and creatine phosphokinase (CPK) levels begin to rise in 4 to 6 hours and peak in 18 to 28 hours.[3–6] With *bead embolization,* which causes microinfarcts, serum GOT elevation appears earlier, in 3 to 5 hours, and also peaks sooner, in 9 to 23 hours.[7,8] After coronary arterial ligation, *myocardial GOT content* begins to decrease in 4 hours and is reduced only 40 to 50 percent in 24 hours.[3,9] The known delay in the development of significant Q waves after myocardial infarction prompted Prinzmetal et al.[10] to defer their experiments on Q wave genesis for 11 to 139 hours after coronary occlusion.

The work reported here was designed to help explain the delay in appearance of these laboratory indexes of myocardial infarction in relation to the early electron microscopic findings of irreversible damage. In acute experiments, with use of a stop-flow technique and sham-operated controls, coronary sinus and venous enzyme levels and the emergence of significant electrocardiographic Q waves were assessed during and after release of coronary occlusion of 1 to 3 hours' duration. In addition, the preparation permitted study of the indexes of myocardial ischemia: S-T segment elevation in the electrocardiogram, contractility of the myocardium supplied by the occluded vessel, and reactive hyperemia after release of occlusion. The preliminary results have been reported previously.[11]

Methods

Acute experiments were performed in 25 dogs weighing 13 to 21 kg; 20 were subjected to coronary occlusion, and 5 served as sham-operated controls. Each animal was anesthetized with intravenously administered sodium pentobarbital, 30 mg/kg body weight, and placed in the left oblique position. With use of artificial ventilation through a tracheal cannula, the chest was entered by block resection of a portion of the chest wall including the left third, fourth and fifth ribs. As little traumatized tissue as possible was left in the animal so that there would be minimal release of enzymes from injured skeletal muscle into the circulation.

The pericardium was incised and the heart suspended in a pericardial cradle. A segment of the left anterior descending coronary artery was dissected and a snare of thin rubber band was placed around it in 14 dogs including the 5 sham-operated dogs. In 11 experiments the left anterior descending artery was cannulated and perfused from the left carotid artery. In the latter group, blood flow was measured with an electromagnetic flowmeter (Biotronex model BL310) using an extracorporeal flow transducer interposed in the perfusion circuit. A Walton-Brodie strain gauge was sutured to the epicardium to record myocardial contractility of an area supplied by the left anterior descending artery. In this same area, a plunge electrode made of Teflon®-coated stainless steel wire, 0.01 mm in diameter with a 0.5 mm bare tip, was inserted subepicardially to record a unipolar electrocardiogram.

A modified Morawitz cannula was introduced through the left external jugular vein and ligated in the coronary sinus. The coronary sinus blood returned to the right atrium through a cannula inserted into the right external jugular vein. A T tube interposed in the circuit allowed sampling of the coronary sinus blood. A cannulated femoral vein permitted sampling of systemic venous blood and administration of drugs. All animals were given heparin, 10 mg/kg. In later experiments, lidocaine, 20 to 50 μg/kg per min, was infused intravenously for up to 15 minutes immediately after coronary occlusion and release to reduce the incidence of serious ventricular arrhythmias. A femoral artery was cannulated and attached to a Statham transducer (model 23AC) to measure arterial blood pressure.

Recordings were made on a Beckman Dynograph (type R) with two motor drives. Arterial blood pressure, blood flow in the left anterior descending coronary artery and myocardial contractility were recorded continuously at a paper speed of 25 mm/min. On two additional channels, tracings of myocardial contractility and the electrocardiogram were recorded intermittently at a paper speed of 25 mm/sec. Heart rate was measured from the electrocardiogram.

Before operation, a clotted venous blood sample was obtained. After operation, paired samples of coronary sinus and systemic venous blood were drawn at 30 to 60 minute intervals. In 20 animals the left anterior descending artery was occluded for 1 to 3 hours, and then the occlusion was released. Paired blood samples were obtained every 30 to 60 minutes after occlusion, and more frequently after release. In the five sham-operated control animals, paired samples were drawn at hourly intervals after operation. All blood samples were assayed for serum GOT and CPK levels by spectrophotometric methods.[12,13] The coronary sinus and systemic venous enzyme levels were plotted against time in each experiment, and the slope of each curve before release of occlusion was compared with the slope after release, using the analysis for the fitted least-square line.[14]

Reactive hyperemia was recorded after a 1 minute clamping of the perfusion circuit in the animals with coronary blood flow measurements, both before occlusion and 30 to 60 minutes after release. The magnitude of reactive hyperemia was calculated as the peak increase in flow compared with the control value. The magnitude of hyperemia obtained after release of occlusion was compared with that obtained before release in the same animal and expressed as percent reduction. The distance from the left coronary ostium to the point of occlusion of the left anterior descending artery was measured post mortem.

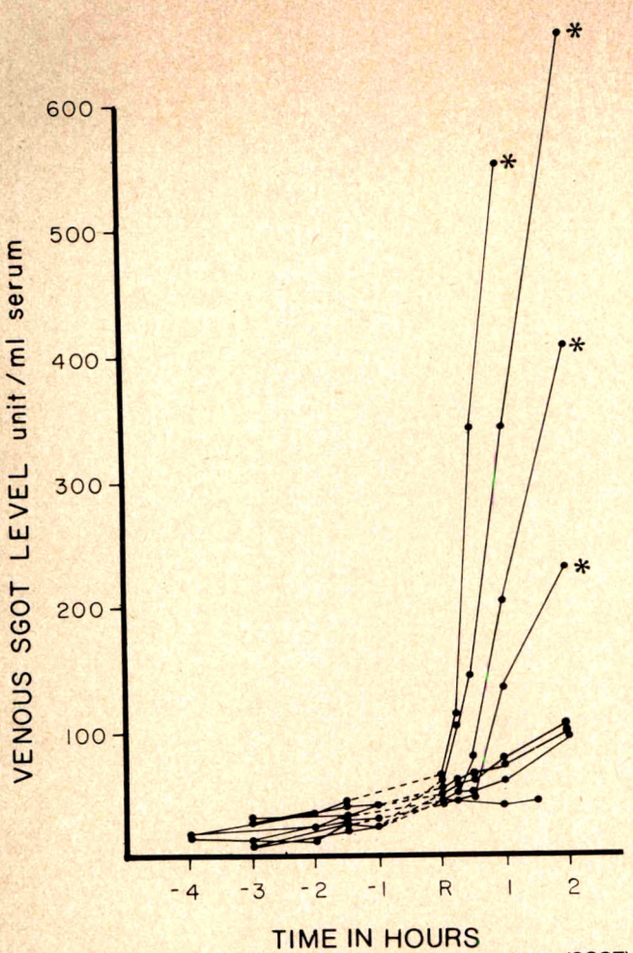

FIGURE 2. Venous serum glutamic oxalocetic transaminase (SGOT) values in international units in eight animals with 1 to 1 1/2 hours of occlusion of the left anterior descending coronary artery. **Broken line** indicates period of occlusion: 1 hour in five experiments and 1 1/2 hours in three experiments. R indicates time of release of occlusion; * indicates significant rise in enzyme levels after release.

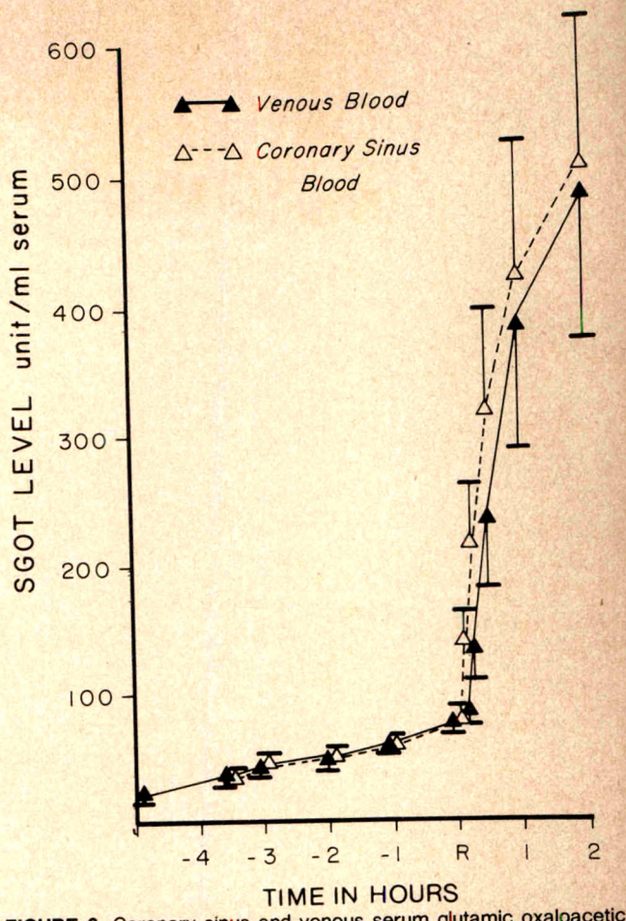

FIGURE 3. Coronary sinus and venous serum glutamic oxaloacetic transaminase (SGOT) levels in 12 animals with 2 to 3 hours of occlusion mean ± standard error of the mean. R indicates time of release of occlusion. Elevation of the coronary sinus SGOT level precedes elevation of venous level by 10 to 20 minutes after release of occlusion.

Results

Twenty animals were successfully brought to the conclusion of the experiment; 8 dogs underwent coronary occlusion for 1 to 1 1/2 hours and 12 dogs for 2 to 3 hours. In addition, five sham-operated dogs were followed up for 6 1/2 hours to serve as controls in the study of elevation of enzyme levels due to the operative procedure.

Serum Enzymes

Sham-operated animals: Figure 1 shows the composite results in five sham-operated animals of serum GOT and CPK determinations in coronary sinus and venous samples. The levels of both enzymes rose gradually to approximately four times control levels in 6 1/2 hours (5 hours after completion of operation). Coronary sinus and venous values were in close agreement at each sampling time. At no period was there an abrupt change in enzyme levels in any of the animals.

Experimental animals: In Figure 2 venous serum GOT values are plotted against time for the eight animals with coronary occlusion of 1 to 1 1/2 hours' duration (five with 1 hour and three with 1 1/2 hours of occlusion). The enzyme levels remained in the range established by the control animals until release of the occlusion. After release, the slope of the curve showed no significant change in four animals (two with 1 hour and two with 1 1/2 hours of occlusion), but increased significantly in the remaining four ($P < 0.05$). Parallel results were obtained for venous CPK values. Coronary enzyme curves also remained in the range of values of the sham-operated dogs until release of occlusion. After release, the same four animals also had significant enzyme increases, but the change in slope preceded the change in venous slope by 10 to 20 minutes as described later for the animals with 2 to 3 hours of occlusion.

Twelve animals had occlusion of the left anterior descending coronary artery for 2 to 3 hours: six for 2 hours, three for 2 1/2 hours and three for 3 hours.

Serum enzyme values remained within the control range before release of occlusion as in the animals with 1 to 1 1/2 hours of occlusion, but the slope of the curve rose significantly after release in all 12 dogs with 2 to 3 hours of occlusion. Mean values and standard error were used to compare coronary sinus and venous enzyme levels at each sampling time (Fig. 3 and 4). Again, there was close agreement between coronary sinus and venous enzyme values before release of occlusion. After release, the coronary sinus level was higher than the venous level at each sampling time, thus confirming the heart as the source of the increase in serum enzymes. However, the time required for the venous level to reach any specific coronary sinus level remained 10 to 20 minutes even after the slope had begun to decrease. These observations pertained for both serum GOT and CPK levels throughout the experiment. The marked individual variations in the magnitude of the enzyme increase after release of occlusion is represented by the large standard error of the mean.

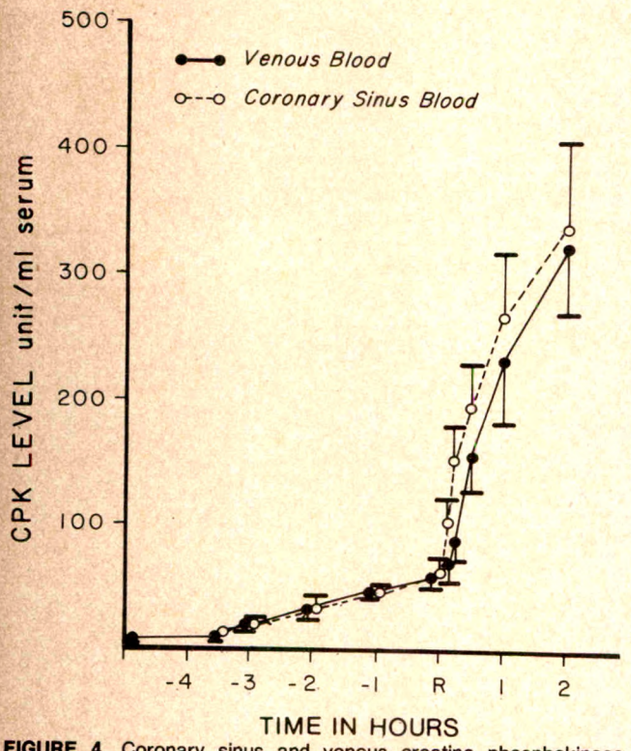

FIGURE 4. Coronary sinus and venous creatine phosphokinase (CPK) levels in the 12 animals whose data are shown in Figure 3. All values are mean ± standard error of the mean. Again, elevation of coronary sinus CPK precedes elevation of venous CPK by 10 to 20 minutes after release (R) of occlusion.

Other measurements: With coronary occlusion, mean arterial blood pressure decreased from an average of 95 to 83 mm Hg, but in none did it fall below 60 mm Hg. Mean heart rate rose from 164 to 177 beats/min. The distance from the left coronary ostium to the site of occlusion of the left anterior descending coronary artery ranged from 1.5 to 3.1 cm. No correlation could be found between any of these variables and the magnitude of enzyme increase in this small series.

Electrocardiogram

The QRS complex and the S-T segment were considered separately in determining electrocardiographic changes. During the experiments, the T waves followed no definite pattern. A Q wave was considered significant if it measured more than 50 percent of the QRS complex. S-T segment elevation of more than 2 mm was considered significant.

QRS complex: In the group with 1 to 1 1/2 hours of occlusion, the four animals with no significant increase in serum enzymes had no significant Q waves. The four animals with a significant increase in serum enzymes all manifested significant Q waves after release of occlusion. Of the 12 animals that underwent 2 to 3 hours of occlusion, 10 had significant Q waves; in the remaining 2, the pattern changed from Rs to rS. Although all 12 of these animals had increased serum enzymes after release of occlusion, the increase was relatively small in the latter two.

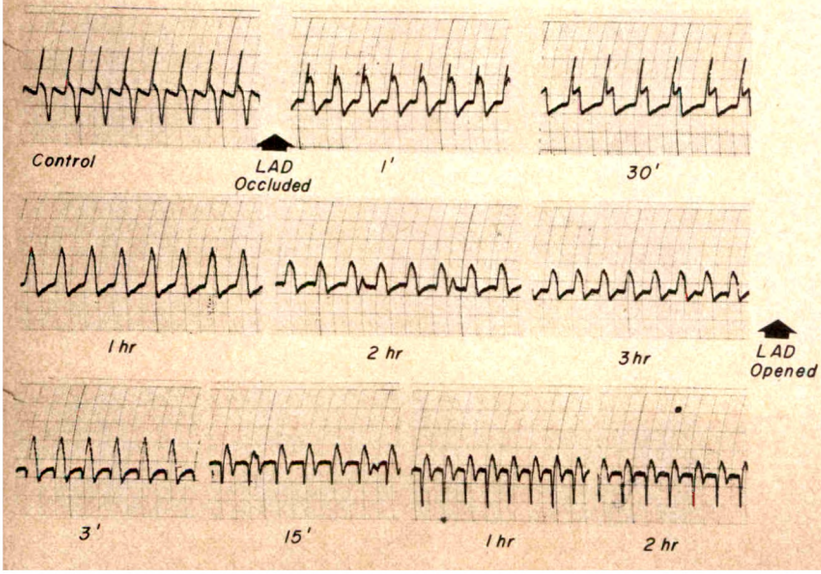

FIGURE 5. Subepicardial electrocardiogram in an animal with 3 hours of occlusion of the left anterior descending coronary artery (LAD). No q wave appeared during the period of occlusion; 3 minutes after release of occlusion (**second arrow**) a q wave appeared and became significant 15 minutes after release. The S-T segment was elevated 7 minutes after occlusion and was still elevated 2 hours after release.

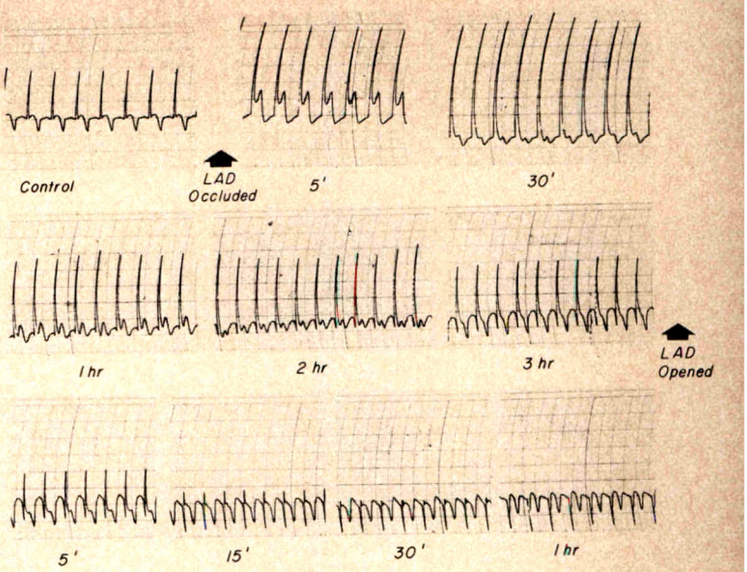

FIGURE 6. Subepicardial electrocardiogram in an animal with 3 hours of occlusion of the left anterior descending coronary artery (LAD). A small q wave developed 1 hour after occlusion; 15 minutes after release (**second arrow**) a significant Q wave was present. The S-T segment was elevated 5 minutes after occlusion, returned to normal in 30 minutes and remained normal for the duration of the experiment.

Thus, significant Q waves were noted in 14 animals, 4 with 1 to 1 1/2 hours and 10 with 2 to 3 hours of occlusion; in all, the electrocardiographic changes developed 15 to 30 minutes after the release of occlusion. Among those with 2 to 3 hours of occlusion, three showed no q wave until after release of occlusion (Fig. 5); in the other seven a small q wave developed during occlusion (Fig. 6 and 7). Surprisingly, the Q waves became significant while serum enzyme levels were rising steeply.

S-T segment: All of the 16 dogs with a significant increase in serum enzymes (4 with 1 to 1 1/2 hours and all 12 with 2 to 3 hours of occlusion) had S-T segment elevation within 2 to 3 minutes after occlusion. The S-T segment remained elevated after release of occlusion in 3 dogs (Fig. 5) and returned to control level during occlusion in 2 dogs (Fig. 6); the dominant pattern, observed in 11 dogs, was a return to control level after release of occlusion (Fig. 7).

In two animals with this dominant pattern, the left anterior descending coronary artery was reoccluded 1 1/2 hours after release of the first occlusion. The S-T segment again became elevated, the Q wave persisted and, on release of occlusion, the S-T segment once again returned to normal (Fig. 7).

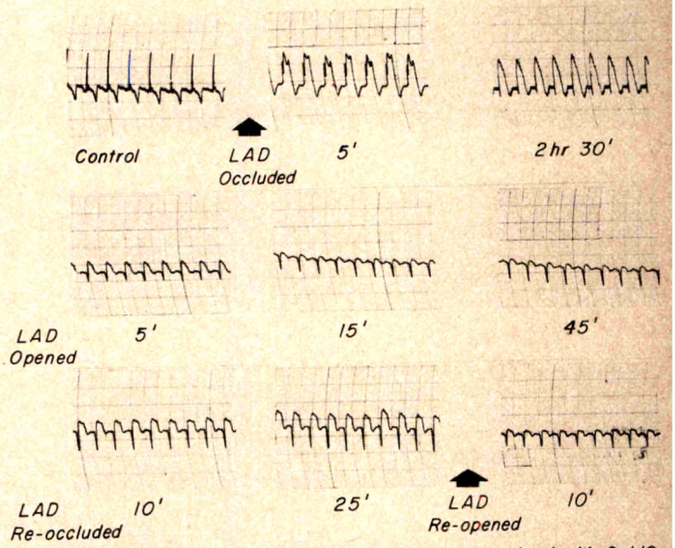

FIGURE 7. Subepicardial electrocardiogram in an animal with 2 1/2 hours of occlusion of the left anterior descending coronary artery (LAD) and reocclusion 1 1/2 hours after release. A small Q wave was present 2 1/2 hours after occlusion and became significant 15 minutes after release. The S-T segment was elevated 5 minutes after occlusion, remained elevated for the duration of occlusion, and returned to normal 15 minutes after release. Ten minutes after reocclusion, the S-T segment again became elevated and the Q wave persisted; 10 minutes after release of this second occlusion, the S-T segment returned to normal.

Myocardial Contractility and Reactive Hyperemia

Myocardial contractility*: Contractility was recorded from the area supplied by the occluded coronary artery in 8 animals with 1 to 1 1/2 hours of occlusion and in 10 with 2 to 3 hours of occlusion. Four of the eight dogs with 1 to 1 1/2 hours of occlusion that had no significant increase in serum enzyme levels had a reduction in contractility of less than 45 percent (range 0 to 44 percent), the same decrement noted in the sham-operated animals. The remaining four dogs in this group had significant serum enzyme increases and a reduction in myocardial contractility of more than 55 percent (range 56 to 77 percent). All 10 dogs with 2 to 3 hours of occlusion also had a reduction in contractility of more than 55 percent (range 56 to 91 percent).

After occlusion, the myocardial contractility tracing characteristically assumed a flat-top appearance as opposed to the sharp spike seen before occlusion

* Myocardial contractility, as recorded with a Walton-Brodie strain gauge, is a measurement of isometric contraction in a stretched segment of epicardium. The recording is affected by the direction of the underlying muscle fibers and the change in shape of the ventricle with contraction, and it does not quantitatively reflect the change in contractility of the entire thickness of the myocardium. The results presented here, comparing recordings obtained before and after occlusion and expressed as percent change, should be interpreted with this reservation.

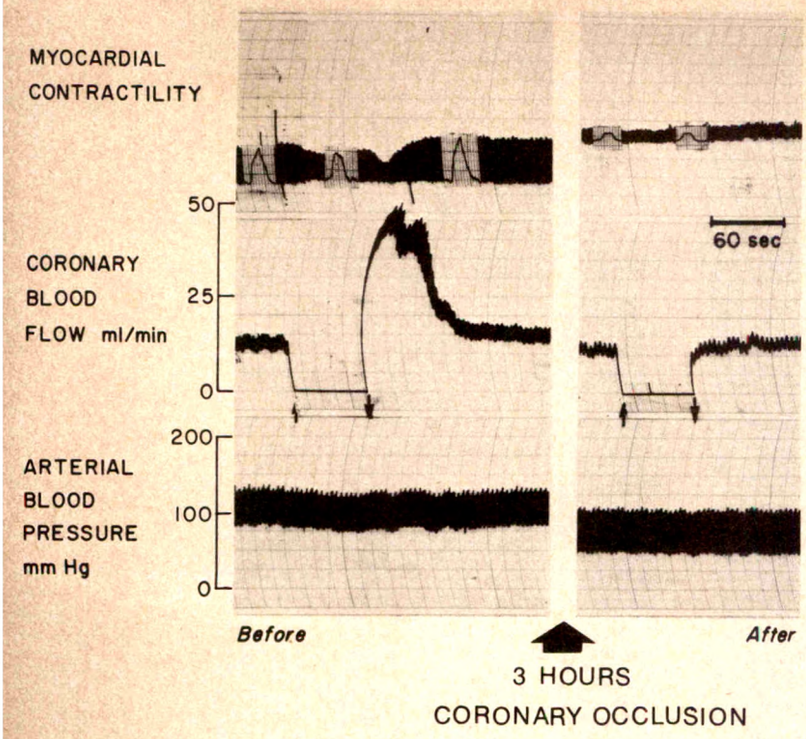

FIGURE 8. Effect of 3 hours of occlusion of the left anterior descending coronary artery on myocardial contractility, reactive hyperemia as shown in the tracing of blood flow in the left anterior descending artery, and arterial blood pressure. **Left panel,** tracing obtained during 1 minute of clamping of the artery before occlusion. **Right panel,** tracing obtained after release of occlusion. Rapid traces of myocardial contractility are superimposed upon the slow tracings. After the 3 hour period of occlusion reactive hyperemia was absent. Myocardial contractility and arterial blood pressure were not affected by the 1 minute period of clamping (**right panel**).

(Fig. 8, top tracing, right panel). Contractility decreased rapidly with occlusion, as illustrated during the 1 minute period of clamping before occlusion in Figure 9, left panel. A temporary increase in contractility was observed after the release of a 1 minute clamping during the control period (left panels, Fig. 8 and 9).

Reactive hyperemia: This variable was measured after 1 minute of clamping in 11 animals before occlusion, and the measurement was repeated 1/2 to 1 hour after the occlusion had been released. Before occlusion, reactive hyperemia peaked at 1.5 to 3.8 times the control rate of blood flow in the left anterior descending artery, and subsided in 2 to 4 minutes. Of three dogs with occlusion for 1 to 1 1/2 hours, two had no rise in serum enzyme levels; one of these had no change in reactive hyperemia and the other only a 12 percent reduction. The third dog had a significant rise in serum enzyme levels and a 29 percent reduction in reactive hyperemia. The eight dogs with 2 to 3 hours of occlusion had a reduction in reactive hyperemia of 35 to 100 percent (mean 67 percent).

Figures 8 and 9 illustrate, for two experiments, the changes in reactive hyperemia, myocardial contractility and arterial blood pressure associated with 1 minute of clamping before and after a 3 hour occlusion of the left anterior descending coronary artery. Figure 8 shows a complete loss of reactive hyperemia after occlusion and a 75 percent reduction in myocardial contractility (right panel). Arterial blood pressure values were not affected by the 1 minute of clamping after occlusion compared with the slight reduction in values before occlusion (left panel). In another animal (Fig. 9, right panel), reactive hyperemia was reduced by only 35 percent. This retained capacity for reactive hyperemia was associated with a slight decrease in myocardial contractility during clamping and a temporary increase on release, as well as a slight reduction in arterial blood pressure during clamping. These changes were much smaller than those that occurred before occlusion (left panel), but are indicative of remaining myocardial function in the infarcted area after occlusion and are in contrast to the findings illustrated in Figure 8 (right panel).

Discussion

Coronary occlusion leads to myocardial ischemia and thence to myocardial infarction. In the experiments reported here, the presence of myocardial infarction was suggested by an abrupt rise in serum enzyme levels and a rapid development of significant electrocardiographic Q waves after release of occlusion. These findings occurred in some animals even after occlusion of only 1 hour's duration. Ancillary evidence of infarction included loss of myocardial contractility and reduced reactive hyperemia. Residual viable muscle in the infarcted area was assumed to be present when (1) reocclusion caused elevation of the S-T segment in the electrocardiogram, (2) some return of myocardial contractility followed release of occlusion, and (3) some capacity for reactive hyperemia was retained after release of occlusion.

Serum Enzymes

The sham-operated control animals manifested a range of elevation of serum enzyme levels caused by the operative procedure alone. These values are in agreement with previously reported observations.[15]

In the animals that underwent coronary arterial occlusion and release, three pertinent observations emerged. First, in every dog that underwent 2 to 3 hours of coronary occlusion, elevated serum enzyme

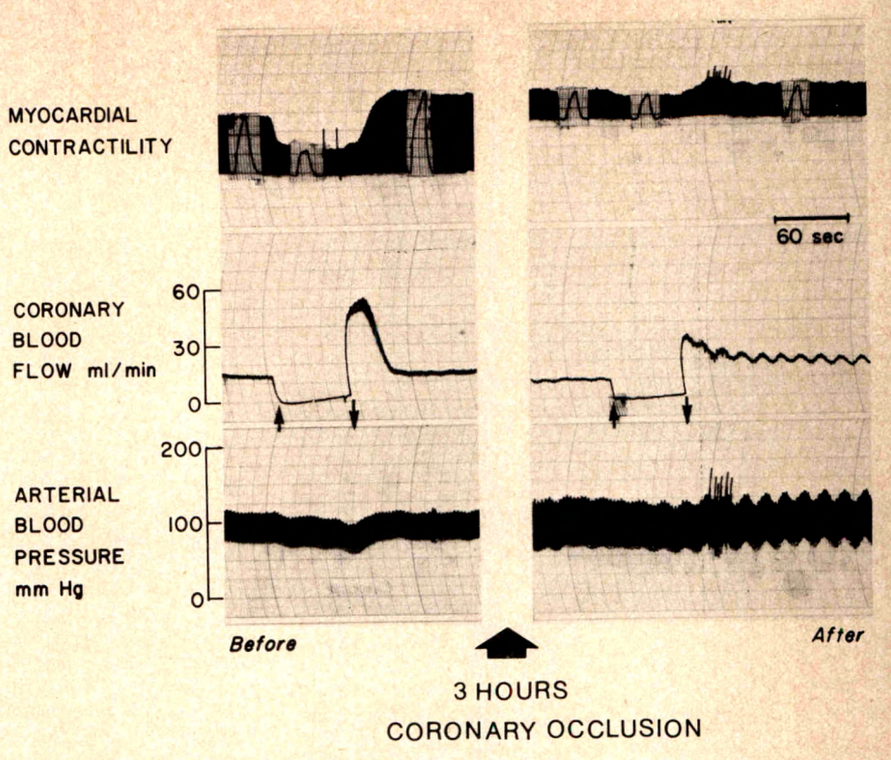

FIGURE 9. Effect of another 3 hour occlusion experiment. Records as in Figure 8. After 3 hours of occlusion, some capacity for reactive hyperemia was retained, associated with some loss of myocardial contractility and a slight reduction in arterial blood pressure during the 1 minute clamping period (**right panel**).

levels occurred almost immediately after release of occlusion (Fig. 3 and 4); serum enzymes were increased in some dogs that underwent 1 to 1 1/2 hours of occlusion but not in others (Fig. 2). Second, restoration of circulation to the infarcted area was responsible for the abrupt rise in enzyme levels; the myocardium was the source of this rise since elevation of enzyme levels in coronary sinus blood preceded that in venous blood. Third, venous enzyme elevation after release of occlusion lagged only 10 to 20 minutes behind the enzyme elevation in coronary sinus blood; this lag was apparent immediately on release of occlusion and remained fairly constant even as the rate of rise began to decrease 1 to 2 hours after release. On the basis of these observations, the time from coronary occlusion to the appearance of elevated venous enzyme levels can be divided into three periods for the purpose of discussion: the *viable period,* when heart muscle cells may still recover if circulation is restored; the *stagnant period,* when the cells are irreversibly damaged but there is insufficient circulation to remove the enzymes; and the *lag period* between the rise of enzyme levels in the coronary sinus blood and enzyme elevation in venous blood.

Viable period: Our data on serum enzyme levels suggest, on first inspection, that the *viable period* lasts less than 2 hours since all animals with occlusion of 2 hours or more had increased serum enzymes after release (Fig. 3 and 4). Indeed, the increase in serum GOT after release of a 1 hour occlusion in three animals (Fig. 2) closely corroborates the electron microscopic data derived from papillary muscle having no collateral circulation and showing irreversible damage after 40 to 60 minutes of occlusion.[2] However, four of our animals with 1 to 1 1/2 hours of occlusion had no significant increase in serum GOT after release, and therefore probably sustained no irreversible myocardial damage. Moreover, there were wide individual variations in the degree of enzyme elevation after release of 2 to 3 hours of occlusion, illustrated by the large standard error of the mean in Figures 3 and 4. This variation did not correlate with the distance from the coronary ostium to the point of occlusion. Some other mechanism or mechanisms must pertain. Prinzmetal[10] and Maxwell[16] and their coworkers described two types of experimental myocardial infarction on the basis of pathologic changes: transmural and patchy. Their two types of myocardial infarction and our variations in enzyme increase may both be attributable to the degree of existing collateral circulation before coronary occlusion. This concept is supported by the observation that drugs that affect collateral vessels influence infarct size.[17] Moreover, it has been shown that smaller infarcts and higher survival rates are found when additional collateral circulation is stimulated by coronary arterial constriction before ligation.[18] In this context, the short, viable period observed electron microscopically in posterior papillary muscle may be related to the known absence of collateral circulation to this area, whereas the more variable and generally longer viable period in our experiments may be a result of existing collateral circulation. Interestingly, the relatively rich collateral circulation of the dog heart has been likened to that in the human heart with coronary artery disease.

Stagnant period: This period, so-called because of poor circulation in the infarcted area, was abridged in our experiments by reperfusion. Ample support for a relatively long clinical *stagnant period* is afforded by reports of other investigators. For example, heart muscle loss of GOT does not begin until 4 hours after

occlusion and only 40 to 50 percent of the enzyme is lost in 24 hours.[3,9] In fact, even 24 hours after coronary occlusion, the circulation in the infarcted area is only 12 percent of that in the noninfarcted myocardium as measured by injection of microspheres.[19] The truth is that enzymes cannot be removed if there is no circulation to remove them. However, other factors also influence the speed of removal of enzymes from infarcted myocardium. The anatomy of the infarct is relevant since elevated serum enzyme levels appear sooner than usual after microinfarcts produced by bead embolization.[7,8] Another factor is molecular weight, since enzymes of lower molecular weight became increased in the serum before those of higher molecular weight.[20] Most interesting of all is the observation that reperfusion 40 to 60 minutes after occlusion causes more rapid destruction of sarcolemmal membranes and extrusion of intracellular contents[21] although reperfusion *per se* actually decreases infarct size.[22] Nonetheless, in our experiments, the more rapid destruction of sarcolemmal membrane of irreversibly damaged cells could have contributed to the abrupt rise in coronary sinus and then venous enzyme levels.

Lag period: The time required for the venous enzyme level to reach a specific coronary sinus enzyme level defines the *lag period.* Of the three periods, this one is best illustrated by the experiments reported herein. The lag period is shown in Figures 3 and 4 as the distance along the abscissa from the coronary sinus curve to the venous curve after release of occlusion. With recognition of the assumptions of constant coronary blood flow and blood volume, and the need for corrections for mixing time and half-life of enzymes, it can be expressed as follows:

$$\text{Lag period (min)} = \frac{\text{Blood volume (ml)}}{\text{Coronary blood flow (ml/min)}}$$

Substituting standard values supports the gross applicability of this formula to the experimental findings. Especially relevant in the mathematical derivation is the fact that a slow rise or fall in the rate of enzyme leaving the infarcted myocardium does not greatly affect this approximation.* For example, a 20 percent decrease during one lag period (approximately 20 minutes) would prolong the lag by 10 percent or 2 minutes. Thus, this conception of a relatively short lag period is applicable to myocardial infarction in man. In effect, venous enzyme elevation detected clinically presumably lags only minutes behind coronary sinus levels. This relationship can be adapted to other organ effluents monitored by peripheral venous sampling provided that the necessary assumptions and corrections are acceptable: the lag period varies inversely with the organ blood flow and directly with the fluid volume into which the substance mixes.

* When the rate of release of enzyme (E) from the infarcted myocardium is changing slowly, and the change during one lag period is represented by ΔE, the following formula pertains:

$$\text{Lag (min)} \approx \frac{\text{Blood volume (ml)}}{\text{Coronary blood flow (ml/min)}} \cdot \left(1 - \frac{1/2\ \Delta E}{E}\right)$$

Electrocardiogram

Q waves became significant within 30 minutes after release of occlusion in 14 of 16 animals with serum enzyme elevations. Clinically, Q waves are delayed at least as long as required for elevation of serum enzyme levels. The telescoping of Q wave formation in our experiments parallels the washout of enzymes after release of occlusion. One possibility suggested by this correlation is that removal of one or more substances allows the emergence of cavity potential. However, it is possible that preservation of the sarcolemmal membranes in the early periods of myocardial infarction[21] delays appearance of the Q wave. With reperfusion, disruption of these membranes might alter the electrophysiologic properties of the cells in a way that could accelerate Q wave emergence. The precise explanation awaits further studies. Nevertheless, at this juncture it seems reasonable to conclude that the delay in Q wave appearance in clinical myocardial infarction is a result of the compromised perfusion of the infarcted area and does not imply a prolonged period during which death of heart muscle slowly occurs.

S-T segment shift: Alteration in the S-T segment represents a prompt and reversible response to myocardial ischemia.[23] S-T elevation recorded on multiple epicardial electrocardiograms has been used to map the ischemic area shortly after coronary occlusion.[17] In our experiments, with only one subepicardial recording near the center of the ischemic area, the S-T segment rose promptly after coronary occlusion. In the majority of experiments, the S-T segment manifested persistent elevation throughout occlusion and returned to normal with reperfusion. This pattern, which suggests subsidence of ischemia in remaining viable myocardial cells, occurred despite the concomitant appearance of Q waves. In two experiments (one shown in Fig. 7), 1 1/2 hours after release of occlusion, the left anterior descending artery was reoccluded, and the S-T segment again became elevated while the Q wave remained; the S-T segment returned to normal on release of this second occlusion. We conclude that in these experiments the infarcted area contained viable myocardial cells as well as cells with irreversible damage. The implication for myocardial infarction without reperfusion is that either these cells survive, forming patchy infarction, or that they eventually succumb.

Myocardial Contractility and Reactive Hyperemia

Myocardial contractility decreases very promptly upon occlusion of a coronary artery, demonstrating an even more rapid response to myocardial ischemia than that of S-T elevation and occurring long before either index of infarction develops. In some of our experiments, no recovery of contractility appeared after release of occlusion (Fig. 8), and this finding implies that transmural infarction had occurred. In others, some return of contractility was apparent (Fig. 9), indicating patchy infarction with areas of viable muscle that resumed contraction when circulation was re-

stored. These observations are consistent with results of cineradiographic studies in coronary arterial reperfusion experiments.[24] They further corroborate the observation that an asynergic area revealed by ventriculography in man does not exclude the presence of viable ischemic myocardium.[25]

Reactive hyperemia represents one or more vasodilating mechanisms in viable ischemic muscle that affect the vascular bed. In our experiments, the magnitude of reactive hyperemia correlated with the return of myocardial contractility. Moreover, it was a more reliably measured index of salvageable or salvaged ischemic myocardium after coronary occlusion. Indeed, diastolic reactive hyperemia is being used to evaluate the benefit derived from coronary artery bypass operations.[26]

Clinical Implications

In selecting patients for coronary artery bypass surgery, the *sine qua non* is the demonstration of an operable lesion by angiography. Our data pertain to further selection of patients after myocardial infarction and to postoperative evaluation.

The usual clinical indicators of acute myocardial infarction, a rise in venous enzyme levels and significant electrocardiographic Q waves, do not obtain during the first few hours after coronary occlusion. Indeed, after coronary artery bypass surgery for acute myocardial infarction, increase in serum enzyme levels and progressive development of a Q wave may represent the natural course of reperfusion rather than damage resulting from operation. Before and after operation, the venous enzyme level reliably reflects the coronary sinus enzyme level minutes later.

During the postinfarction period, S-T segment deviation identifies ischemic myocardium even in the presence of Q waves. The use of grid electrocardiography for this determination has already been reported.[17]

After operation, the value of measurement of reactive hyperemia in the bypass graft to assess the effectiveness of the procedure is supported by our data. These results should correlate with myocardial contractility demonstrated by ventriculography.

Acknowledgment

We thank Mr. Philip Goad for his technical assistance and Dr. Martin Kruskal, professor of astrophysical sciences and applied mathematics, Princeton University, for his aid in explaining the lag between coronary sinus and venous enzyme levels after release of coronary occlusion.

The effects on myocardial function, metabolism and ultrastructure of 60 minutes of reperfusion, instituted after 30, 60 and 90 minutes of occlusion of the left anterior descending coronary artery, were studied in 48 dogs. Twelve sham-operated dogs served as controls. Coronary occlusion for 60 or 90 minutes caused significant depression in the first derivative of left ventricular pressure (dP/dt) ($P < 0.05$) that could not be reversed by reperfusion. Upon reperfusion, creatine phosphate stores in myocardium made ischemic for 30 and 60 minutes, but not for 90 minutes, returned toward control levels, but stores of adenosine triphosphate (ATP) and total nucleotides and the ATP/adenosine diphosphate ratio of myocardium subjected to 60 and 90 minutes of ischemia were further decreased. After 60 and 90 minutes of ischemia, swelling of the sarcoplasmic reticulum and mitochondrial damage (swelling, decreased matrix density and partial loss of cristae) were seen. Myofibrils were relaxed in all these groups. Reperfusion produced gross contraction of myofibrils and aggravated these changes in mitochondria and sarcoplasmic reticulum. In the hearts subjected to 90 minutes of ischemia these changes were gross. The levels of creatine phosphokinase, glutamic oxaloacetic transaminase and lactic dehydrogenase in the coronary sinus blood increased dramatically ($P < 0.05$) upon reperfusion after 60 or 90 minutes of occlusion, indicating severe impairment of cell membranes. This secondary rise in serum enzyme activity during reperfusion should be taken into consideration when estimating the size of a myocardial infarct from enzyme changes alone. It appears that 60 and 90 minutes of ischemia cause severe myocardial damage that is not reversed by reperfusion maintained for 1 hour although longer periods of reperfusion may be beneficial.

Although ischemia produced by coronary occlusion has repeatedly been demonstrated to produce dramatic changes in myocardial function, ultrastructure and metabolism, there are only a few reports concerning the effects of reperfusion on the ischemic myocardium. Such information is considered of crucial importance in determining the timing and feasibility of coronary bypass surgery in patients with myocardial infarction. Recently, deterioration of the contractile activity of the ischemic zone upon institution of reperfusion after 1 to 2 hours of occlusion has been reported.[1] In this paper we demonstrate that irreversibility of ischemic myocardial function upon reperfusion after 1 to 2 hours of coronary occlusion is associated with dramatic changes in myocardial metabolism, ultrastructure and enzyme leakage.

Methods

Sixty healthy mongrel dogs, of either sex and an average weight of 30.9 ± 5.8 (mean ± standard error of the mean) kg body weight, were used in these experiments. After anesthesia induced with sodium pentobarbital, 20 mg/kg intravenously, the animals were intubated and controlled positive pressure respiration was instituted with use of a Harvard respirator pump. Tidal volume was adjusted to individual body weight (Kleinman-Radford tables) and the animals breathed an air-oxygen mixture with an inspiration/respiration ratio of 45:55. These variables were reviewed and readjusted periodically so as to maintain a stable level of arterial partial pressure of oxygen and pH. In the entire series PO_2 was maintained between 93 and 152 mm Hg (mean 117 ± 21.9) and pH between 7.3 and 7.4 (mean 7.379 ± 0.037). Bilateral femoral cutdown procedures were performed and catheters placed for continuous monitoring of central venous pressure, central arterial pressure, left atrial pressure and left ventricular pressure and its first derivative (dP/dt).

Lateral thoracotomy through the fourth intercostal space was employed to expose the heart. The pericardium was incised 1 cm anterior to the phrenic nerve. The left anterior descending coronary artery was dissected for about 1 cm just distal to the origin of its first major perforating septal branch. A loop of fine Dacron® tape was used to compress the artery against a soft rubber tube so as to cause occlusion without kinking. Visible collateral vessels from the circumflex coronary arterial system entering this zone were transfixed with 2-0 silk ligature. This produced a clearly demarcated area of acute ischemia corresponding to the distribution of the left anterior descending coronary artery distal to the occlusion. In the sham-operated control group, the left anterior descending coronary artery was dissected and looped but not occluded. An exploring electrode was used to detect the center of the infarct, which was the area of most severe change in epicardial electrograms within the cyanotic ischemic area. Electrodes were then placed in the center as well as at the margin of the ischemic zone and over the normal left ventricular wall to monitor the surface electrocardiogram continuously.

Protocol

In 16 animals occlusion of the left anterior descending coronary artery was maintained for 30 (no. = 4), 60 (no. = 6) and 90 (no. = 6) minutes after which a whole thickness tissue biopsy specimen was obtained from the ischemic area for electron microscopic studies with use of a no. 10 Silverman needle. A large punch biopsy specimen (about 10 g of tissue) of the whole thickness of myocardial wall from the ischemic zone was then obtained, using a special instrument that had been precooled in liquid nitrogen, for subsequent homogenization and biochemical analysis.

In an identical group of 16 experiments, myocardial ischemia was maintained for 30 (no. = 4), 60 (no. = 6) and 90 (no. = 6) minutes, and at the end of this period a biopsy specimen from the ischemic zone was obtained for electron microscopic studies. The coronary occlusion was then released and a 1 hour period of reperfusion of the ischemic zone permitted. At the end of this period another biopsy specimen for electron microscopic study was taken and a final punch biopsy specimen for biochemical analysis was obtained as previously outlined.

In a third group of 16 experiments, myocardial ischemia for 30 (no. = 4), 60 (no. = 6) and 90 (no. = 6) minutes was followed by a 1 hour period of reperfusion. A polyethylene

Groups I, II and III refer to animals with 30 (no. = 4), 60 (no. = 6) and 90 (no. = 6) minutes of coronary occlusion, respectively. Each bar represents the mean ± standard error of the mean. Lt. = left.

catheter (internal diameter 2 mm) was passed by way of the right jugular vein and positioned in the main body of the coronary sinus for obtaining blood samples. In this group the myocardial surface electrogram, central venous pressure, arterial pressure and left ventricular dP/dt were monitored continuously. Blood samples from the coronary sinus were obtained for assessing serum creatine phosphokinase (CPK), glutamic oxaloacetic transaminase (GOT), lactic dehydrogenase (LDH) and blood lactates. Samples for biochemical studies, as well as myocardial tissue biopsy specimens for electron microscopic study, were obtained (1) before occlusion of the left anterior descending coronary artery, (2) at the end of the period of ischemia and (3) at the end of 60 minutes of reperfusion following the release of coronary occlusion. This protocol provided a correlative study of myocardial performance (left ventricular dP/dt), coronary sinus serum enzymes (CPK, SGOT, LDH), myocardial energy metabolism and myocardial ultrastructure before, during and after myocardial ischemia.

For the study of myocardial ultrastructure the tissue was immediately immersed in a solution of 5 percent glutaraldehyde in 0.1 molar phosphate buffer (pH 7.4) and allowed to fix for 1 hour. It was further fixed in buffered 1 percent osmium tetroxide for 1 hour, then dehydrated in graded ethanol series and embedded in Epon 812. Sections were made with a Sorval MT-II Porter-Blum Ultra-microtome using a diamond knife. Sections were stained for 30 minutes using 6 percent uranyl acetate in 70 percent methanol and post-stained with Reynold's lead citrate for 15

minutes. Sections were observed on a Zeiss EM9S electron microscope.

High energy phosphates were measured in tissue frozen in liquid nitrogen as follows: A sample weighing 0.5 to 0.7 g was pulverized in liquid nitrogen to a fine powder. Ten volumes of 0.6 N $HClO_4$ was added with stirring. The mixture was allowed to thaw and then centrifuged at 5° C temperature and 2,000 to 3,000 × *g* for 10 minutes. The supernatant was decanted into a precooled beaker in an ice dish and neutralized using 3 molar K_2CO_3. It was further centrifuged as before and the supernatant decanted once again. This protein-free extract was used for measuring creatine phosphate (CP), and adenosine triphosphate (ATP), diphosphate (ADP) and monophosphate (AMP) by enzymatic determination technique.[2] Serum CPK was measured by the technique of Rosalki[3] using an ICN single vial reagent kit and Gilford spectrophotometer. Serum GOT and LDH were measured by automated procedure (Technicon SMA-12/60 system) based upon the technique of Levine and Hill[4] and Morgenstern et al.[5] Lactates were measured by enzymatic determination[6] using Unicam Instruments (SP 500-2 Series) spectrophotometer and BMC test combination reagent kits.

Results

Left Ventricular Performance

The effect of 60 minutes of reperfusion on left ventricular dP/dt was studied in dogs after 30, 60 and 90 minutes of coronary occlusion (Fig. 1). Neither 30 minutes of ischemia nor subsequent reperfusion affected dP/dt values. However, these values were significantly depressed ($P < 0.05$) after 60 or 90 minutes of ischemia and did not show improvement upon reperfusion.

Coronary Sinus Serum Enzymes

Coronary occlusion for 30, 60 or 90 minutes slightly (but not significantly, $P > 0.05$) increased CPK and GOT activity levels in coronary sinus blood (Table I). LDH activity did not change significantly ($P > 0.2$).

Upon reperfusion, serum activity levels of CPK, GOT and LDH in coronary sinus blood did not rise significantly ($P > 0.05$) in the group with 30 minutes of ischemia. By contrast, a dramatic increase in the activity of these enzymes was noted upon reperfusion after 60 or 90 minutes of ischemia ($P < 0.05$).

High Energy Phosphate

Coronary occlusion for 30, 60 and 90 minutes decreased ($P < 0.05$) the creatine phosphate content of the left ventricular muscle (Fig. 2). Sixty minutes of reperfusion of myocardium made ischemic for 30 or 60 minutes resulted in partial return to normal creatine phosphate levels ($P > 0.05$); however, no change was seen upon reperfusion after 90 minutes of ischemia. There was a progressive decrease in myocardial adenosine triphosphate, total nucleotides (Table II) and the ratio of adenosine triphosphate to adenosine diphosphate (Fig. 3) after 30, 60 and 90 minutes of coronary occlusion. These variables returned to a level slightly higher than their respective control values upon reperfusion after 30 minutes of myocardial ischemia but were further reduced upon reperfusion after 60 or 90 minutes of ischemia ($P < 0.05$).

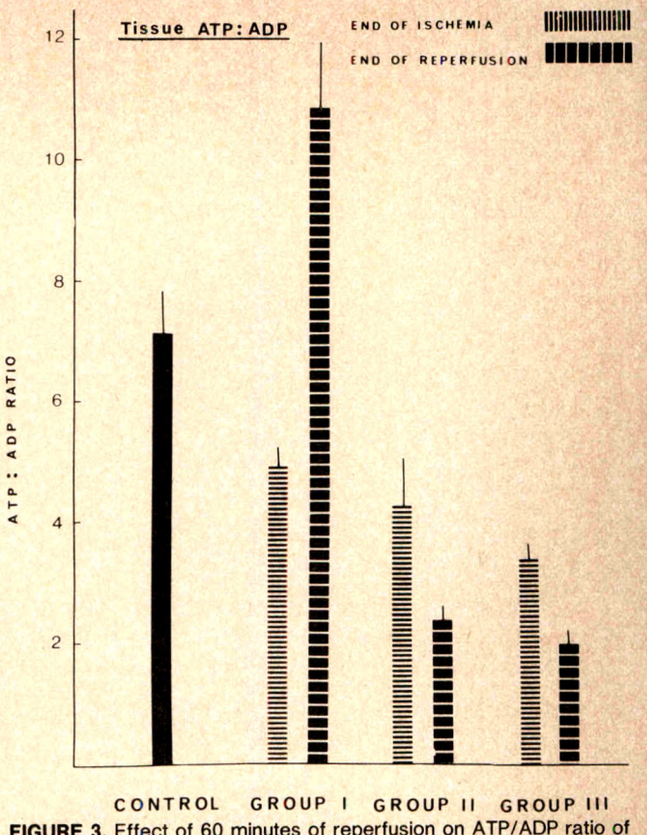

FIGURE 3. Effect of 60 minutes of reperfusion on ATP/ADP ratio of the ischemic dog myocardium. Groups I, II and III as defined in Figure 1.

Ultrastructure

Sections of the left ventricular myocardium subjected to 30 minutes of ischemia revealed that myocardial ultrastructure (Fig. 4A) was not apparently different from that of the sham-operated control heart. The muscle was in a relaxed stage and mitochondria were packed with cristae. However, reperfusion for 60 minutes of myocardium subjected to 30 minutes of ischemia resulted in contracted myofibrils (Fig. 4B).

Although 60 minutes of ischemia resulted in various degrees of damage to the mitochondrial ultrastructure and swelling of sarcoplasmic reticulum (Fig. 5A), the muscle was in a relaxed state. However, mitochondria were markedly swollen, and myofibrils were contracted upon reperfusion after 60 minutes of ischemia (Fig. 5B). Examination of sections obtained from myocardium made ischemic for 90 minutes revealed marked swelling of mitochondria and damage to cristae (Fig. 6A), whereas these muscles after reperfusion showed areas of disrupted myofibrils and extensive mitochondrial damage (Fig. 6B).

Discussion

The aim of the study was to correlate myocardial performance, ultrastructure and biochemical measurements during a period of acute ischemia and to study the effect of reperfusion in reversing any deleterious effects of ischemia on these variables. It was also intended that these correlates be studied in the same hearts as far as possible. The investigations involving myocardial performance, electrophysiology, coronary sinus biochemistry and biopsy studies for electron microscopy can all be performed in the same hearts but an open chest preparation is needed to obtain a biopsy specimen at the end of the ischemic period, which is almost at the middle of the experiment. An open chest preparation was therefore adopted in spite of the known superiority of the closed chest preparation advocated by Corday et al.[7] Every precaution was taken to keep respiratory and hemodynamic variables as stable as possible, as reflected by the stable blood PO_2 and pH values as well as the values of maximal left ventricular dP/dt reported in this series.

Almost all animals had transient cardiac arrhythmias 4 to 8 minutes after the coronary arterial occlusion but in most cases these arrhythmias disappeared spontaneously. The four animals in which the arrhythmias did not disappear spontaneously are not included in this study. Arrhythmias during the period of reperfusion were more severe and persistent. The critical period was between 8 and 20 minutes after the start of reperfusion. Animals that survived this period showed stable cardiac rhythm thereafter and completed the study. In 19 animals, ventricular fibrillation ensued, resulting in a 37 percent mortali-

ty rate due to postperfusion arrhythmias in 51 experiments. These animals are not included in our study because the variable periods of arrhythmia, associated hypotension and direct effect of direct-current countershock, if attempted, would have invalidated the serum enzyme data[8] and to some extent the ultrastructural findings. Thirty-two complete studies were carried out in the remaining animals and are reported here. The series is selective to this extent but has the advantage of being uniform in the course of events, and the values presented show a true relation to each other. Except for the study of high energy phosphates, which required a terminal biopsy specimen, all values presented belong to the same animals.

Myocardial function after reperfusion: Significant deterioration in cardiac function has been re-

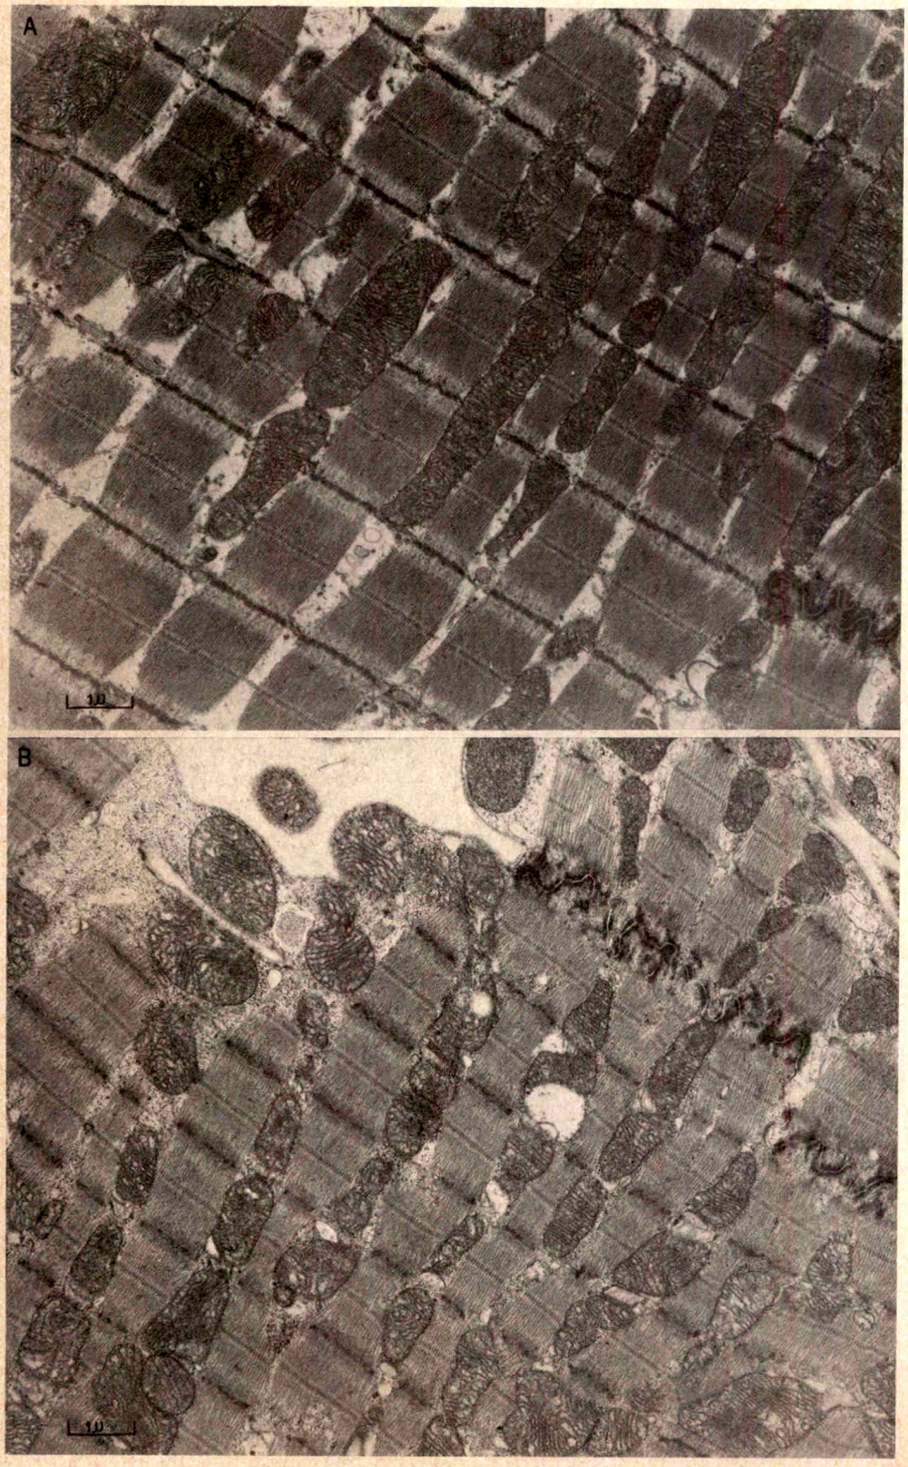

FIGURE 4. Left ventricular cardiac muscle after 30 minutes of coronary occlusion **(A)**, followed by 60 minutes of reperfusion **(B)**. (×16,500, reduced by 50 percent.)

ported by Meerbaum et al.[9] 5 to 30 minutes after occlusion of the left anterior descending coronary artery in a closed chest experimental preparation. Our data in open chest animals are in agreement with this finding but also demonstrate that the reduced maximal left ventricular dP/dt of myocardium made ischemic for 60 to 90 minutes does not increase after 60 minutes of reperfusion. The irreversibility of depressed myocardial contractility upon reperfusion after 1 to 2 hours of coronary occlusion has also been demonstrated by other investigators.[1,10–12] This inability of left ventricular performance to recover upon reperfusion after 60 to 90 minutes of ischemia may be due to a reduced energy state[13] and damaged ultrastructure of the myocardium.[14] Whatever the mechanism of the irreversible damage to ischemic

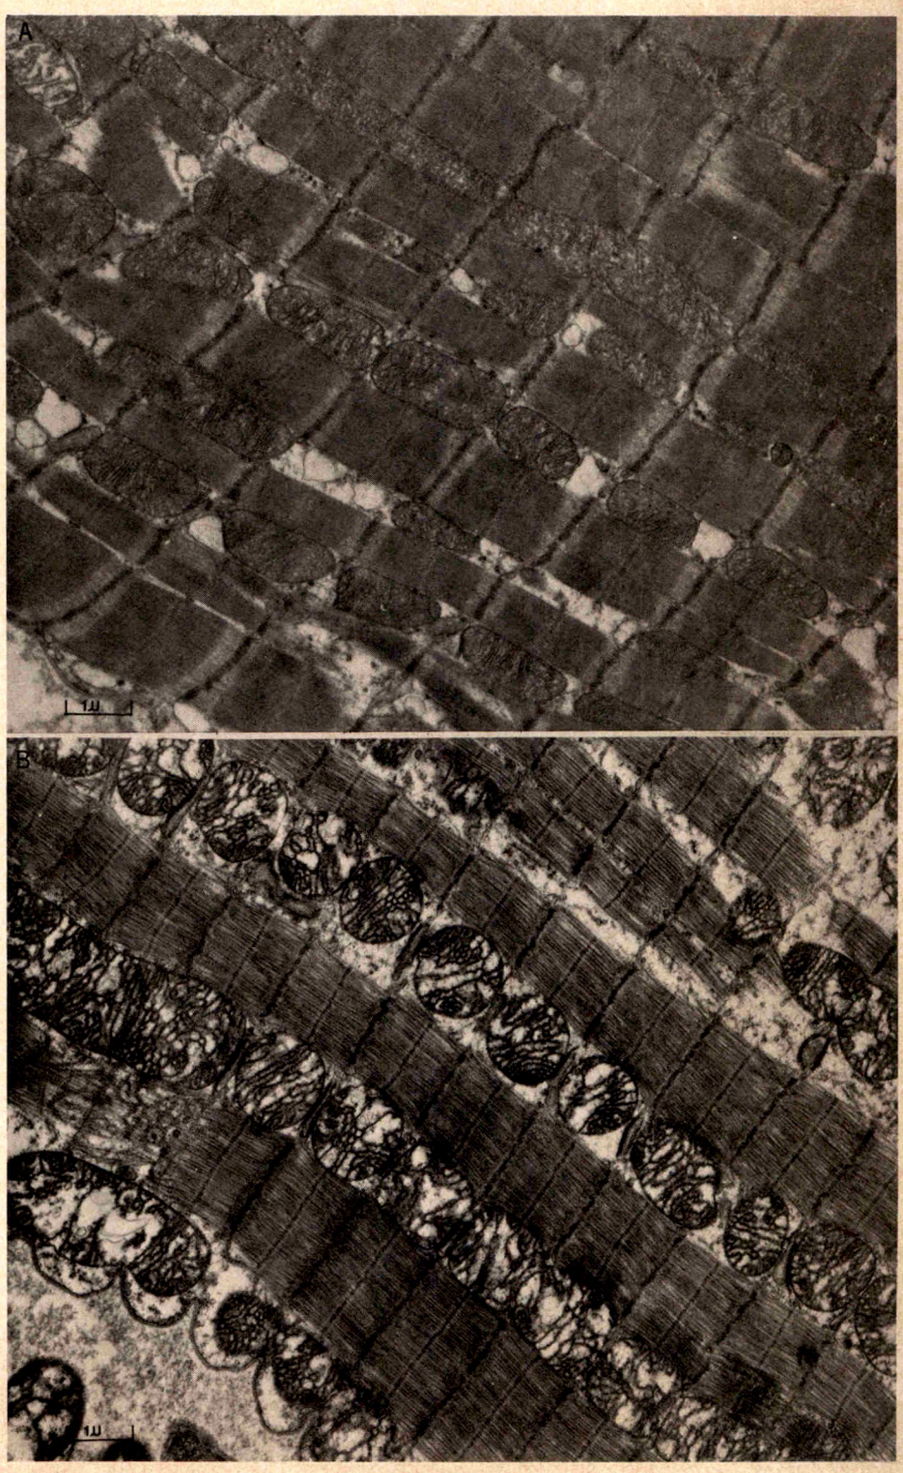

FIGURE 5. Left ventricular cardiac muscle after 60 minutes of coronary occlusion **(A)**, followed by 60 minutes of reperfusion **(B)**. (×16,500, reduced by 50 percent.)

myocardium may be, our results clearly indicate that revascularization of myocardium after 60 to 90 minutes of ischemic insult may not be attended with immediately demonstrable improvement in myocardial function. Periods of reperfusion longer than 60 minutes may be necessary for restoration of myocardial contractility.[15–17]

Infarct size after reperfusion: In experiments utilizing a closed chest experimental preparation,[7] Maroko et al.[15] have reported that infarct size as determined by S-T segment elevation and myocardial creatine phosphokinase activity can be markedly reduced by reperfusion after 3 hours of coronary occlusion. Similar results on myocardial structure have been reported by Ginks et al.,[18] who found a substantial circumferential reduction in infarct size after 7 days of reperfusion. This is understandable if it is realized that the degree of ischemic damage dimin-

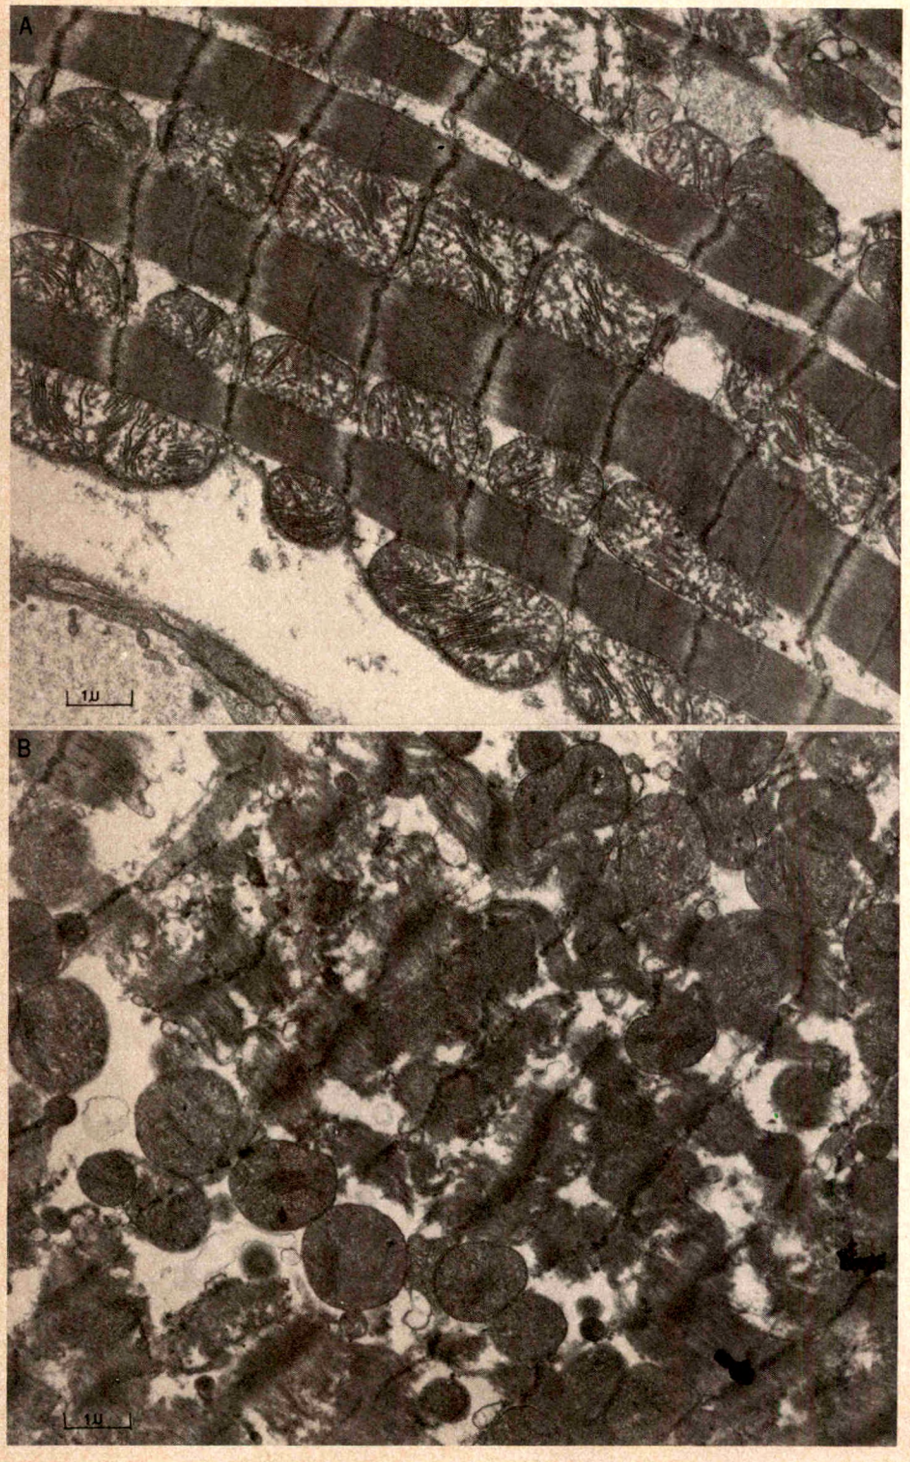

FIGURE 6. Left ventricular cardiac muscle after 90 minutes of coronary occlusion **(A)**, followed by 60 minutes of reperfusion **(B)**. (×16,500, reduced by 50 percent.)

ishes progressively from the central zone of maximal ischemia to the peripheral border zone of partial ischemia and that changes in this "twilight zone" between absolute ischemia and area of normal perfusion are reversible if reperfusion is prolonged beyond 60 minutes. This view is also substantiated by our data from myocardial surface electrograms recorded in the central zone of the infarct. Dissection of the left anterior descending coronary artery before its occlusion produced S-T segment elevation of 3.17 ± 1.25 mv (mean ± standard error of the mean). S-T segment elevation increased significantly ($P < 0.02$) within 15 minutes after coronary occlusion, and this trend was maintained throughout the period of ischemia. At the peak of the ischemic period the value was 11.33 ± 2.66 and it was still high (6.60 ± 1.49 mv) at the end of 60 minutes of reperfusion, a value not significantly low ($P > 0.1$) when compared with that at the end of the ischemic period. Slight but insignificant ($P > 0.05$) improvement in maximal left ventricular dP/dt noted in the group with 30 minutes of ischemia may partly be due to altered compliance of the ischemic zone, which changes from a relaxed noncontracting area to a contracted, edematous and stiff segment upon reperfusion. Our data on ultrastructure during reperfusion appear to support this hypothesis.

Myocardial high energy stores after reperfusion: Inability of myocardial contractility to recover after 60 minutes of reperfusion can also be examined in the light of our findings on high energy stores. Depressed high energy phosphate levels after 60 or 90 minutes of ischemia did not turn to normal upon reperfusion. Since the values for creatine phosphate, ATP and total nucleotides in this study are expressed in terms of wet tissue weight, it is possible that decreases in these variables after reperfusion of myocardium subjected to 60 and 90 minutes of ischemia may have been due to an increase in cell water.[23,26] This can not be entirely so because the ATP/ADP ratio was also depressed in reperfused myocardium after 60 or 90 minutes of ischemia. Since this ratio is a well known sensitive index of the status of oxidative phosphorylation, we suggest that the inability of the ischemic myocardium after 60 and 90 minutes of coronary occlusion to recover its high energy phosphate stores to control levels upon reperfusion may partly be due to a defect in the ability of mitochondria to generate energy.

Serum enzymes and myocardial ultrastructure after reperfusion: Serum enzyme determinations have been widely used in the diagnosis and assessment of myocardial infarction.[8,20–23] In this study an attempt was made to correlate directly the serum enzyme levels (CPK, GOT and LDH) in coronary sinus blood to the ultrastructure of the myocardium during experimentally induced ischemia and subsequent 60 minutes of reperfusion. Biopsy material and samples of coronary sinus blood were obtained simultaneously in the same hearts. The initial values indicated the effect of thoracotomy, pericardiotomy and dissection of the left anterior descending coronary artery on the enzyme activity in coronary sinus blood serum. Subsequent ischemia for 30, 60 and 90 minutes produced various degrees of change in enzyme levels, but the most dramatic changes were observed upon reperfusion, particularly in hearts subjected to 60 and 90 minutes of ischemia. All three enzymes studied (CPK, GOT and LDH) showed several-fold increases in activity levels ($P < 0.05$) in coronary sinus blood serum. This finding can be interpreted to reflect damage to the cell membranes and leakage of intracellular enzymes during reperfusion.

Actual breakdown of sarcolemmal membranes upon reperfusion of an ischemic myocardium has been demonstrated by several workers.[14,16,17,23–25] Functional impairment of cell membranes alone should be sufficient to provide such changes in enzyme levels, and this is particularly true of our group with 60 minutes of ischemia, which had the highest level of changes. There is no doubt that gross changes in ultrastructure are noticeable upon reperfusion in this group but these cells are by no means necrotic as they would be under the classic description of an infarct. It is also noteworthy that the highest degree of change in the surface electrocardiogram, noticed at the end of the ischemic period, did not correspond with the highest enzyme levels in coronary sinus blood serum, and in this respect our findings appear to differ from those of Maroko et al.[15] and Ginks et al.[18] Caution should therefore be exercised in estimating the degree of ischemia and the size of the ischemic area from the level of serum enzymes alone. The size of the ischemic area was essentially similar in all three groups (30, 60 and 90 minutes of ischemia) as were the serum enzyme levels at the end of the ischemic period. However, during the period of reperfusion there were dramatic differences that could be interpreted as indicating increased infarct size if a direct relation between enzyme levels and infarct size is accepted. It should be clear that functional damage to cell membranes is as important in this respect as the number of cells involved. The very steep rise of serum enzyme levels during reperfusion by comparison with the levels during ischemia would, in a clinical setting, suggest development of collateral blood flow.

Cell damage after reperfusion: Changes in myocardial ultrastructure due to acute ischemia and the effect of subsequent reperfusion have been amply reported,[14,16,17,23–26] and our findings are in essential agreement with previous studies. The two electron photomicrographs pertaining to each of the groups with 30, 60 or 90 minutes of ischemia belong to the same heart. Biopsy specimens for these studies were obtained from sites in the central area of the ischemic zone about 5 mm apart from each other. Comparison of Figures 4A, 5A and 6A clearly demonstrates the progression in damage to myocardial cells as the duration of ischemia is prolonged. All the recognized changes,[14,20,23,25,26] such as relaxed myofibrils, intracellular edema, swelling of the sarcoplasmic reticu-

lum and mitochondrial damage, decrease in electron density of the matrix and partial loss of cristae, can readily be seen ranging in degree from minimal (after 30 minutes of ischemia) to gross (90 minutes of ischemia). Reperfusion after a period of ischemia produces gross contraction of myofibrils and further damage to mitochondria and sarcoplasmic reticulum (Fig. 4B, 5B and 6B). Jennings et al.[14] have suggested that cell damage is reversible by reperfusion after 15 to 20 minutes of ischemia. About 50 percent of the myocardial cells in the ischemic zone are regarded as irreversibly damaged after 40 minutes of ischemia, and 60 minutes of absolute ischemia produces irreversible damage to about 100 percent of the cell mass in the ischemic area. Adverse effects of reperfusion such as breaking of sarcolemmal membranes have been shown by Kloner et al.[23] Furthermore, dramatic alteration in the electrolyte contents of the ischemic myocardium has been shown to occur upon reperfusion.[26]

It has been suggested[26] that damaged myocardial cell membrane will permit abnormal entry of calcium ion during reperfusion and will cause calcium overload.[14,17] Several authors[14,24,25] have described the appearance of dense bodies within the mitochondria at this stage, and these are regarded as calcium deposits. Our results and those of others[14,23–26] concerning contracted myofibrils in reperfused ischemic myocardium can be explained on the basis of elevated levels of intracellular calcium ion. It has also been suggested[28] that intracellular calcium overload is involved in myocardial fiber necrosis, and it is likely that this is the mechanism of the observed extensive ultrastructural damage brought about by reperfusion of the ischemic myocardium. Areas showing a high degree of partial contraction have been demonstrated during the early stages of ischemia in the peripheral zone of the ischemic myocardium.[24,25] Korb and Totovic[24] have suggested that these areas may be caused by an influx of blood plasma constituents from the surrounding nonischemic myocardium into this damaged area. If this is so, then their origin is very similar to that of the contracted myofibrils seen after reperfusion of ischemic myocardium.

Clinical implications: Our results suggest that changes brought about by 30 minutes of myocardial ischemia are reversible upon reperfusion and the same may be true for 60 minutes of ischemia. Ninety minutes of myocardial ischemia will produce serious biochemical and ultrastructural damage that may show further deterioration during the first 60 minutes of reperfusion. Longer periods of reperfusion may be beneficial, but further study is required to determine if areas of myocardial damage will improve after prolonged reperfusion. Complete salvage of grossly damaged areas that represent the very core of the myocardial infarct may not be possible unless reperfusion is established within 60 minutes, and in this respect we agree with the conclusions of Jennings et al.[14] However, this is not the heart of therapeutic and surgical strategy in the management of acute and progressing myocardial infarction. The major thrust of these measures is against the area of partial loss of perfusion that occupies the peripheral zone of the infarct. It has been shown[15–18] that substantial recovery, sometimes as much as 90 percent of the initial overall size of the infarct, can be made even after 3 hours of total coronary occlusion. This may therefore be regarded as a reasonable limit of time available for revascularization procedures. Further studies with prolonged perfusion of the ischemic myocardium are warranted in order to establish the pattern of recovery of the damaged heart cells, and these are currently in progress in our laboratory.

Contractile and Biochemical Effects of Coronary Reperfusion After Extended Periods of Coronary Occlusion

PRITPAL S. PURI, MD, FACC

Detroit, Michigan

The effects of coronary reperfusion on recovery of regional myocardial contractility and high energy phosphate levels were studied in dogs after various periods of coronary occlusion. Segmental changes in myocardial contractility were measured by means of a strain gauge-tipped, two-pronged catheter probe that measures myocardial fiber shortening. The curves of contraction are sensitive to the effects of ischemia. Coronary occlusion resulted in a rapid replacement of fiber shortening by passive fiber lengthening. If coronary occlusion was released and blood flow restored within 45 minutes, myocardial contractility returned promptly; adenosine triphosphate and creatine phosphate values were restored to normal. With coronary occlusion of 1 hour or longer, contractility failed to return in the immediate postperfusion period, but delayed return was recorded after 2 weeks of reperfusion. The extent of such recovery varied with the duration of preceding occlusion. Thus, reperfusion after 1 hour of occlusion was followed by return of fiber shortening over the entire reperfused region. With 2 hours of occlusion, recovery occurred over 75 percent of the reperfused myocardium. With 3 hours of occlusion followed by reperfusion, recovery of contractility was only partial, comprising approximately 60 percent of the reperfused region. High energy phosphate content of the reperfused myocardium showed a similar pattern of recovery. With occlusion of longer duration, reperfusion failed to restore contractility to any significant extent. These findings indicate that reperfusion after coronary occlusion of 1 to 3 hours may restore contractility over a period of 2 weeks, but the extent of such recovery diminishes with the increase in the duration of occlusion.

With the advent of surgical revascularization of ischemic myocardium in man, it has become of clinical importance to establish the maximal period of coronary occlusion that is compatible with contractile recovery upon reperfusion. The factors that determine myocardial viability are numerous and remain ill defined.[1–5] A difference is known to exist between viability of the whole heart subjected to surgical anoxic arrest and that of regionally ischemic myocardium when only a segment of coronary circulation is interrupted. In coronary occlusion, the need for maintenance of contractile activity with its attendant demands for efficient aerobic metabolism plays a major role in increasing the severity of ischemic injury and in reducing survival time.[1,2]

Studies of the reversibility of myocardial ischemic injury by other investigators[6–11] have focused primarily on the immediate postperfusion period. Hamer,[12] on the other hand, suggested that slow contractile recovery may occur with reperfusion even after prolonged periods of coronary occlusion. In this study, whose preliminary results were first reported in 1971;[13,14] both the immediate and the delayed effects of coronary reperfusion were examined. Contractile recovery was

studied by means of a strain gauge-tipped catheter probe that measures myocardial fiber shortening [15,16] by mapping segmental changes in myocardial contraction over the surface of the left ventricle.[16] The curves of cardiac contraction so obtained are extremely sensitive to the effects of ischemia and reperfusion.[16,17] Two types of contractile responses to reperfusion were recorded. If reperfusion occurred within 45 minutes of coronary occlusion, there was an immediate return of contractility. With extended periods of coronary occlusion, reperfusion failed to restore contractility in the early postperfusion period, but a delayed recovery of contractility occurred over a period of 2 weeks subsequent to reperfusion. Since high energy phosphates provide the energy for contractile functions of the myocardium,[18–20] a study of changes in adenosine triphosphate (ATP) and creatine phosphate (CP) content of the myocardium was undertaken. Changes in contractility were compared with alterations in high energy phosphate content of the reperfused myocardium.

Methods

Experiments were performed in 60 mongrel dogs weighing 15 to 22 kg and anesthetized with sodium pentobarbital (25 mg/kg) given intravenously. The trachea was intubated and artificial ventilation, using room air, was instituted by means of a Harvard respirator pump. Thoracotomy was performed in the fifth left intercostal space and the pericardium was opened anterior to the left phrenic nerve. The left anterior descending coronary artery was mobilized by dissection and a rubber-sheathed curved arterial clamp described previously[16] was used to produce intermittent occlusion of one of its major branches. Left ventricular pressure was monitored through a stiff-walled catheter directly connected to a Statham P23Db transducer system and an Electronics for Medicine recorder. Zero level for pressure measurements was set at the mid-chest position. Left ventricular end-diastolic pressure was recorded using higher sensitivity at the end-expiratory phase of the respiratory cycle.

Regional contractility: A strain gauge catheter probe that measures myocardial fiber shortening, previously described in detail,[15,16] was used to measure segmental changes in contractility. Briefly, the device consists of two strain gauge-bearing prongs mounted on a stylette. There is a linear relation between the spacing of the prongs and the strain in the gauges. The distance between the prongs is 2.5 mm, thus permitting study of the curves of contraction over small segments of myocardium. The prongs were extended to the outside of the catheter and were directly inserted into the subepicardial surface of the left ventricular wall. Only terminal points of the prongs were engaged into the myocardium. As described previously, to obtain smooth curves of fiber shortening devoid of deformities the prongs are positioned parallel to the axis of myocardial fibers.[15,16] As the prongs follow the course of fiber shortening in systole, curves of contraction are inscribed in an upward direction on a beat to beat basis. Deeper insertion or slippage of the prongs results in development of deformed curves. Maintenance of subepicardial placement of the prongs is essential for continuous recording of the curves of fiber shortening. The validity and stability of the measurements of these curves obtained with the strain gauge probe have been tested and reported in a series of publications.[15,16] In this study the probe was used primarily to demonstrate the directional changes in the curves of shortening after coronary occlusion and subsequent reperfusion. Curves of shortening as measured with the strain gauge probe are extremely sensitive to the effects of transient ischemia and reperfusion.[17]

Coronary occlusion: By occluding one of the major branches of the left anterior descending coronary artery, medium-sized areas of ischemia were produced.[17] By means of the strain gauge probe, control curves of contraction were obtained from the region supplied by the artery to be occluded. The probe was positioned in the center of this area and recordings were made continuously as the artery was occluded. In this manner, the exact time course of changes in the curves of contraction were studied. As the probe was inched away from the center toward the periphery, the ischemic zone was mapped out as the region in which contractility was lost and replaced by the inverted curve (inscribed downward) of passive fiber lengthening.[17]

In six control dogs, coronary ligation was made permanent. The ischemic area was studied for 3 hours after coronary occlusion. Thereafter, the chest was closed and the animals were restudied 2 weeks later following a protocol similar to that for the animals undergoing reperfusion except for omission of the release of coronary occlusion.

Coronary reperfusion: In 25 experiments in 15 dogs (Group I), the immediate effects of coronary reperfusion on recovery of contractility were studied after a period of coronary occlusion that ranged from 10 to 55 minutes. The occlusion clamp was released and blood flow restored at 10 minute intervals up to 30 minutes of occlusion and thereafter at 5 minute intervals. In 34 animals (Group II) the period of occlusion ranged from 1 to 5 hours. Possible return of contractility was studied for 2 to 3 hours after release of occlusion in each of the animals. If contractility failed to return, then the chest was closed in layers, pneumothorax was evacuated and the animals were allowed to recover. Possible delayed recovery of contractility was studied by reexamining the reperfused region 2 weeks later. Thoracotomy was performed and hemodynamics were measured in a manner similar to that of the initial study.

To study recovery of contractility, mapping of the reperfused region was carried out by means of the strain gauge probe. Since the distance between prongs of the probe is 2.5 mm, it is possible to differentiate segmental areas showing myocardial contraction (upwardly inscribed curve) from the adjoining noncontracting segments (inverted curve). As the probe was inched away from the center toward the periphery, the segmental changes in the curves were recorded. Schematic diagrams showing distribution of changes in curves were made using arteries and veins as the landmarks. A rough estimate of the area that registered curves of contraction was made and expressed as a percentage of the total reperfused region.

Biochemical measurements: Myocardial biopsy samples were taken by means of a bone rongeur precooled in liquid nitrogen as reported previously.[21] Biopsy samples were obtained from the center of the reperfused area and from the noninfarcted areas of the left ventricle. The myocardial samples were immediately placed (within 1 second) in precooled Freon 21®. The latter produces rapid and thorough freezing of the samples. The specimens were then transferred to and stored in liquid nitrogen. After the tissue was weighed, the frozen samples were pulverized and homogenized with 1 ml of perchloric acid per 100 mg tissue. Adenosine triphosphate (ATP) content was determined according to Adam[22] as described previously.[23] Creatine

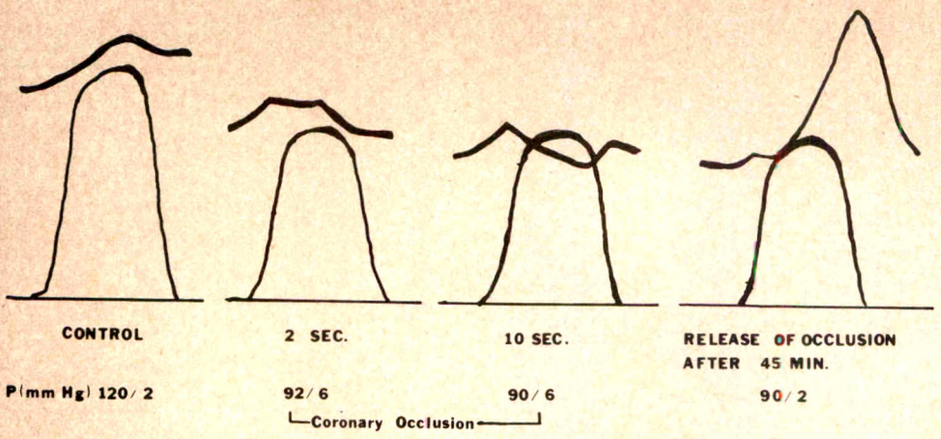

FIGURE 1. Effect of coronary reperfusion on the curves of myocardial contraction. In the control state the curve of myocardial contraction is inscribed in an upward direction. Two seconds after occlusion, the late systolic portion of the curve begins to show inversion. At 10 seconds the curve is inverted, indicating loss of fiber shortening and its replacement by passive fiber lengthening. After release of coronary occlusion at 45 minutes, the original upward inscription of the curve associated with an initial overshoot is restored, indicating recovery of contractility. P = left ventricular pressure.

phosphate (CP) was measured by utilizing the following reaction[23]:

$$CP + ADP \xrightarrow{CPK} C + ATP$$

where ADP = adenosine diphosphate and C = carbon. The adenosine triphosphate formed was subsequently determined as mentioned. The recovery of creatine phosphate was 95 percent ± 4 percent (standard error of the mean). Biopsy samples were taken at the time of the study of recovery of contractility. The results were expressed in micromoles per gram of tissue. In animals with 45 minutes of coronary occlusion, samples were taken 5 minutes after reperfusion. In animals with 1 to 3 hours of occlusion, samples were taken during the study for delayed recovery of contractility 2 weeks after reperfusion. Biopsy samples were also obtained from 5 sham-operated animals in which the same protocol was followed except for the omission of coronary ligation.

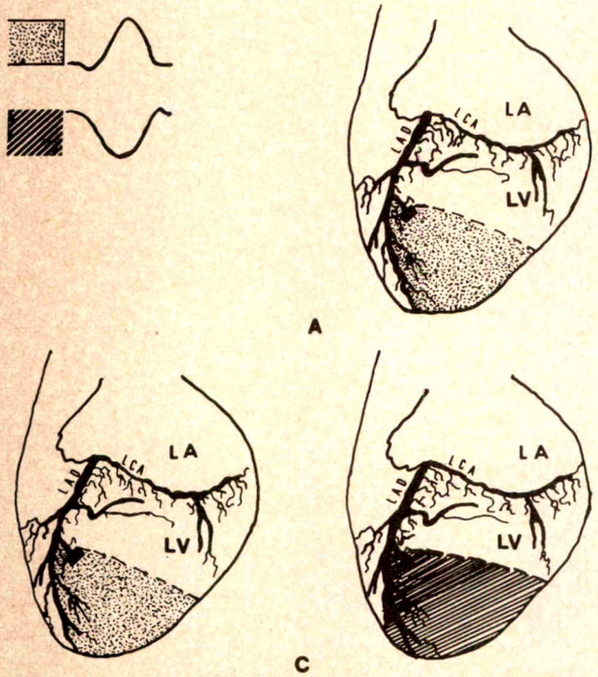

FIGURE 2. Recovery of contractility in the immediate postperfusion period. Schematic representation of the mapping of the reperfused region by means of the strain gauge catheter probe shows that reperfusion after 30 minutes **(A)** and 45 minutes **(B)** of coronary occlusion results in prompt return of contractility over the entire region (upward curve). However, reperfusion after 50 minutes of occlusion **(C)** fails to restore contractility (inverted curve). LA = left atrium; LAD = left anterior descending coronary artery; LV = left ventricle.

Histology: Random myocardial specimens were obtained for histologic examination from the center and periphery of the reperfused region as well as from the nonischemic area. The specimens were fixed in a solution of 10 percent formalin and stained with hematoxylin-eosin and Giemsa stains. The sections were examined independently of the knowledge of the experimental protocol. The presence of infarction was identified and its extent estimated from the relative amounts of normal and infarcted tissues in a given section, but histologic examination was not used to quantitate the total extent and distribution of infarcted myocardium in the reperfused region.

Results

Early Postperfusion Period

The systolic curve of myocardial contraction (fiber shortening) is inscribed upward. In diastole, corresponding to myocardial relaxation and fiber lengthening, the curve is inscribed downward (Fig. 1). Coronary occlusion resulted in an immediate decline in the amplitude of the curve of contraction. At 2 to 5 seconds, the late systolic portion of the curve was inverted and at 10 to 30 seconds the entire curve was inscribed downward, indicating loss of systolic fiber shortening and its replacement by dyskinetic passive fiber lengthening (Fig. 1). Release of coronary occlusion and restoration of blood flow resulted in a prompt return of the original upward inscription of the curve, indicating recovery of contractility. There was an initial overshoot in the amplitude of the curve of contraction coinciding with the phase of hyperemia (Fig. 1). This sequence of events in which the curve of contraction becomes inverted with coronary occlusion and returns to the upright inscription with release of occlusion could be repeated several times in the same animal. Reproducibility of these changes was established in 15 experiments, thereby demonstrating that the curve of contraction is extremely sensitive to the effects of ischemia and reperfusion.

Coronary occlusion was released at 10, 20 and 30

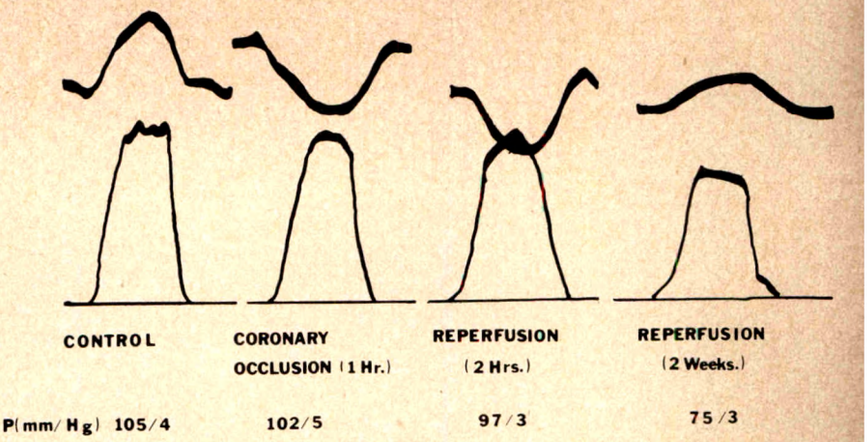

FIGURE 3. Effect of reperfusion after 1 hour of coronary occlusion. The inverted curve of passive fiber lengthening that followed coronary occlusion remained unchanged for several hours after release of occlusion. Two weeks later, however, the upward inscription of the curve was restored, indicating recovery of fiber shortening.

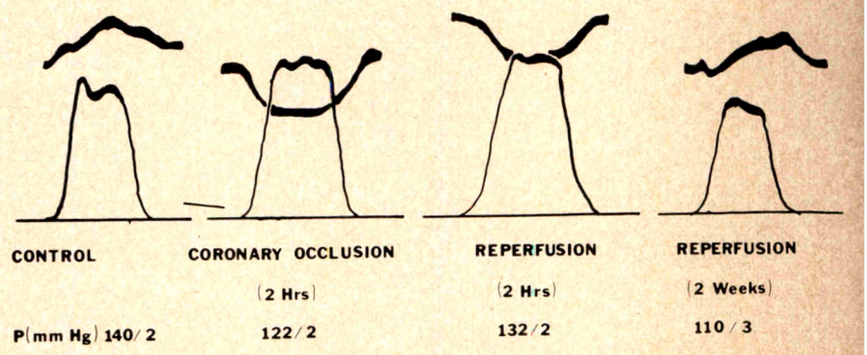

FIGURE 4. Effect of reperfusion after 2 hours of coronary occlusion. Release of occlusion failed to restore contractility in the immediate postperfusion period. Two weeks later, however, the upward curve of fiber shortening was registered, indicating return of contractility.

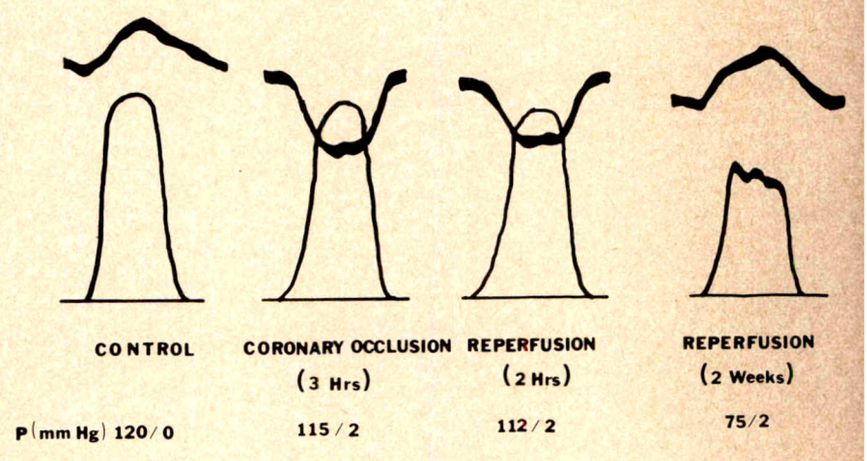

FIGURE 5. The inverted curve of fiber lengthening that followed coronary occlusion remained inverted for 2 to 3 hours after release of occlusion. After 2 weeks of reperfusion, however, the upward curve of myocardial contraction was again recorded.

minutes in three experiments each. The curve of contraction returned promptly in each instance. Subsequently, effects of reperfusion at 35, 40, 45, 50 and 55 minutes were studied in three experiments each. In all experiments with reperfusion occurring at 35, 40 and 45 minutes, recovery of contractility promptly followed the release of occlusion (Fig. 1 and 2). However, with reperfusion at 50 and 55 minutes, curves of contraction failed to return over a period of 2 hours during which the observations were made (Fig. 2).

Delayed Recovery of Contractility

As the duration of occlusion was increased from 1 to 5 hours, reperfusion failed to restore contractility over a period of 2 to 3 hours during which the observations were made (Fig. 3 to 5). When these animals were reexamined after 2 weeks of reperfusion, curves of contraction were recorded over the reperfused region; the extent of recovery of contractility varied with the duration of the preceding occlusion. In six dogs in which coronary occlusion was released after 1 hour, contractility returned over the entire reperfused region. A representative tracing (Fig. 3) and the schematic mapping of the reperfused region (Fig. 6) are shown. In eight animals with 2 hours of coronary occlusion followed by reperfusion, curves of fiber shortening were recorded over an average of 75 percent of the reperfused myocardium (Fig. 4 to 6). The

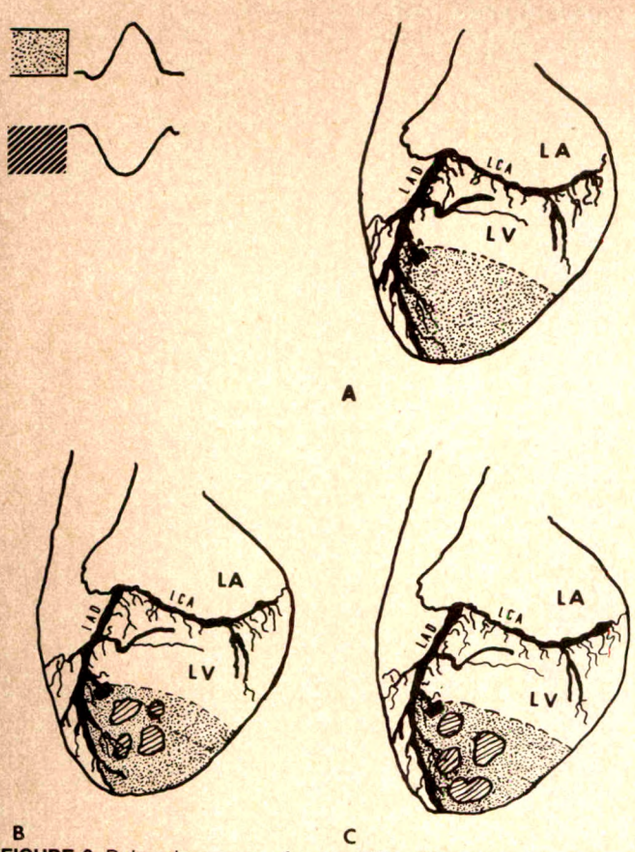

FIGURE 6. Delayed recovery of contractility at 2 weeks after reperfusion. Schematic representation of the mapping of the reperfused region is shown. **A,** in an experiment with 1 hour of coronary occlusion, curves of fiber shortening (upward curve) were recorded over the entire reperfused region. **B,** in an experiment with 2 hours of occlusion, the distribution of the curves of fiber shortening versus the curves of fiber lengthening (downward curve) indicated that contractility returned over approximately 75 percent of the reperfused region. **C,** in an experiment with 3 hours of occlusion, curves of fiber shortening were recorded over an area constituting approximately 60 percent of the reperfused region.

noncontracting myocardial segments were mostly clustered in the center of the reperfused region. In six of the eight animals with 3 hours of occlusion, 2 weeks of reperfusion resulted in only partial recovery of contractility. As seen in Figure 6, curves of contraction were recorded over an average of 60 percent of the reperfused region. Noncontracting segments were chiefly concentrated in the center and extended outward. In two animals, contractility failed to return. Of six animals with 4 hours of occlusion, only two showed some recovery of contractility over an estimated area of 15 to 20 percent of the reperfused region; in the remaining four animals, reperfusion failed to restore contractility. Of six animals with 5 hours of coronary occlusion, curves of contraction failed to return over most of the reperfused region.

In the group of six control animals in which coronary occlusion was not released, the inverted curve of dyskinesia was recorded over the ischemic area for 1 to 3 hours after ligation. Two weeks later when these animals were restudied, the ischemic myocardium showed either dyskinesia (inverted curve) or akinesia (flat curve). In none of these animals were curves of fiber shortening indicative of the recovery of contractility recorded over the ischemic region.

Biochemistry

There was a decrease in the myocardial adenosine triphosphate and creatine phosphate content of the nonischemic region of the left ventricle as compared with control values obtained from the sham-operated animals without coronary occlusion (Table I). This was particularly marked in animals with 3 hours of occlusion in which adenosine triphosphate decreased by 23 percent and creatine phosphate by 30 percent as compared with the control values. In view of these changes in the nonischemic zone, the reperfused region was compared with the control values obtained from the sham-operated animals. Reperfusion after 45 minutes of coronary occlusion resulted in complete restoration of both the adenosine triphosphate and creatine phosphate values. In animals with 1 to 3 hours of coronary occlusion, study after 2 weeks of reperfusion showed that changes in high energy phosphates varied with the duration of preceding coronary occlusion. Thus in animals with 1 hour of occlusion, myocardial adenosine triphosphate content of the reperfused region was 87 percent and creatine phosphate content was 95 percent of the control values. In animals with 2 hours of occlusion, adenosine triphosphate values were 75 percent and creatine phosphate values 83 percent of control levels. Reperfusion after 3 hours of occlusion resulted in adenosine triphosphate content that was 56 percent and creatine phosphate content that was 60 percent of control values.

Histology

Histologic examinations of the nonischemic area and the periphery of the reperfused region revealed no significant abnormalities. The center of the reperfused region in four animals with 1 hour of coronary occlusion showed no evidence of an infarct. In the remaining two animals, the infarcted tissue constituted 5 to 10 percent of the myocardial tissue in the section. In animals with 2 hours of occlusion, there were scattered focal areas of infarction that constituted 15 to 25 percent of the tissue in the section. In animals with 3 hours of occlusion, scattered areas of focal infarction constituted 30 to 40 percent of the myocardium in the section. In animals with occlusion of 4 or 5 hours, extensive infarction was seen in the section. These observations based on single histologic section obtained from the center of the reperfused region do not provide quantitative delineation of the distribution of contracting versus noncontracting segments.

Discussion

Development of methods to salvage ischemic myocardium is central to the evolution of a successful treatment program for acute myocardial infarction. It has recently been emphasized that there is a close

correlation between the number of myocardial contractile units lost and the mortality in acute myocardial infarction.[24–26] A number of physiologic and pharmacologic interventions have been shown to modify myocardial infarct size.[17,27] In our previous study,[17] we demonstrated that of cardiac stimulant drugs, isoproterenol is most likely to extend infarct size. An increase in afterload with methoxamine also results in an extension of infarct. Maroko et al.[27] have reported that interventions with oxygen-sparing agents such as propranolol may decrease the extent of ischemic injury. Hyaluronidase and corticosteroids[28] have also been credited with a similar effect. This ability to alter infarct size is essentially dependent upon the presence of ischemic but viable myocardial cells.

The factors that determine myocardial viability have not been precisely defined. The magnitude of ischemic injury is dependent on the state of cells prior to injury, the level of endogenous glycogen stores, cellular pH and ionic milieu, substrate availability and the state of collateral circulation.[1–3,29] The point of irreversible injury is controlled by the combined effects of metabolic breakdown of energy production, autolysis, protein denaturation, efflux from within the cell of enzymes, coenzymes and electrolytes.[3,10,29,30] Recovery is possible as long as the nuclei and cell membranes are intact.[1]

Contractile changes in early reperfusion period: In this study, the effects of ischemia and reperfusion were studied by means of a strain gauge-tipped catheter probe that measures myocardial fiber shortening.[15,17] The probe registers curves of myocardial contraction over localized segments of the ventricular wall,[16,17,31] which makes it possible to map the ischemic region before and after coronary reperfusion. Curves of contractility are extremely sensitive to the effects of ischemia.[16,17] Contractility decreases immediately and failure of contraction is complete within 15 to 30 seconds after coronary occlusion. Inability to contract is associated with passive distension (fiber lengthening) as ischemic myocardium yields to intraventricular pressure. This is reflected in the inversion or downward inscription of the curve in systole (dyskinesia) (Fig. 1). If coronary occlusion is released at any time within 45 minutes, the original upward inscription of the curve of myocardial contraction is promptly restored, indicating return of contractility (Fig. 2). This sequence of events is reproducible in the same animal as well as in a group of animals. These findings indicate that 45 minutes is the time limit of coronary occlusion compatible with an immediate return of contractility upon reperfusion. Results of similar previous studies have been variable. Thus, Tennant and Wiggers[6] suggested that recovery of contractility over 23 minutes of occlusion was only partial or absent. Blumgart et al.[7] using light microscopy observed that with occlusion of 25 to 45 minutes, gross detectible lesions were present that were roughly proportional to the duration of occlusion. Studies of Yabuki et al.[8] indicated that with release of occlusion in less than 30 minutes changes were only minimal; with occlusion of 45 minutes, however, necrosis was present. Krug et al.[9] reported that revival time for contractility after coronary occlusion was 30 to 45 minutes. Morphologic studies by Jennings et al.[10] have shown that after 45 minutes of ischemia, more than 60 percent of affected cells remained viable.

Delayed recovery of contractility: The delayed recovery of contractility observed after 2 weeks of reperfusion is a significant observation. The extent of recovery varied with the duration of preceding occlusion. Thus, after 1 hour of occlusion, contractile recovery occurred over most of the reperfused region (Fig. 3 and 6). As the duration of occlusion was increased to 2 hours, only 75 percent of the reperfused myocardium recovered (Fig. 4 and 6). With 3 hours of coronary occlusion, the extent of contractile recovery was further reduced to about 60 percent of the reperfused region (Fig. 5 and 6). With longer periods of occlusion of 4 to 5 hours, there were only a few focal areas registering curves of contraction. These findings, originally observed in 1971,[13] constituted the

first demonstration of regional functional recovery and reversal of paradoxical motion of ischemic myocardium upon reperfusion after extended periods of coronary occlusion. Study of the high energy phosphate metabolism in the reperfused myocardium, the preliminary report of which was published earlier,[14,32] indicates that corresponding to the contractile recovery, there occurred resynthesis of myocardial high energy phosphates. Coronary occlusion results in depletion of myocardial adenosine triphosphate stores.[18–20] Reperfusion after 1 hour of coronary occlusion resulted in almost complete restoration of adenosine triphosphate and creatine phosphate values. With longer periods of occlusion there was a progressive decrease in the recovery of these values after reperfusion (Table I). Since adenosine triphosphate provides the energy for contractile functions of the myocardium,[18–20] the parallel seen between resynthesis of adenosine triphosphate and recovery of contractility is of significance.

In a recent study, Ginks et al.,[33] using epicardial electrograms and myocardial enzymes, showed that reperfusion after 3 hours of coronary occlusion resulted in a decrease in infarct size at 1 week. On the other hand, studies in the immediate postperfusion period after coronary occlusion of 3 to 5 hours by Lang et al.[34] and by Bresnahan et al.[35] have suggested hemodynamic and metabolic deterioration and hemorrhagic extension of infarct. It seems to us, however, that contractile recovery can occur even after prolonged periods of ischemia, but the process is a slow one extended over a period of weeks. These observations confirm the contention of Hamer,[12] who suggested that slow contractile recovery is possible with reperfusion even after prolonged periods of occlusion. One of the factors contributing to myocardial salvage may be the fact that not all myocardial fibers are unalterably necrosed at the same time. In a given population of myocardial fibers there seem to be various degrees of biologic resistance to ischemic injury. Thus, contracting and noncontracting fibers were found to lie adjacent to each other. Whether this difference is dependent merely on the presence or absence of collateral circulation or is related to an intrinsic variation in metabolic characteristics of fibers is not known. In our previous study on coronary occlusion,[17] we showed that interposed between the central zone of complete ischemia and the nonischemic myocardium is an intermediate zone of partial ischemia in which contractility is diminished but not lost. Lushnikov[36] and Cox et al.[37] described a similar zone by means of histochemical studies. Diminished contractility of the myocardium in the intermediate zone with attendant decrease in its energy requirements will have the effect of prolonging its viability in the face of diminished oxygen delivery.[38]

Clinical implications: It may be concluded that at least partial salvage of ischemic myocardium is possible by coronary reperfusion even after extended periods of coronary occlusion. However, such recovery may not occur in the immediate postperfusion period but may require a period of 1 to 2 weeks. Although one must be cautious in extrapolating results of canine experiments to patients, these findings have obvious clinical application to the surgical revascularization of ischemic myocardium in man.

Maximal Revascularization (Reperfusion) in Intact Conscious Dogs After 2 to 5 Hours of Coronary Occlusion

VIRENDRA S. MATHUR, MD
GENE A. GUINN, MD, FACC
WALTER H. BURRIS, III, RN

Houston, Texas

Acute infarction was produced in intact conscious dogs by inflating a previously implanted balloon cuff around the left anterior descending coronary artery. The artery was occluded in 26 control dogs and reperfused by deflating the balloon cuff after 2 hours of occlusion in 19 dogs (group II) and after 5 hours in 11 dogs (group III). Serial studies were performed and repeated after 48 hours and 7 days. All three groups revealed hemodynamic and metabolic deterioration with coronary occlusion and infarct production. Immediately after reperfusion, arrhythmias developed in groups II and III and persistent ventricular tachycardia was present 2 to 3 hours after reperfusion in 74 percent of animals in group II and 82 percent of those in group III compared with 6 percent and 13 percent incidence rates at corresponding times in control dogs. Q waves developed in 83 percent of animals in group II and 100 percent of those in group III but in only 12 and 27 percent of control animals at corresponding times. Hemodynamic deterioration was accelerated in the postreperfusion period in both groups II and III. Angiographic assessment revealed improvement in 42 percent of dogs in group II, but in none of those in group III after reperfusion. Myocardial oxygen extraction diminished to subnormal levels after reperfusion, indicating either reactive hyperemia or shunting effect. Mortality was not significantly influenced by reperfusion. Infarct size was more than 15 percent of ventricular mass in 92 percent of control dogs and in 100 percent of dogs in group III, but in only 50 percent of those in group II.

The data indicate that reperfusion in conscious dogs representing early, noninvasive maximal revascularization under ideal circumstances fails to prevent deterioration or death; instead it hastens the development of arrhythmias and myocardial injury. Reperfusion, although deleterious in the first few hours, can reduce infarct size if performed after 2 hours, but not after 5 hours, of occlusion.

Acute myocardial infarction continues to be a major cause of death in spite of strides in treatment made in the past decade. In many cases the mortality and subsequent complications depend on the total mass of myocardium involved in infarction.[1–4] Studies in experimental myocardial infarction have suggested that it is possible to alter the ultimate size of the infarcted tissue by interventions applied early in the course of evolution of infarction[5,6]; the jeopardized zones of myocardium may respond to favorable interventions, whereas blighted and necrotic zones are unlikely to respond.[7] Because the major determinant of ischemic injury is an imbalance between supply and demand of oxygen and other substrates, it is logical to expect beneficial results from an increase of blood flow to the affected area. This restoration of blood flow may allow the border zones to escape infarction and recover partly or completely. Suggestions that this may be the case in man have come from results of several studies employing

streptokinase in the early stages of acute myocardial infarction,[8–11] a form of medical revascularization. A few centers have even employed surgical revascularization using aortocoronary bypass grafts in the early stages of infarction and have interpreted the results as satisfactory.[12–14]

This study was initiated to test the hypothesis that early revascularization of the ischemic myocardium in evolving infarction can alter the course favorably and possibly reduce infarct size. To achieve maximal revascularization, restoration of normal blood flow was attempted by reperfusing the occluded coronary artery. A model of intact conscious dogs was employed to preserve all the reflexes, study the influence of infarction alone rather than that of associated surgery and anesthesia and allow collection of data pertaining to the whole animal rather than to a portion of its myocardium. Since the initiation of this study, Maroko et al.[15] and Ginks et al.[16] have presented data in anesthetized dogs indicating that coronary arterial reperfusion can improve local myocardial function and reduce infarct size.

However, Lang et al.[17] have reported quite opposite effects. They found serious abnormalities in hemodynamic status, metabolic function and morphologic features of the heart when they reperfused seven dogs after 3 hours of coronary occlusion. Also, Banka et al.[18] found that reperfusion after 1 hour of occlusion resulted in further accentuation of contractile abnormalities in the ischemic zone of the myocardium in each animal and in the border zone in four of six animals. They further reported that after 2 and 3 hours of coronary occlusion, reperfusion was uniformly followed by further decreases in function of both the ischemic and border zones.

Studies in 56 intact conscious dogs involving electrocardiographic patterns, left ventricular function, myocardial metabolic derangements, infarct size and mortality are presented in this communication.

Methods and Materials

Procedures: Large mongrel dogs weighing 25 to 30 kg were operated on under general anesthesia, and through a thoracotomy a balloon cuff device (Brunswick Manufacturing Company, Quincy, Massachusetts) was implanted around the left anterior descending coronary artery. The dogs were then allowed to recover for 7 to 10 days. With use of local anesthesia and light morphine sedation (10 to 15 mg subcutaneously) with animals in the awake state, the femoral and carotid arteries and jugular vein were exposed. A transducer-tipped catheter (Millar Instruments, Houston, Texas) to obtain high fidelity recordings of pressure and derivatives of pressure was positioned in the left ventricle, a thermistor-tipped catheter was placed in the pulmonary artery and other catheters were positioned in the aorta, coronary sinus and right atrium under fluoroscopic control for constant pressure monitoring, sampling, thermodilution cardiac output determinations and angiography. The electrocardiogram was monitored throughout with lead V_4. Control measurements were then made of pressures from the chambers cited, first derivative of left ventricular pressure (dP/dt), heart rate, cardiac output, calculated stroke volume and work, oxygen and lactate content of arterial and coronary sinus blood, calculated oxygen and lactate transmyocardial extraction data and left ventricular angiogram with calculated ejection fraction.

TABLE I

Case Material

First series (survived for 2 hours)	35
Control (occlusion maintained)	16 (group IA)
Reperfusion after 2 hours	19 (group II)
Second series (survived for 5 hours)	21
Control (occlusion maintained)	10 (group IB)
Reperfusion after 5 hours	11 (group III)

After the recording of control measurements, myocardial infarction was produced in the intact conscious animal by slight modification of the technique of Hood et al.[19] The Silastic® tubing connected to the balloon cuff device around the left anterior descending coronary artery was exteriorized and the balloon progressively inflated in stepwise fashion over the next 10 to 15 minutes with use of an insulin syringe and manual control until signs of acute ischemia appeared. These signs included peaked T waves, tachycardia and increased left ventricular end-diastolic pressure (Fig. 1 to 3). The balloon was further inflated to ensure complete occlusion of the left anterior descending coronary artery. Arrhythmias appearing in the first 30 minutes after occlusion were treated with lidocaine (a bolus injection of 40 mg followed by infusion of 1 to 4 μg/min). All measurements were then serially repeated. In addition, coronary angiography was carried out before and after reperfusion to visualize an occluded left anterior descending coronary artery before reperfusion and a patent artery after reperfusion. Heparinized saline solution was infused to maintain patency of all the catheters throughout the procedure, the total amount of heparin used being 15 mg or approximately 1,500 units per hour.

Studies: In the first series (Table I), 35 animals survived for 2 hours, when they were randomly divided into two groups. The balloon cuff was kept inflated and the left anterior descending coronary artery remained occluded in 16 control dogs. In 19 dogs the balloon was deflated after 2 hours of occlusion to allow the artery to reopen, thereby achieving reperfusion and maximal revascularization of the area. The patency of the artery after reperfusion was angiographically confirmed in each animal. In addition, electrocardiographic and metabolic changes (presented under Results) permitted confirmation of patency of the artery after deflation of the balloon cuff.

In the second series, 21 dogs survived for 5 hours and were divided into two groups. Ten in which the artery remained occluded served as control animals and the other 11 underwent reperfusion. For purposes of analysis, the data for both control groups have been combined. Thus, of 56 dogs, 26 served as control animals (group I), 19 underwent reperfusion after 2 hours (group II) and 11 underwent reperfusion after 5 hours (group III).

The short-term studies were carried out for 5 hours after infarction (2 hours before and 3 hours after reperfusion) in the first series of dogs and for 7 hours (5 hours before and 2 hours after reperfusion) in the second series, and the dogs were then allowed to recover. Daily electrocardiograms including 1 minute rhythm strips were recorded. All surviving dogs underwent repeat cardiac catheterization studies, 7 days after infarction in the first series and 48 hours after infarction in the second series. The dogs were then killed, and the heart removed. The left ventricle was sectioned to obtain 1 cm thick slices and photographed, and the area of the infarcted myocardium as well as normal muscle was de-

termined. In addition, the infarcted myocardium was removed from each slice and the infarcted and noninfarcted portions were weighed.

Statistical methods: Student's t test was employed to detect significant differences between the control and study animals, and the chi square test was employed to compare the frequency of events in these groups.

Results

Heart rate: After increasing sharply during infarction, the heart rate stabilized and was similar in all groups until the time of reperfusion (Fig. 4). In group II, soon after reperfusion the rate increased and became more rapid 2 hours later because of the development of persistent ventricular tachycardia. Dogs in group III, who underwent reperfusion after 5 hours of infarction, also exhibited a sharp increase in heart rate after reperfusion. At the time of the second study the heart rate in both study groups was similar to that of the control group.

Ventricular arrhythmia: Premature ventricular

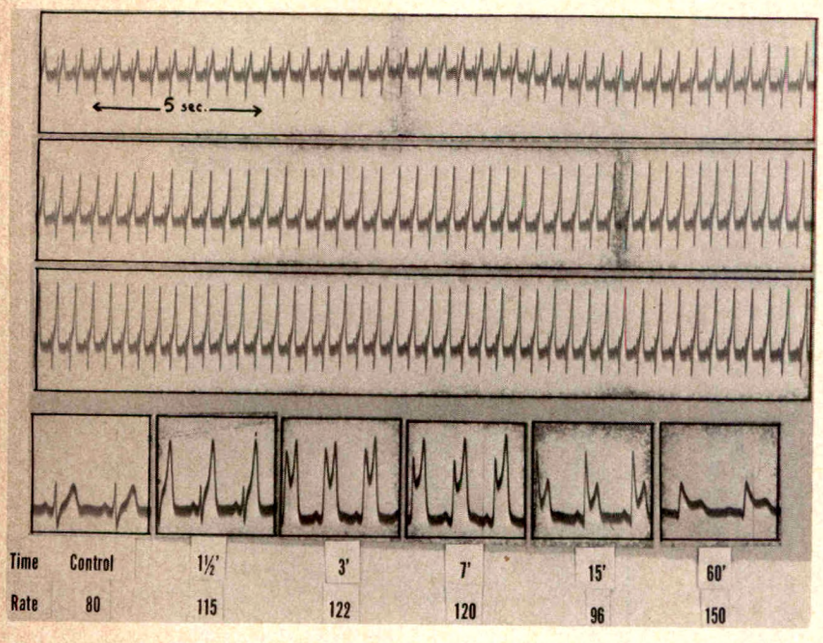

FIGURE 1. Changes in electrocardiogram with acute infarction. The **top three panels** are continuous strips of lead V_4 (paper speed 10 mm/sec) showing progressive peaking of the T wave after occlusion of the left anterior descending coronary artery. Within 1 minute the height of the T wave has doubled. The **bottom panel** shows the change in the heart rate (beats/min) and configuration of S-T segment and T waves at 1 1/2, 3, 7 and 15 minutes (paper speed 25 mm/sec) and 1 hour (paper speed 50 mm/sec) after infarct production.

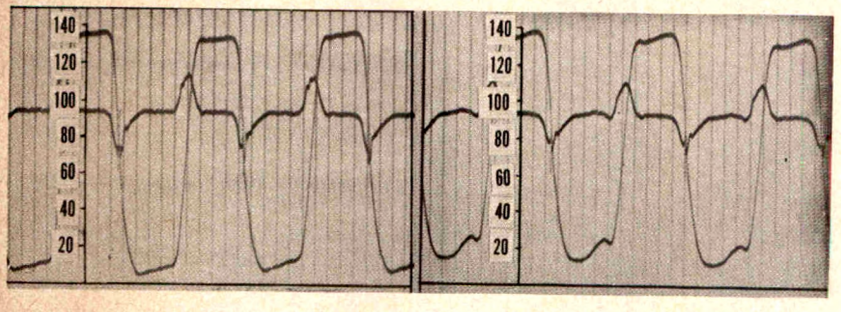

FIGURE 2. Changes in left ventricular pressure **(lower tracing)** and dP/dt **(upper tracing)** with acute infarction. The left ventricular pressure before infarction **(panel A)** is normal. The end-diastolic pressure 15 minutes after infarction **(panel B)** is 23 mm Hg, an increase of 13 mm Hg from the preinfarction value of 10 mm Hg.

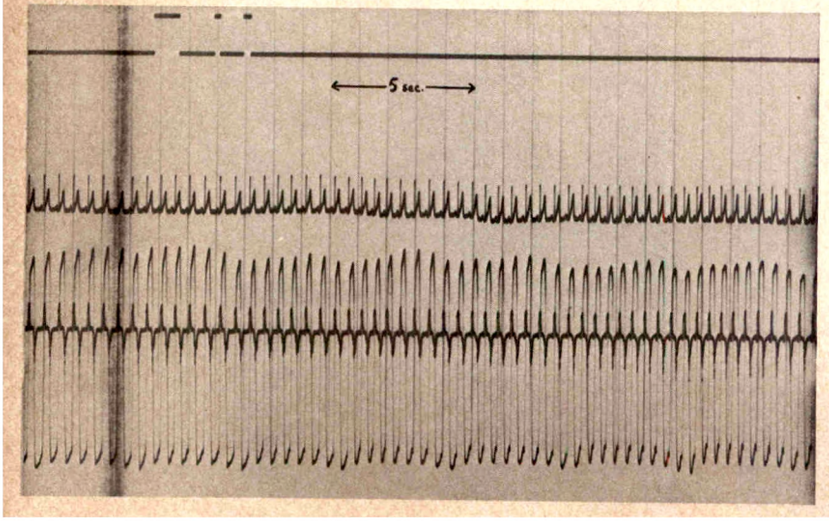

FIGURE 3. Changes in electrocardiogram and left ventricular pressure with acute infarction. Continuous strip (paper speed 10 mm/sec) showing electrocardiographic lead V_4 at top, high fidelity left ventricular pressure recorded by manometer-tipped catheter below it and its first derivative (dP/dt) in the middle of left ventricular pressure. At the time of the first mark, the left anterior descending coronary artery is occluded, resulting in immediate peaking of T wave and an increase in heart rate and left ventricular end-diastolic pressure.

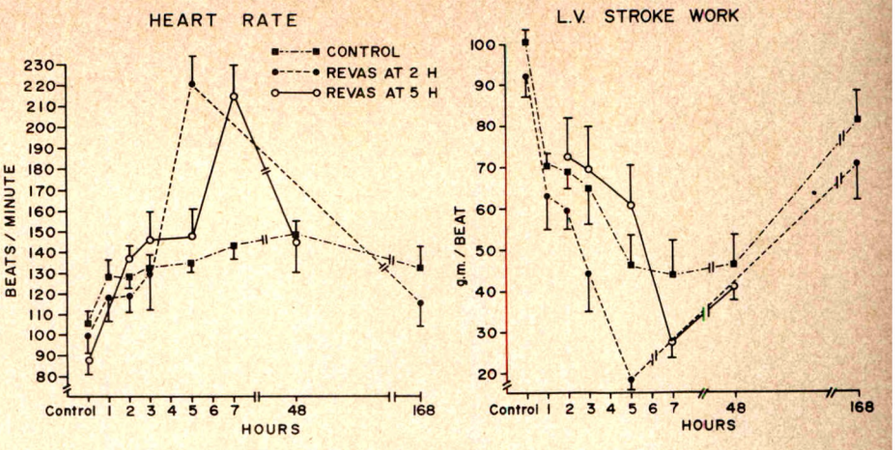

FIGURE 4. Changes in heart rate and left ventricular stroke work. The **left panel** depicts mean values of heart rate with standard error of the mean. The heart rate in group II, undergoing reperfusion at 2 hours (H), was significantly higher than control at the 5th hour (3 hours after reperfusion) with P value <0.01. The heart rate of group III, reperfused at the 5th hour, was significantly higher than control ($P<0.05$) at the 7th hour. The **right panel** shows a significant reduction of stroke work after reperfusion in both groups II and III ($P<0.05$). L.V. = left ventricular; REVAS = revascularization.

contractions and short runs of ventricular tachycardia were frequent in the first 30 minutes after infarction and were treated with lidocaine. At 2 hours after infarction, the rhythm was generally stable. In group II, within 20 to 120 seconds of reperfusion, frequent, repetitive and multiformed premature ventricular contractions developed in *each* animal and progressed to prolonged periods of ventricular tachycardia alternating with sinus tachycardia. The duration of episodes of ventricular tachycardia kept increasing until persistent ventricular tachycardia with multiformed irregular beats became the rule. The difference between the frequency of this arrhythmia in groups I and II at the 3rd and 5th hours after infarction was highly significant ($P<0.01$). After the initial experience of refractoriness of these arrhythmias to lidocaine, no attempt was made to treat them.

The pattern of arrhythmia in animals in group III undergoing reperfusion after 5 hours of infarction was similar to those undergoing reperfusion after 2 hours of infarction, and persistent ventricular tachycardia at the 7th hour of infarction was significantly more frequent than in the control group ($P<0.05$) (Table II). Among control animals not only did fewer dogs have ventricular tachycardia so early but also the arrhythmia was rarely persistent. However, at 24 hours the pattern in all groups was similar and ventricular tachycardia was almost universal. During recovery in the next 7 days, no significant difference was observed between the control animals and those undergoing reperfusion.

Q waves: Lead V_4 was monitored throughout the acute study. Significant and pathologic Q waves of 25 msec or longer duration were not present in any animal before infarct production. In the control group they generally developed after 5 hours (Table III). In group II pathologic Q waves were not present in any dog at 2 hours just before reperfusion but developed rapidly in 68 percent of the animals within 10 minutes of reperfusion. Either a very small insignificant Q wave widened or an initial R wave lost its amplitude and was quickly replaced by a Q wave (Fig. 5). The rapidity with which these changes developed can be seen in Figure 6. Ultimately, however, there was no difference between the control and reperfusion groups since the development of Q waves was almost universal. Dogs in group III also had a high incidence

TABLE II

TABLE III

Incidence Rate (%) of Significant Q Waves at Various Intervals After Infarct Production in Survivors

Interval (hrs)	Group I	Group II	Group III
2	4	0	9
3	12	68	18
5	27	83	45
7	50	...	100
24	89	80	100

Group I = control group; Group II = group undergoing reperfusion 2 hours after infarct production; Group III = group undergoing reperfusion 5 hours after infarct production.

rate of rapidly developing Q waves immediately after reperfusion.

Cardiac output, stroke volume and stroke work: Throughout the acute study, cardiac output, stroke volume and stroke work progressively deteriorated after infarction in the control group (Table IV, Fig. 4) and were returning toward normal at the time of follow-up study. In both groups II and III, reperfusion resulted in a steeper short-term decline in these values, mostly because of concomitant ventricular tachycardia. The differences between values in these groups and the control group were not statistically significant, except in the immediate postreperfusion state when these hemodynamic data were worse in groups II and III than in control dogs.

Left ventricular pressures and dP/dt: In both reperfusion groups, the abnormalities in end-diastolic and developed pressure and dP/dt were accentuated in the immediate postreperfusion period concomitant with ventricular tachycardia (Fig. 7). At the time of repeat catheterization, there were no significant differences between the control and reperfusion groups. The end-diastolic pressure was significantly increased in all groups at the time of repeat study ($P < 0.01$).

Left ventricular contractility index: The velocity of contractile element (Vce) was calculated according to the method of Mason et al.[20] by relating the dP/dt and developed pressure during isovolumic systole recorded by manometer-tipped catheters. The value of Vce at a developed isovolumic pressure of 40 mm Hg is presented in Table V. Serial changes in this value reflect alterations in the contractile state,[21] which was depressed in all three groups after infarction. Reperfusion in groups II and III did not result in any significant difference from the control group.

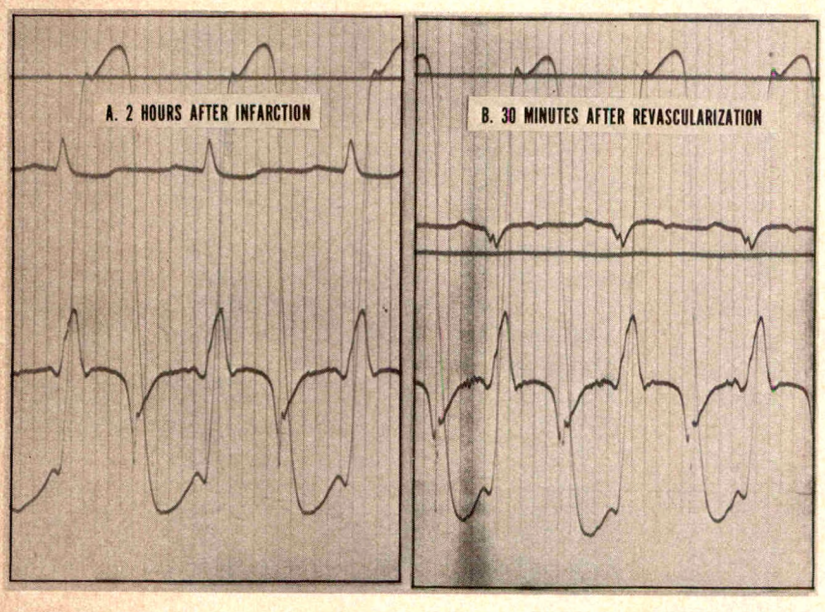

FIGURE 5. Effect of reperfusion on electrocardiogram and left ventricular pressure. The electrocardiogram (lead V_4), left ventricular pressure and its first derivative (dP/dt) are recorded at a paper speed of 100 mm/sec with time lines 0.04 second apart. Lead V_4 reveals a prominent R wave in **panel A,** 2 hours after infarction and immediately preceding reperfusion. **Panel B,** recorded 30 minutes after reperfusion (revascularization), reveals a dramatic change in QRS configuration; the same lead V_4 now has a QS pattern.

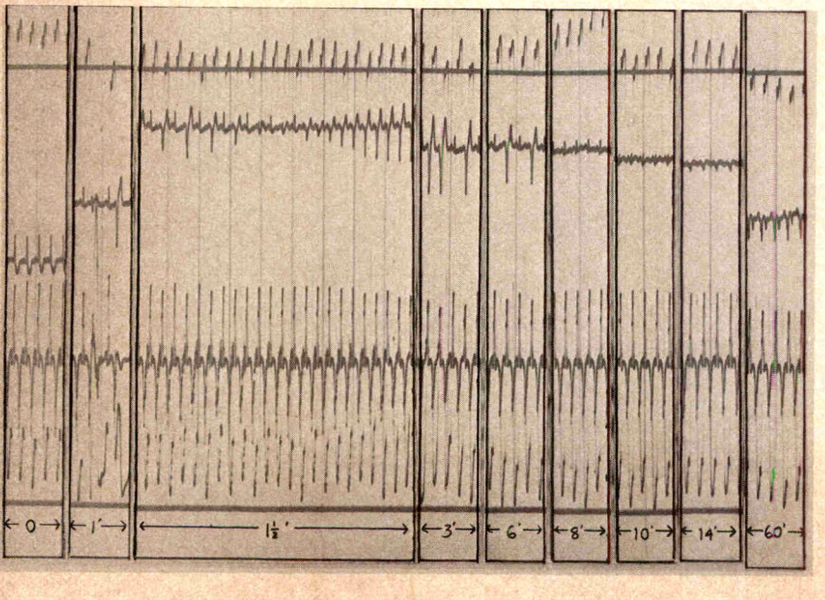

FIGURE 6. Immediate effects of reperfusion on electrocardiogram. Records of electrocardiogram (lead V_4), together with left ventricular pressure and its dP/dt at slow paper speed (10 mm/sec with time lines 1 second apart) reveal the rapidity of changes after revascularization (reperfusion). The numbers at the bottom indicate the time in minutes after reperfusion. At zero time a prominent R wave is recorded in lead V_4; after 1 minute the height of the R wave is reduced and premature ventricular contractions appear. At 1 1/2 minutes, premature contractions increase, leading to ventricular tachycardia. Progressive reduction in the amplitude of the R waves is noted in the sinus beats and at 10 minutes they are very small. At 14 minutes, QS configuration is seen and at 60 minutes QS configuration with inverted T waves is recorded.

168	6.13 ± 0.74	46.4 ± 5.9	4.51 ± 0.67	42.2 ± 6.2	. . .	. . .

CO = cardiac output in liters/min; SV = stroke volume in ml/beat.

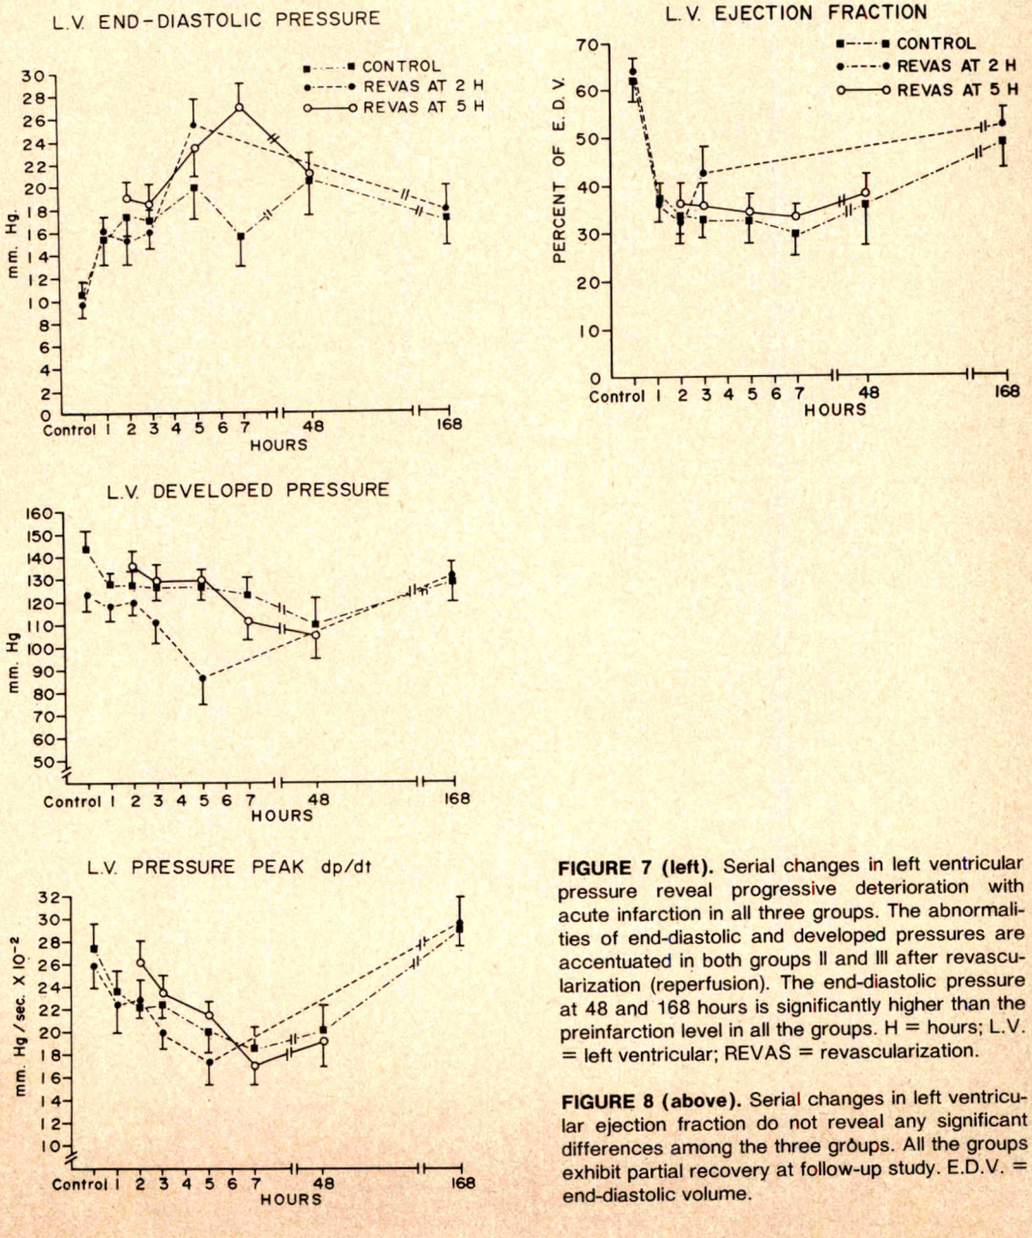

FIGURE 7 (left). Serial changes in left ventricular pressure reveal progressive deterioration with acute infarction in all three groups. The abnormalities of end-diastolic and developed pressures are accentuated in both groups II and III after revascularization (reperfusion). The end-diastolic pressure at 48 and 168 hours is significantly higher than the preinfarction level in all the groups. H = hours; L.V. = left ventricular; REVAS = revascularization.

FIGURE 8 (above). Serial changes in left ventricular ejection fraction do not reveal any significant differences among the three groups. All the groups exhibit partial recovery at follow-up study. E.D.V. = end-diastolic volume.

Ejection fraction and regional function: Selective left ventriculograms demonstrated definite areas of akinesia and dyskinesia in every animal in each group after infarction with reduction of ejection fraction. No significant differences in serial ejection fractions were observed among the three groups (Fig. 8) and in all animals repeat catheterization studies demonstrated improvement in values over those of the acute stage. The magnitude and extent of the dyskinetic or akinetic segment did not change in the control group between 2 and 5 hours after infarction. In group II, improvement was seen in 42 percent of dogs 1 hour after reperfusion (Fig. 9). No such improvement was found in group III after reperfusion at 5 hours.

Myocardial metabolic derangements: The transmyocardial oxygen extraction was calculated from arteriovenous oxygen difference as a fraction of arterial content [(arterial-venous/arterial)]. With the production of infarction, the extraction value increased in all groups (Fig. 10). In groups II and III, it diminished acutely (immediately after reperfusion) and during the next 2 to 3 hours was less than the preinfarction level. This sharp and sudden change was a valuable indicator of acute alteration in myocardial blood flow with reperfusion. At the time of follow-up catheterization, the values were returning toward normal in all three groups. The difference between groups I and III was significant at 48 hours ($P < 0.05$), but on the 7th day no difference was observed between the control and reperfusion groups. The responses of transmyocardial lactate extraction in different animals varied; the mean values for the three groups were not significantly different from each other.

Mortality: The overall mortality rates in the three groups were similar (31, 21 and 36 percent, respectively). All the deaths occurred within 24 hours, except for one death after 48 hours in group II. Three animals died during monitoring and experienced ventricular fibrillation at a time when their left ventricular systolic and diastolic pressures were comparable with values in the rest of the group; none had pulmonary edema or severe hypotension. In addition, primary ventricular fibrillation developed during monitoring in four other dogs, but these animals were successfully resuscitated.

Infarct size: In the control group, the infarct size averaged 30 percent of the left ventricular mass. In 2 of 26 dogs the infarct was less than 15 percent of the left ventricular mass and was considered small. In 9 of 18 dogs of group II, the size of the infarct was less than 15 percent of the left ventricular mass. The difference in the frequency of small infarcts, 50 percent in group II versus 8 percent in the control group, was significant ($P < 0.05$). However, in the other nine dogs of group II infarct size ranged from 20 percent to 44 percent of left ventricular mass and in six was more than 30 percent. Therefore, although the infarct was smaller than expected in half the group, its size was uninfluenced in others, and in some dogs was actually larger and hemorrhagic (Fig. 11). The average infarct size for all animals in group II was 20 percent of left ventricular mass; the difference from values in the control group was not statistically significant. Infarct size in animals in group III averaged 34 percent. None of the 11 animals had small infarcts (less than 15 percent of left ventricular mass). Thus, this group did not differ from the control group either in average infarct size or in frequency of smaller infarcts. In most instances in the reperfused groups the infarct was dark and hemorrhagic.

TABLE V

Velocity of Contractile Element at a Developed Pressure of 40 mm Hg

Interval (hr)	Group I	Group II	Group III
Preinfarct	1.62 ± 0.09	1.51 ± 0.12	. . .
1	1.48 ± 0.09	1.47 ± 0.11	. . .
2	1.41 ± 0.10	1.37 ± 0.09	1.59 ± 0.08
3	1.44 ± 0.10	1.31 ± 0.16	1.51 ± 0.10
5	1.39 ± 0.08	1.37 ± 0.17	1.42 ± 0.10
7	1.12 ± 0.14	. . .	1.29 ± 0.14
48	1.19 ± 0.09	. . .	1.37 ± 0.16
168	1.61 ± 0.16	1.66 ± 0.12	. . .

Velocity of contractile element (Vce) is calculated by the formula Vce = (dP/dt)/(K × IP) according to Mason et al.,[20] where dP/dt is the rate of rise of left ventricular pressure, IP is developed isovolumic pressure recorded by manometer-tipped catheter and K is the constant to obtain series elastic modulus or stiffness factor and is equal to 32. All values are in muscle lengths/sec with mean values and standard error of the mean and represent Vce calculated at a developed pressure of 40 mm Hg.

Discussion

Deleterious effects of reperfusion: The results of this study raise some important issues and contain some surprises. On the basis of the studies of Maroko et al.[15] and Ginks et al.,[16] we not only expected to find smaller infarct size and improved myocardial function with reperfusion, but also presumed that these changes would result in overall improvement of left ventricular function and better prognosis. In the group undergoing reperfusion after 2 hours of occlusion (but not in the one undergoing reperfusion after 5 hours) we did find evidence of improvement in dyskinetic and akinetic segments, but in only 42 percent; we also found smaller than expected infarcts in 50 percent of animals, but we failed to document any overall improvement. On the contrary, several deleterious effects became apparent immediately after reperfusion. Ventricular tachycardia developed almost immediately after reperfusion, even in those exhibiting reduction in dyskinesia and akinesia and a smaller infarct subsequently, and the arrhythmia invariably resulted in deterioration of overall left ventricular performance. The hemodynamic status of both reperfused groups was significantly worse 2 to 3 hours after reperfusion than that of the control group at corresponding times. In this regard, our findings are in agreement with those of Lang et al.[17] In our studies some dogs, in spite of reperfusion or indeed as

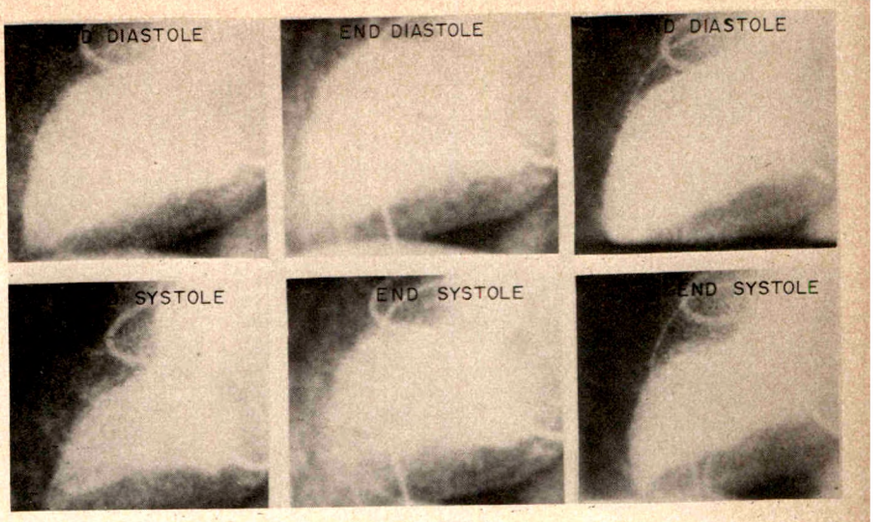

FIGURE 9. Left ventricular angiograms in left lateral projection. The **left panels** reveal a normal contractile pattern in the preinfarction state. In the **middle panels,** after coronary occlusion, marked impairment of contraction in the anterior wall is observed with dyskinesia in the anteroapical region. In the **right panels,** following reperfusion after 2 hours of occlusion, partial recovery is observed.

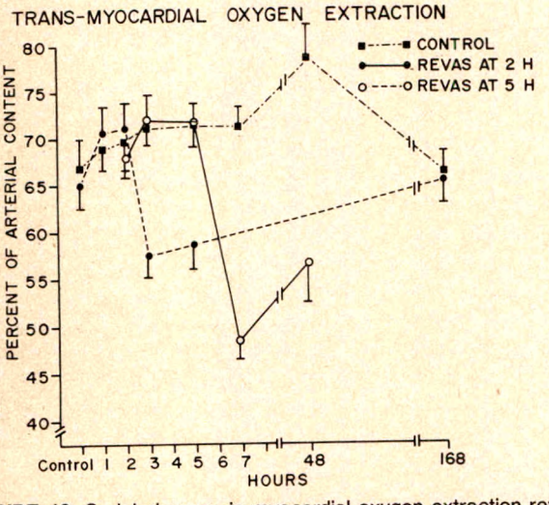

FIGURE 10. Serial changes in myocardial oxygen extraction reveal increased extraction after infarction in all groups. After revascularization (reperfusion) the level of oxygen extraction in groups II and III is acutely reduced, indicating increased blood flow due to reactive hyperemia or to nonutilization of oxygen by damaged myocardial tissues and an arteriovenous shunting effect. Findings in groups I and II are identical at 168 hours, but at 48 hours those in group III differ significantly from values in the control group ($P < 0.05$).

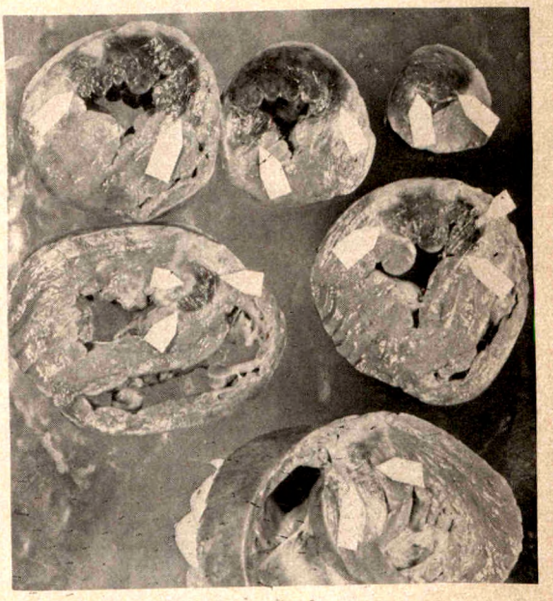

FIGURE 11. Heart of a dog subjected to reperfusion after 2 hours of coronary occlusion and killed on the 7th day. Slices have been cut transversely from the apex toward the base. A very large, dark, hemorrhagic infarcted area **(arrows)** is seen extending from the apex to the base with transmural involvement of anterior and lateral walls.

a result of reperfusion, ultimately had very large infarcts. Pathologic Q waves indicating transmural injury and infarction developed sooner in the animals undergoing reperfusion, and overall mortality was not influenced by reperfusion. Some recent studies[17,18,22] tend to support the argument that reperfusion can indeed be deleterious. It is entirely possible that in our studies the electrical instability and arrhythmias noted after reperfusion were primarily responsible for the early deterioration and that, if they had been controlled, the outcome might have been more favorable in the group undergoing reperfusion after 2 hours of occlusion.

A period of 5 hours of coronary occlusion in our model of awake dogs appears to be too long a time to expect any improvement or reversal of injury with reperfusion. Our findings are at variance with those of Bresnahan et al.,[22] who reported smaller than predicted infarct size in 9 of their 16 dogs undergoing reperfusion 5 hours after occlusion. Several others have found either irreversible injury[23–26] or only partial recovery[27] with shorter periods of occlusion.

Hemorrhagic changes after reperfusion: The development of Q waves almost immediately after reperfusion, in some dogs as early as 6 minutes, is intriguing. We have not investigated the causes of this change, but the finding of large hemorrhagic infarcts in most of these animals supports the theory recently

advanced by Bresnahan et al.[22] that reperfusion in awake animals with evolving infarction can result in extravasation of blood due to disruption of capillaries that have lost their structural integrity during the preceding period of occlusion. We found hemorrhagic infarcts, not only in those dogs reperfused after 5 hours of occlusion as did Bresnahan et al.,[22] but also in those reperfused after 2 hours. The latter finding is at variance with the results of Ginks et al.,[16] who did not report any hemorrhagic infarcts in their studies. It is not clear if the use of anesthesia in the studies of Ginks et al.[16] can account for this difference.

Determination of adequacy of coronary flow during reperfusion: One important question that must be answered in our studies, as well as those of others, is how certain are we that release of the occluding cuff, snare or other devices around the coronary artery results in true reperfusion or revascularization of ischemic and border zones. The instant development of arrhythmias with reperfusion in our studies assured us that some acute change had occurred in the affected zone, and the patency of the artery was subsequently confirmed angiographically. We realize that angiographic patency cannot be equated with adequate blood flow, and it is indeed possible that smaller capillaries had become closed off during the period of coronary occlusion in spite of administration of heparin. The angiographic appearance of arteries after reperfusion in four dogs in which the margins of the patent artery were somewhat irregular and emptying was delayed is consistent with such a possibility. Jarmakani et al.,[28] using an implanted flowmeter and external snare around the coronary artery to occlude it temporarily, were able to demonstrate return of flow, at a higher level than control level, within 15 minutes of reperfusion after 3 hours of occlusion. It is entirely possible though that structural changes in the reperfusion bed produced by 3 to 6 hours of coronary occlusion and myocardial ischemia severely limit future myocardial perfusion, even if flow is reestablished,[28,29] and that recovery may take 2 to 5 days or remain incomplete.

The demonstration of reduced myocardial oxygen extraction immediately after reperfusion in our study, as well as that of Lang et al.,[17] also indicates increased flow or reestablishment of flow. The subnormal oxygen extraction values in our studies can be explained by reflex hyperemia following a period of ischemia. The persistence of this phenomenon for 2 hours can be interpreted optimistically as indicating presence of viable tissue capable of responding by hyperemia. Alternatively, it can be explained by reduced oxygen utilization by the necrosed myocardium and production of an arteriovenous shunting effect.

Beneficial effects of reperfusion: Our interpretation that the presence of smaller infarcts in 50 percent of animals in group II suggests a possible beneficial effect of reperfusion at 2 hours may be criticized on the grounds that we compared this group with another group of animals rather than predicting infarct size in each animal before reperfusion. Such methods have been described using serum creatine phosphokinase activity[30,31] and surface mapping of S-T segment elevation.[32] The former would require a minimum of 5 hours of coronary occlusion and a suggestion has been made that the blood level of this enzyme depends not only on infarct size, but also on the perfusion and flow through involved areas.[33] The surface mapping of S-T segment elevation is a complicated technique and posed problems in our conscious dogs, which could not be kept still for such prolonged periods. We did study angiographically the movement of the ventricular wall and the extent of akinetic and dyskinetic segments. As mentioned previously, improvement after reperfusion at 2 hours was observed in 42 percent of dogs suggesting that function returned or improved in some zone of myocardium bordering necrotic or ischemic zones.

Clinical Implications

With the knowledge that infarct size can be modified in acute experimental myocardial infarction, both favorably and unfavorably,[6] and that medical revascularization using fibrinolysing agents may be beneficial in human myocardial infarction,[8–11] we attempted to study the influence of revascularization under most ideal circumstances and in a controlled manner. To achieve maximal revascularization we reperfused the occluded artery, thus restoring near normal blood flow through normal channels in dogs free of coronary atherosclerosis or other types of heart disease, within 2 to 5 hours of acute occlusion. The major difference from most previous studies was the use of intact, conscious animals and direction of observations toward the whole animal rather than portions of myocardium or some aspect of metabolism. Our studies were extended for up to 7 days. Our results indicate that if reperfusion is performed very early (2 hours after occlusion) under such ideal circumstances and noninvasively, we may indeed reduce the ultimate infarct size in some animals; however, the overall mortality remains unchanged. The process of reperfusion actually hastens the development of severe arrhythmias leading to early hemodynamic deterioration and, in many, results in immediate development of pathologic Q waves and large hemorrhagic infarcts.

We do not know the extent to which similarities with human myocardial infarction exist. Dogs have a propensity for rapid development of collateral channels, and indeed in this study, we found dramatic recovery of function within 7 days of acute infarction in the control animals that did not undergo reperfusion. Therefore, it is possible that acute reperfusion has less to offer in this species, but the fact that reperfusion is deleterious at least for a period of time in most animals is a disturbing observation. Should a similar phenomenon exist in man, acute surgical revascularization may be dangerous in the early stages of acute infarction even if in some it ultimately limits infarct

size. Such experience in acute infarction has been reported[34,35] with disastrous results, although others[12,14] have found a satisfactory outcome. Although there are definite differences between the animal model employed and patients with acute infarction, circumstances are far more favorable in our study than they are likely to be in patients with coronary disease. The ability to restore near normal blood flow noninvasively and so early in hearts that were previously normal and in which other arteries are normal is unlikely to be encountered in the course of clinical disease. If under such ideal circumstances revascularization is dangerous rather than beneficial, more studies using other species are indicated before attempting large scale surgical revascularization in the early stage of human myocardial infarction.

Successful Partial Excision of an Intramural Fibroma of the Left Ventricle

GEORGE J. REUL, Jr., MD, FACC*
JIMMY F. HOWELL, MD, FACC
PEDRO A. RUBIO, MD
PAUL K. PETERSON, MD, FACC

Houston, Texas

A report of the only surviving adult to undergo partial excision of an intramural cardiac left ventricular fibroma is presented. Good results were obtained by relieving outflow tract obstruction through partial excision of the tumor from the septum and left ventricle. The need for conservative surgical treatment of patients with this rare, benign tumor is emphasized.

Intramural fibromas of the heart are thought to comprise less than 5 percent of primary heart tumors.[1] Since the first case of fibroma of the heart was reported by Luschka[2] in 1855, more than 40 others have been reported.[3–15] This report describes successful partial resection of a massive intramural fibroma involving the posterior wall of the left ventricle and most of the interventricular septum.

Case Report

A 31 year old man first presented to the Methodist Hospital in July 1969 with the chief complaints of syncopal episodes and chest pain of 4 years' duration; the chest pain was described as dull and squeezing, followed by a sensation of dizziness. Attacks were precipitated by rapid changes in position or sudden exertion and were relieved by squatting. Past history revealed that a heart murmur was first heard at age 11 years, when a diagnosis of mitral stenosis was made. One year before admission, chest roentgenograms showed calcification in the mitral valve area.

Examination of the patient was essentially normal except for the presence of a grade 2/6 systolic ejection murmur over the entire precordium. Heart rhythm was regular and there was no detectable cardiomegaly.

Laboratory studies, including complete blood count, blood urea nitrogen, fasting blood sugar, serum electrolytes, serum lipids, uric acid and liver profile, were within normal limits. An electrocardiogram was normal except for occasional premature ventricular contractions. The chest roentgenogram revealed calcification in the area of the left ventricle and a 6.5 cm well marginated calcific lesion in the lower lobe of the right lung that was thought to be a hamartoma (Fig. 1). Chest fluoroscopy disclosed a large mass of calcium in the left ventricular wall.

A left ventricular angiogram (Fig. 2) demonstrated a calcified tubular mass arising from the free wall of the left ventricle just proximal to the aortic valve, descending on the outflow tract and projecting into it. Coronary arteriograms were normal and did not show involvement with the mass or staining in the area of mass. Left and right heart catheterization data were relatively normal, but exercise pressure data were not obtained.

Surgical findings and treatment: A preoperative diagnosis of left ventricular tumor and lower right pulmonary lobe hamartoma was made and the chest was explored through a median sternotomy on August 20, 1969. The posterior left ventricle was nodular to palpation and, on elevation of the heart, a bulky tumor could be seen in this area. Total cardiopulmonary bypass was established and the aorta cross-clamped. Through a transverse aortotomy, a large, glistening nodular mass could be seen projecting from the endocardium just inferior to the aortic valve. The mass obstructed the outflow tract, which measured approximately 1.5 cm in diameter. A left atriotomy was performed and the hard mass was palpated through the mitral valve. It

then became apparent that the nodular calcific mass involved the entire posterior left ventricular wall and most of the interventricular septum extending just below the mitral valve to the apex; the bulk of this mass occupied approximately one half of the left ventricular cavity. A biopsy specimen was taken, a frozen section examined, and the diagnosis of benign fibroma made. The left ventricular outflow tract was cleared by excision of the nodular mass to normal myocardium where possible. Nodules extending into the left atrium were also resected. Satisfactory withdrawal of the projecting portion of the tumor from the left ventricular cavity was performed without left ventriculotomy; because of the extent of involvement, the septum and remainder of the posterior wall were left intact with some of the benign tumor remaining. The aortotomy and atriotomy were closed, and the heart was returned to a normal sinus rhythm after defibrillation. The mass in the lower lobe of the right lung was then removed by wedge resection. Diagnosis, after examination of a frozen section of the lung mass, was fibrous mesothelioma. The sternotomy was closed.

The patient's postoperative course remained uneventful and a left ventricular angiogram 1 month postoperatively revealed no outflow tract obstruction despite persistence of part of the calcified mass in the left ventricular wall. The patient has now returned to gainful employment and is asymptomatic 4 1/2 years after surgery. Permanent sections of the fibrous tumor of the left ventricle are shown in Figure 3.

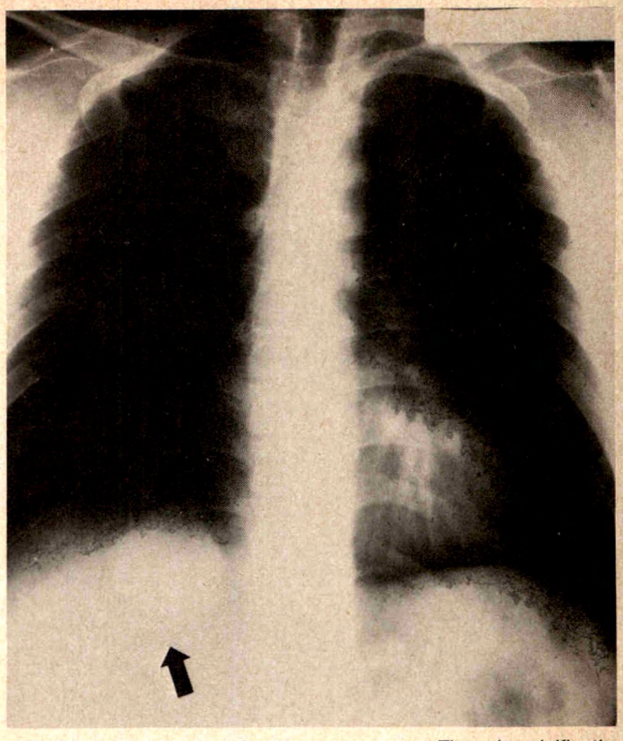

FIGURE 1. Preoperative chest roentgenogram. There is calcification in the left ventricle. **Arrow** points to a large calcified mass in the lower lobe of the right lung, later proved to be a fibrous mesothelioma of the lung.

Discussion

Patients reported to have intramural ventricular cardiac fibroma have ranged from newborns to 65 years of age but most have been children. Approximately 30 percent of the patients in previously reported cases died from "sudden death," presumably because of interference with cardiac conduction or because of outflow tract obstruction.[1]

The clinical diagnosis of intracardiac fibroma has been elusive. Findings have been confused with those of endocardial fibroelastosis[4] and pulmonary stenosis.[1] Our patient's condition was diagnosed as mitral stenosis and insufficiency for several years. Most intramural fibromas present with ventricular calcification and cardiomegaly; the final diagnosis has been made by ventriculogram, in most cases preoperatively.

Surgical excision: Because of the difficulty in diagnosis and the rarity of this tumor, only a few cases with successful surgical treatment have been reported. The first successful excision was reported by Parks et al.[3] in 1962. Their patient was a 26 month old boy with a left ventricular hamartoma composed of fibrous and cardiac muscle elements. The specimen weighed 61.5 g and calcification was present.

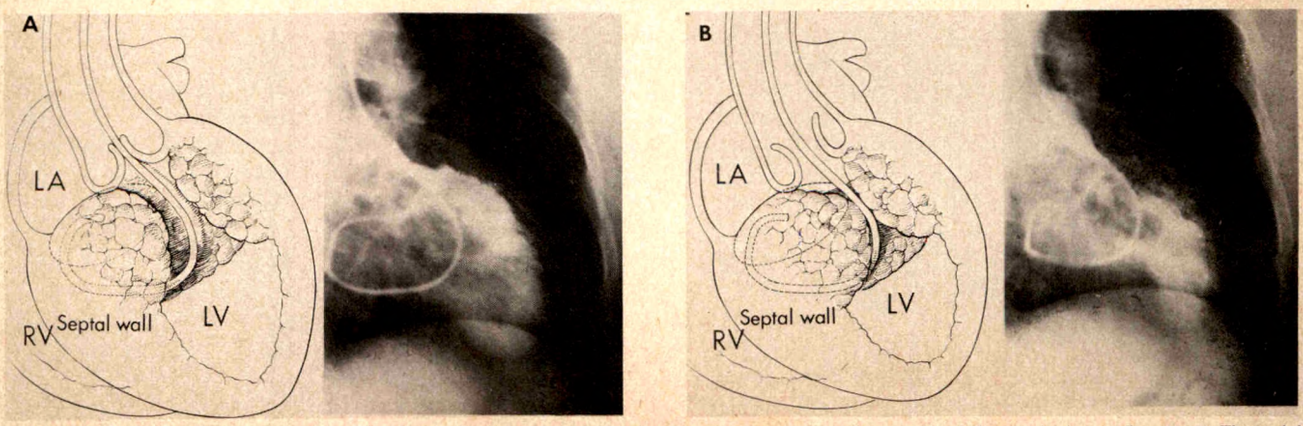

FIGURE 2. Left ventricular angiograms. **A,** during diastole, demonstrating the fibroma encroaching on the left ventricular outflow tract. The calcification can be noted in the anterior wall of the left ventricle (LV). **B,** during systole, there is further encroachment on the outflow tract. Note the large amount of calcium in the anterior wall and septum of the left ventricle.

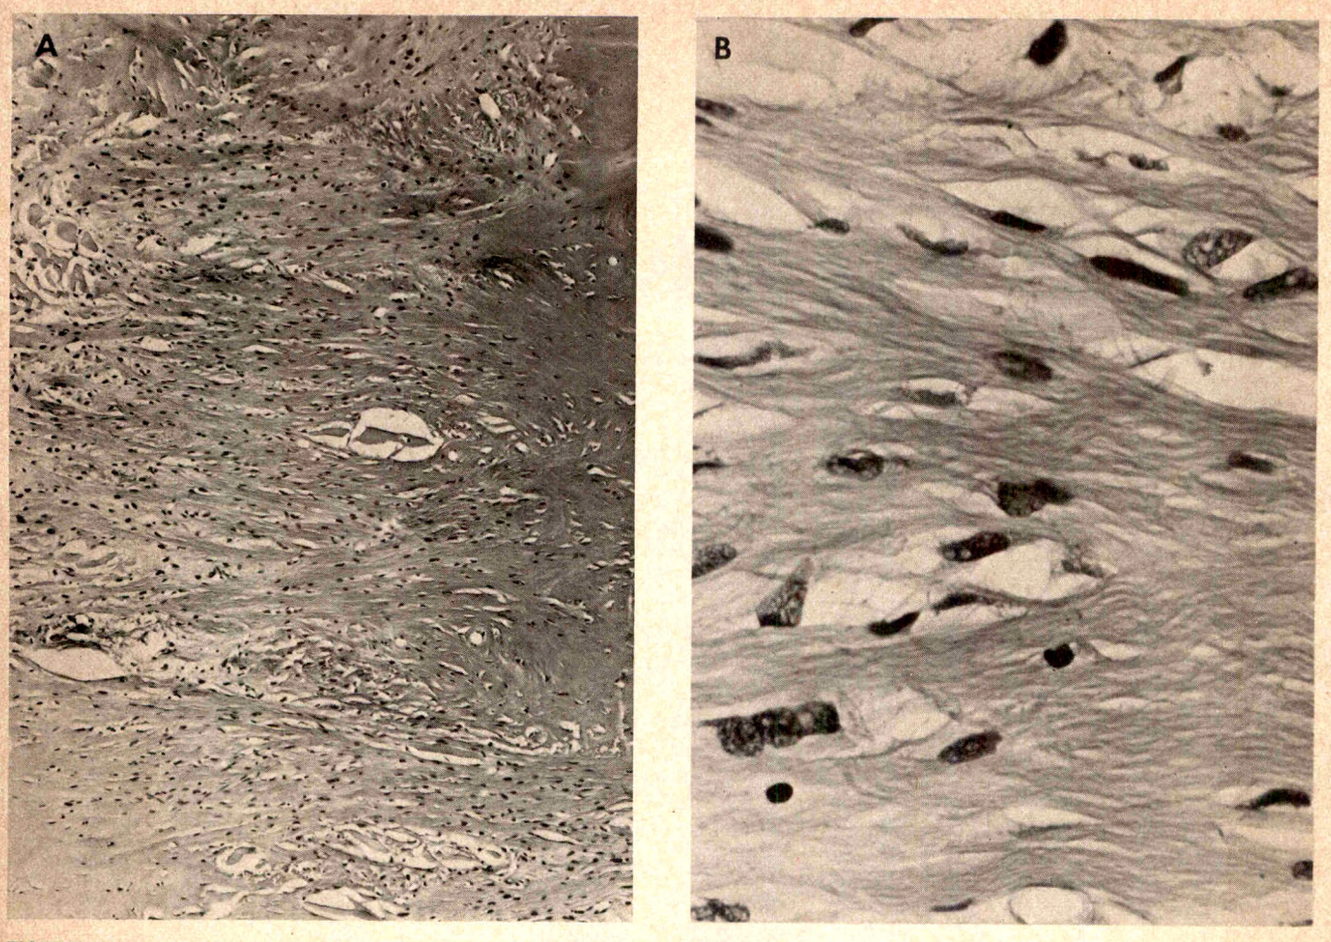

FIGURE 3. Microscopic sections of the excised tumor. **A,** the fibroma has the appearance of normal fibrous tissue with thick bundles of collagen surrounding normal fibrocytes. Note the lack of cardiac muscle. (Hematoxalin-eosin stain ×90, reduced by 25 percent.) **B,** high power view. Normal appearing fibrocytes are surrounded by large amounts of collagen. (Hematoxylin-eosin stain ×900, reduced by 25 percent.)

Excision was accomplished from the lateral and posterior aspects of the ventricular wall. The patient was followed up for 2 years and remained symptom-free.

Geha et al.[1] reported successful excision of fibroma in two children. The first, a 27 month old boy, presented with syncopal attacks and arrhythmia. A ventriculogram revealed a partly calcified intramyocardial mass. The excised mass had occupied the interventricular groove, weighed 72 g and was 6 cm in diameter. The second patient was a 38 month old boy with a systolic murmur, left ventricular calcification and cardiomegaly; a 118 g fibroma was removed from the left ventricle. Both patients apparently fared well postoperatively.

In 1968 Kay et al.[5] reported excision of an intramural fibroma of the right ventricle and interventricular septum in a 9 year old boy. The child presented with atrial tachycardia, cardiomegaly and calcification of the right ventricle; a 115 g fibroma was removed from the right ventricle and septum necessitating closure of the defect with a Teflon® patch. After 4 years of follow-up, the child was doing well despite slight calcification in the patch area.

Thomsen et al.[7] and Williams et al.[8] reported successful excision of a left ventricular fibroma in a 17 year old girl and a 30 month old boy. Hall[6] attempted resection of an extensive fibroma of the left ventricle but was unsuccessful because excision of the entire fibroma compromised left ventricular function. Thus, only partial excision is indicated in some patients.

Edlund and Holmadahl[13] were the first to make a gross surgical diagnosis of intramyocardial fibroma, discovered in the left ventricle of a 32 month old child. Valledor[14] attempted to remove an interventricular septal fibroma in an 8 month old infant, but the patient did not survive. Svejda and Tomasek[12] accomplished partial excision of a left ventricular and septal fibroma in a 17 month old infant, who did not survive.

Our patient represents the seventh successful operation for this rare condition and the first successful partial excision in an adult. Because of the biological activity of the fibroma and the extensive involvement of the left ventricle and septum, we elected to clear the outflow tract and increase left ventricular volume by excising only part of the tumor. Although it has been assumed that intramural cardiac fibromas grow by displacing myocardium, complete resection could not be accomplished in this case. Sufficient muscle mass remained to maintain good cardiac output, ade-

quate left ventricular volume, a normal conduction pattern and an unimpeded outflow tract. Moreover, the avoidance of ventriculotomy in this case preserved the remaining left ventricular muscle and its blood supply. Four years postoperatively the patient has returned to full time employment and remains symptom-free.

The incidental finding of a fibrous mesothelioma of the lung probably bears no relation to the intracardiac fibroma. T'so and Teoh[15] described a newborn infant with intramural cardiac fibroma who, at autopsy, was also found to have fibromas of the larynx and tongue and multiple fibromas of the lungs. However, these lesions were of uniform character.

Implanted Pacemakers: Medicolegal Implications

LEONARD S. DREIFUS, MD, FACC
DAVID COHEN, LLB, JD

Philadelphia, Pennsylvania

Cardiac pacing, which has enjoyed rapid development, is an important therapeutic tool for managing patients with cardiac dysrhythmias. The ability of muscle to respond to electrical stimulation has been known since the early experiments of Galvani, but it was not until 1952 that Zoll[1] demonstrated the feasibility of closed chest cardiac stimulation for cardiac resuscitation. Brockman et al.[2] in 1956 showed the clinical feasibility of direct electrostimulation of the myocardium in an 11 month old infant. In 1959 Furman and Schwedel[3] reported on both short- and long-term applications of transvenous cardiac stimulation in man, and in 1960 Chardack et al.[4] implanted pacemakers in patients.

Most modern artificial cardiac pacemakers are of the ventricular pacing variety, with or without sensing function, and are used to manage high degree atrioventricular (A-V) heart block; however, rapid advances in electrophysiology and pacemaker design have caused a proliferation of specialized pacemakers with many useful features for preventing or terminating cardiac dysrhythmias. An amazing fact is that most brands of marketed pacemakers are highly reliable and meet reasonable criteria for safety and fail-safe use. The industry should be commended for manufacturing such excellent devices and for maintaining superb quality control.

Although more than 200,000 patients have escaped sudden cardiac death or have had the quality of life immeasurably improved as a result of implanted pacemakers, certain areas of caution must now be acknowledged in the development and future use of these devices. The natural heart pacemakers and A-V transmission systems can fail; so too, artificial cardiac pacemakers are susceptible to battery and circuitry failure. In addition, they may slip through the net of precise quality control or may be the products of shoddy workmanship.

Areas of potential legal liability: As with any other medical or surgical procedure, implantation of cardiac pacemakers has legal implications. Segall[5] has stated that use of these devices opens up a wide area of legal liability, in tort, related to charges of malpractice against consulting or treating physicians, surgeons, hospitals and manufacturers. Malpractice charges may arise from (1) delay in reaching a decision to implant a pacemaker when implantation is clearly medically indicated; (2) failure to warn of potential complications, after effects and risks; (3) selection of a device and pacemaker system inappropriate to the patient's problem; (4) poor postimplantation care and advice; or (5) improper design or defective manufacture of the pacemaker or its impulse generator.

Other sources of possible liability include injuries due to radioactivity from nuclear-powered generators or failure to warn against pacemaker catastrophes in connection with microwave ovens, magnetic fields, radar and other possible electronic areas of interference. Liability may also be incurred when patients wearing pacemaker devices are involved in litigation resulting from automobile accidents or other areas of traumatic negligence common to the general population.

Selection of pacemakers and pacemaker failure: One important area of possible medicolegal conflict relates to the indications for and selection of pacemaker types for particular cardiac dysrhythmias. Another is a situation wherein a patient with heart disease might benefit from pacemaker implantation but a suitable device is not inserted because of inadequate or inappropriate studies and improper identification of the kind of heart disease. Undue delay in pacemaker implantation or temporary pacemaker implantation in a clinic without adequate techniques and inventory for prompt permanent pacemaker implantation and replacement may also constitute negligence. On such occasions, the need for temporary pacemaker implantation while a generator or electrodes or other connecting parts are being awaited may become urgent. During such a delay there could be dislodgment of the unit, followed by grave medical complications or even sudden death, associated with the temporary loss of pacemaker function.

Implantation of a particular type of generator without performing appropriate electrophysiologic studies may now constitute negligence on the part of the attending physician and the surgeon. One example would be the implantation of a fixed type of ventricular pacemaker in a patient who subsequently experiences return of A-V conduction and symptomatic

From the Lankenau Hospital, Philadelphia, Pa.
Address for reprints: Leonard S. Dreifus, MD, 1320 Race St., Philadelphia, Pa. 19107.

competition of the pacemaker and the inherent rhythm. The implantation of pacemakers that pace the ventricles and engender retrograde conduction to the atrium (retrograde P waves either occurring at an unfavorable period in ventricular systole and causing undesirable hemodynamic results or arriving in the atrium during its vulnerable period and producing periods of atrial flutter or fibrillation) may result in legal liability on the basis of unfavorable effects.

Pacemaker monitoring: Perhaps one of the most important areas of consideration concerns adequate surveillance after implantation. Although the rate of most cardiac pacemakers decreases before battery depletion, other units may fail without perceptible warning and hence should not be monitored by the usual methods or by transtelephonic techniques. Wave form analysis can be used to determine impending pacemaker failure, but this method of surveillance is time-consuming, requires special equipment and cannot be performed by telephone. Often patients are discharged from the hospital without being given detailed information concerning the pacemaker, its life expectancy, function, type, hazards and possible complications, or, most important, precise instructions for periodic evaluation and testing of battery function. Certainly the level of sophistication of the practice will govern the surveillance system necessary for patients residing within given geographic areas. Patients who are completely pacemaker-dependent require stricter surveillance than those with comparatively minor disturbances of impulse formation and conduction. In the former, it may sometimes be wise to implant redundant pacemaker systems to protect against sudden lack of pacing, wire breakage or dislodgment since subtle problems, such as minor wire fractures or muscle action potentials, can inactivate demand-functioning pacemakers and cause sudden death.

Complications of pacemaker implantation: It is far too early to anticipate the possible long-term complications of epicardial and transvenous electrode implantation. At present, it appears that the generators themselves are safe, and we are fairly well assured that atomic units are probably also compatible with long-term safe use. However, over long periods such conditions as perforation, thrombosis, fibrosis, constriction of the superior vena cava around one or more pacemaker electrode wires, or trauma associated with attempted removal of old electrodes may entail additional risks, with consequent liability.

Every physician should be conversant with the hazards attending the failure to implant cardiac pacemakers after the development of various kinds of block within the atria, A-V node or fascicles in acute or chronic cardiac disease. The danger of sudden death must be reckoned with both in the acute phase of myocardial infarction and in the long-term clinical course of patients with residual degrees of fascicular block.

Prevention of Legal Liability

Every effort must be made to acquaint patients with the possible complications and potential hazards of pacemaker implantation. Several suggestions appear pertinent because sufficient information is now available to perform electrophysiologic studies to select the appropriate type of pacemaker and recommend postimplantation care to the patient. Failure to observe these precautions may invite legal action.

1. *Preoperative care:* The patient must sign a precise and detailed form giving informed consent. It is the affirmative duty of the physician to inform the patient and his family of the nature of the function of the pacemaker, the scope and method of implantation and the risks of complications of surgery.

2. *Intraoperative care:* A detailed record must be made on the patient's chart and identification cards issued indicating implantation date, model, electronic and electrophysiologic data, electrode threshold and recordings of demand and magnetic mode function when indicated.

3. *Postoperative care:* Since pacemakers have a natural course and are also subject to premature failure, specific recommendations concerning the responsibility for patient follow-up and the precise type of surveillance program utilizing a pacemaker clinic or transtelephonic monitoring should be prescribed before the patient is discharged from the hospital. Pacemaker manufacturers should offer patients booklets to assist them in understanding the function of the implanted unit. Patients should be warned about probable malfunction in the presence of microwave ovens, radar, radio broadcasting stations or magnetometers and should be given reassurance concerning devices that are not harmful.

Negligence as such may not be the principal legal hazard in the field of cardiac pacemakers. However, the clinician is faced with new challenges, in the form of possible suffering and reduced quality of life resulting from failure to implant a pacemaker or, conversely, from mechanical, surgical and the many electrophysiologic problems attendant upon the implantation of certain electronic circuits. The pitfalls inherent in all these situations must be recognized.

Permanent Pacing of the Heart: A Comment on Technique

VICTOR PARSONNET, MD, FACC

Newark, New Jersey

Fixation of electrodes directly into the myocardium, the original technique for pacemaker implantation, almost disappeared from the scene for 10 years. Less than 5 percent of "pacemaker doctors" persisted in transthoracic implantation. As one might suspect, the physicians who persisted were thoracic surgeons; they argued for their method on the basis of its simplicity and swiftness and the long-term security of electrode position. Most other physicians, about one third of whom were cardiologists or internists, and two thirds surgeons, had switched to transvenous pacing because this method could be performed in patients of any age, under local anesthesia, with low operative morbidity and mortality.

Recently an interest in direct myocardial implantation was rekindled by the development of the sutureless or so-called "screw-in" electrode, and by the disclosure by some physicians that in their hands transvenous pacing was associated with a frightfully high incidence of early electrode malposition—as high as 59 percent in one report! (For the sake of brevity, malposition here includes dislodgment and ventricular perforation.) Because proponents of each technique are now figuratively toe to toe, it behooves us to evaluate the relevant arguments.

"Swiftness" and "simplicity" are characteristics that may be attributed to both methods but, one asks, swift and simple for whom? Surely transthoracic pacing would be neither swift nor simple for an internist, nor would transvenous pacing be simple or swift for every surgeon. A cardiologist, actually, could not perform a transthoracic operation, because no hospital would give him operative privileges. And yet, paradoxically, surgeons have slipped into the catheterization laboratory (because a small incision was needed?) and have been inserting transvenous pacemakers. In fact, transvenous pacing is so "simple" that many centers have given this operative responsibility to junior physicians, and sometimes to house officers.

The real issue is the problem of electrode dislodgment. Were electrodes as securely positioned with transvenous pacing as they are with transthoracic pacing, there would be no valid argument for pericardiotomy, however small the opening. Even though transthoracic pacing can be done with little morbidity and mortality, general endotracheal anesthesia is usually used (although epigastric incisions and transthoracic operations may be done under local anesthesia), the pericardium must be opened and the heart must be exposed. There are, of course, those who argue differently, but surely these factors will increase morbidity and mortality. Add to that the problem of infection, should it occur: Removal of wires by the transvenous route is a far less serious consequence than another thoracotomy. Other complications that are peculiar to transvenous pacing, such as damage to the tricuspid valve, air embolization and late perforations are not being ignored in this editorial, but they are relatively rare, and for the sake of this analysis are more than balanced by other complications that are peculiar to transthoracic pacing.

In the Inter-Society Commission for Heart Disease Resources report on pacemakers,[1] the issue of an acceptable incidence of transvenous electrode malposition was discussed. It was suggested that a figure of early dislodgment higher than 5 percent calls for a review of results by a proper audit committee (now probably PSRO), and for modification of physicians' privileges.

Our own figures for 1973 and 1974 show 9 dislodgments in 219 primary ventricular transvenous insertions (4.1 percent). A second repositioning of the 9 was never required. Perhaps this indicates that the operation could have been done better the first time! Permanent transthoracic pacing is never used at our institution except as an incidental procedure when the heart is exposed for another reason, or in rare problem situations. Since 1964 we have used the transthoracic approach five times in 1,030 complete pacemaker insertions.

Transvenous pacing can be done with only a trivial incidence of complications; it is the safest and simplest technique available. In our opinion it is the preferred pacing method in almost all situations, provided the operation is performed by a skilled physician who is *specifically trained* in the technique and all its ramifications.

BEHAVIOR THERAPY FOR TYPE A PATIENTS

This letter briefly introduces a new approach to psychological treatment of the type A cardiac patient; fuller details will be reported later as further analyses are completed. However, some preliminary results show this approach to be promising.

The type A personality was identified by Friedman and Rosenman[1–3] in a series of well designed studies demonstrating the association of this behavioral pattern with high risk for heart disease. They also reported[3,4] that the type A traits were more predictive, with less error, of heart disease than predictions based solely upon examination of lipid data such as the beta/alpha lipoprotein level.

The type A behavioral pattern consists of: a high drive toward poorly defined goals, persistence of work toward recognition and advancement, eagerness to compete, continuous involvement in activities with self-imposed deadlines, working at such activities at a high rate, and a heightened mental and physical alertness.

The pilot program of psychological treatment was a combination of two behavior modification programs developed by Suinn[5]: anxiety management training and visuo-motor behavior rehearsal.[6] The former trains patients in identification of the physical/physiologic signs of stress and elimination of these reactions from the behavior pattern. It has been successful in patients with diffuse anxieties.[7,8] Visuo-motor behavior rehearsal is a method that enables a patient to acquire new adaptive habit patterns through practicing these patterns under controlled imagery conditions. This procedure has been applied to the retraining of executives, concert musicians and members of the United States National Ski Team.[9] The program for cardiac patients is a 5 hour treatment program called Cardiac Stress Management Training (CSMT). Patients are trained in the methods for coping with stress situations and stress arousal, and in the means for altering their lifestyles to reduce stress. It is assumed that the type A patient is particularly susceptible to stress because his behavior places him in situations of stress, for instance, from deadlines. It is also assumed that the type A patient needs to alter his activities significantly in order to avoid further stress.

All patients underwent rehabilitation in the Spalding Rehabilitation Center, Cardiac Reconditioning Unit, Denver, Colorado. This rehabilitation program is comprehensive, involving medical resources, physical exercise and dietary assistance, all individualized for each patient. Patients are introduced into the program within 2 to 4 weeks after infarction, and typically are followed up in an outpatient treatment program three times a week for 8 weeks. Blood lipid measurements are obtained at the beginning and at the end of the program through the laboratory facilities in the hospital attached to the Center.

An experimental group of 10 type A patients was selected for Cardiac Stress Management Training, with a control group of 10 who did not receive this training. All patients had been undergoing the comprehensive medical rehabilitation treatment previously indicated, that is, exercise, dietary assistance and medical supervision.

A questionnaire on the patients' reactions to the stress training program indicated that 83 percent believed it led to substantial improvements in their reactions to stress, and 83 percent believed there were major changes in their behavior patterns or lifestyles.

The median cholesterol and triglyceride levels showed, respectively, a decrease from 215 to 194 mg/100 ml and a decrease from 143 to 104 mg/100 ml in those patients who underwent the stress training. The control group showed no change in cholesterol level from the median of 214 mg/100 ml, and a decrease in triglyceride level from 146 to 130 mg/100 ml. The mean decrease in body weight in the group trained in stress management was 3.0 lb as compared with 1.3 lb for the patients in the control group. The only way in which the two groups differed was in the participation or nonparticipation in the stress management program.

Further detailed statistical analyses are being conducted on the data. At this point the stress management training program seems promising since 8 of 10 patients who participated had a decrease in cholesterol level and 9 of 10 a decrease in triglyceride level, as compared with 5 of 10 patients in the control group who had a decrease in either measurement. Since the program was developed as a short-term treatment program that can be completed in 2 weeks, it may prove to be the first meaningful approach to reducing the psychological risk factors associated with heart disease.

COMMENT

The usual approach to management of a patient after myocardial infarction is alteration of the primary risk factors for infarction by such methods as changing diet, stopping smoking, normalizing weight, reducing serum lipids by diet and medication and enhancing physical activity, and, more recently, by purposeful programs of physical conditioning. Unfortunately, it is clear from published data that such approaches have not been associated with a significant decrease in the rate of recurring coronary events.

The association of type A behavior with the incidence of both primary and recurring coronary events seems clear from our own published data as well as the relevant data from many other investigators. The letter from Suinn et al. strongly indicates that alteration of the patient's behavior

pattern should be attempted with the hope that it may favorably influence the rate of future coronary events. Such attempts have been employed in various European centers for a number of years, and more recently in this country by Dr. Richard Rahe at the University of California at Los Angeles, and by Dr. Joseph Satten and me in our group in San Francisco, which meets twice a month for a group discussion. This behavioral approach to patient management necessarily involves a deconditioning process or a method that may enable a patient to acquire new adaptive habit patterns, as indicated by Suinn and his associates.

The preliminary results reported by Suinn et al. concerning changes in serum lipid levels in their subjects are of great interest since we have observed similar favorable responses in our own subjects after successful alterations of behavior. The low mean serum cholesterol level that Suinn et al. describe in their patients with coronary disease is surprising. However, hospitalization is usually associated with a decrease in serum lipid levels and it would be important for Suinn and his associates to compare their groups' prehospitalization serum lipid levels with the levels observed after the patients' return to usual modes of living.

I await with great interest the results of the studies of Suinn et al. and hope that their report will stimulate other investigators to conduct analogous studies with various modifications.

RELATION BETWEEN S-T SEGMENT DEPRESSION AND S WAVE AMPLITUDE

Linhart's detailed hemodynamic measurements[1] reveal consistent reversible cardiac failure in pacing-invoked angina. We are currently investigating an electromechanical relation between the mathematically interpreted electrocardiogram and cardiac function, as described by Posel.[2,3] We have found that the amplitude of the S wave, in certain leads, can act as a left ventricular function transducer.[4,5] In this context Figure 1 of Linhart's paper[1] is particularly relevant because it demonstrates a direct relation between the left ventricular end-diastolic pressure and the S wave amplitude since they both increase in magnitude simultaneously. This apparent coincidence is also evident in Figure 1 of Linhart's previous paper.[6] The echogram in our Figure 1 reveals a clear decrease in the S wave amplitude with the reduction of left ventricular volume due to the sublingual administration of nitroglycerin.

S-T segment depression is usually associated with an increase in S wave amplitude.[7,8] Our investigations suggest that the S wave changes and the S-T depression may actually be separate though related phenomena, the S-T depression indicating anaerobism and the S wave the associated cardiac failure. We have found that during exercise the S wave changes may precede the S-T depression (Fig. 2).

Linhart has twice published reports of a relation between changes in the S wave amplitude and reversible left ventricular failure. On the basis of his published graphs and our research we expect that a review of his records from this point of view may reveal more correlations of the S wave changes with the left ventricular end-diastolic pressure changes. The accuracy of such a prediction is dependent on the use of mathematically selected leads and the absence of ventricular conduction defects. Nevertheless, we await his findings with confidence.

We believe that the possibility of an electromechanical link between the electrocardiogram and cardiac function and the implications of such a simple atraumatic monitor of cardiac hemodynamic function requires detailed investigation, particularly in the light of the detailed clinical applications described by Posel.[9]

MAXIMAL TREADMILL TESTING

Bruce[1] recently provided convincing data on the multistage maximal treadmill test as the exercise test of first choice. This test has excellent diagnostic value in addition to providing quantitative measurement of the functional capacity of the cardiovascular system. In the prospective study reported, there was some patient selection: The average age of subjects was 45 to 52 years and most were active and working. This could explain the excellent performance and feasibility of the test (97 percent accuracy in 15,000 tests). However, the average cardiac practice contains some patients who are not always able to perform a maximal treadmill test: the elderly (±70 years), the obese, those with musculoskeletal deformities of legs or feet, or patients with claudication or sequellae of hemiparesis or hemiplegia.

It may be a question less of isometric versus dynamic tests or test X versus test Y, than of which test provides which diagnostic value or quantitative measure of cardiovascular function and is feasible not only for the patient but for the budget, time and facilities of the physician or clinic. The popularity and efficacy of the Master two-step test did not happen by coincidence.

There is now a rich variety of diagnostic tests with circulatory implications. The passive muscular tests include postural changes (from Trendelenburg position 10° to tilting [duration variable]); pharmacodynamic interventions (amyl nitrite, isoproterenol, atropine); and atrial pacing.

The active muscular tests include (1) isometric exercise (Valsalva maneuver, unilateral or bilateral handgrip or weight lifting or pushing, waterskiing [easier to study on roller skates and treadmill]); (2) dynamic exercise (walking, stepping, pedaling, jogging, running); and (3) combined isometric and dynamic exercise.

In all these tests, the same classic variables, such as heart rate, blood pressure, electrocardiographic patterns, S-T segment, dysrhythmias and symptoms and duration, are observed to assess the diagnostic value during and after testing. This wide spectrum of diagnostic tests, each with more or less severe limitations, allows most cardiologists to study most patients in most countries with a variable degree of accuracy. These tests are more supplementary than substitutive. A comparative study of most of these tests, used in the same healthy subjects and patients with coronary heart disease would be most interesting.

REPLY

Regarding comments about ages of patients selected for a prospective study and "excellent performance and feasibility of the test," I submit the following data, updated from an earlier report,[1] comparing numbers of male patients stopped by their physicians because of unfavorable responses (numerators) with numbers of patients tested to symptomatic limits (denominators) according to 5 year age groups and clinical diagnosis before testing (Table I). All patients tested were ambulatory and none was considered to have acute or recent illness, especially myocardial infarction. The results obtained suggest both the general feasibility and the value of this method of testing to appraise cardiovascular function. In addition, there is the curious phenomenon that the majority of instances of the physician's stopping the tests occurred in healthy men under 60 years of age.

I agree that there are both multiple objectives and a variety of methods for stress testing the cardiovascular system and that many have enjoyed considerable clinical usage. As for the popular double Master two-step test, the fact that it has been used for several thousand persons does not make it the most appropriate. For example, Rowell and associates[2] pointed out the basic fallacy that, despite an effort to adjust workload in terms of steps per unit time to sex, age and weight, the test actually overtaxes the underweight patient and spares the overweight patient. Furthermore, the average oxygen requirement of 23 ml/kg of body weight per minute published by Blackburn et al.[3] happens to coincide with the average maximal oxygen uptake observed in a series of ambulatory patients with coronary disease.[4] Thus, the demand may represent 100 percent or more of the capacity in about half of patients who might be selected for testing; Master stated that patients who exhibited an unstable abnormal electrocardiogram or recent change in anginal pain at rest should not be tested, and this proved to be an important safety precaution.[5,6] A recent study from this laboratory of patients tested in the same day on both bicycle ergometers and treadmill demonstrated that on the bicycle ergometer significantly higher systemic arterial pressures and pressure-rate products were reached in the *same* patients.[7] Thus, it may be easier to overload a hypertensive or an ischemic left ventricle with this method.

TABLE I

New Data

Age Groups (yr)	Diagnoses Before Treadmill Testing				
			CHD		Prior Cardiac Arrest
	Healthy	Hypertensive	Normotensive	Hypertensive	
30–34	3/155	1/24	0/28	0/2	0/0
35–39	5/397	2/47	0/60	0/21	0/1
40–44	6/488	0/64	1/141	0/37	0/1
45–49	3/453	0/76	4/254	2/103	1/7
50–54	4/351	2/109	3/323	0/138	0/9
55–59	2/159	1/65	1/290	4/138	0/6
60–64	0/42	0/36	0/170	0/79	0/1
65–69	0/4	0/6	0/38	0/22	0/4
>70	0/1	0/8	0/11	0/2	0/1
Total	45/4426 = 1.02%				

CHD = coronary heart disease.

Bruyneel's classification of "passive muscular" diagnostic tests using changes in body posture to alter the distribution of blood volume and preload on the heart, drugs to alter peripheral resistance and myocardial contraction or pacing to alter heart rate have their place in assessing functional responses under selected conditions, but may offer less with respect to clinical diagnosis of heart disease. The isometric tests provide approaches to augmentation of ventricular afterload but, unfortunately for the patient at some risk for arrhythmias, they also evoke exercise pressor responses. Two instances are known of patients with coronary disease participating in waterskiing who experienced sudden death from ventricular fibrillation. (Although this isometric "test method" may be "easier to study on roller skates and treadmill," I seriously doubt the wisdom of having a patient with heart disease unfamiliar with this activity attempt it for the sake of making it "easier" for the observer.)

I agree that the dynamic exercises of walking, stepping, pedaling, jogging or running are better, subject to the reservations cited. For some clinical problems, it can be helpful to initiate symptoms with stressful dynamic arm exercise, either alone or in combination with limited isometric exercise. These stress tests often reveal the pathophysiologic origins of the symptoms. I also agree on the value of observations of symptoms and circulatory and electrocardiographic responses as well as the intensity and duration of exertion that elicited these responses.

As for comparative studies of physiologic responses, I suggest the papers by Doan et al.,[8] Blackburn et al.,[3] Shephard and associates (for both submaximal[9] and maximal exercise tests[10]) and Kasch et al.[11] for maximal tests in normal subjects; with respect to hemodynamic studies in hypertensive patients and those with coronary heart disease, there are additional citations.[12,13]

BOOK REVIEWS

CARE OF THE CRITICALLY ILL, second edition, by Stephen M. Ayres, MD, Stanley Giannelli, Jr., MD and Hiltrud S. Mueller, MD. New York, Appleton-Century-Crofts, 1974, 359 pages, $12.50

This is the second edition of a book that first appeared in 1967. As Max Harry Weil mentions in the foreword, the new edition represents tangible evidence of the evolution of a new service speciality. The first edition, by Stephen Ayres, an internist, and Stanley Giannelli, a surgeon, was the first book to focus on the critically ill patient in the categorical sense. Subsequently, Centers for the Critically Ill arose and in 1970 the Society of Critical Care Medicine was organized. In 1973, the first issue of a new journal, *Critical Care Medicine,* was published under the auspices of the society. Thus, these authors set the stage for critical care medicine in concept and in name.

The present edition, like the first, was written for all concerned with the care of extremely sick people. Basic physiologic concepts are presented in Part 1; the means of applying these concepts to patients with cardiac, respiratory or renal failure, or all three, are presented in the completely rewritten Part 2. This new edition is timely, easily read, simply illustrated and useful.

William C. Roberts, MD, FACC

MICRO-ANGIOGRAPHY OF THE LUNG IN INFANCY AND CHILDHOOD, by Bengt Robertson, MD. Stockholm, Sweden, Proprius, 1973, 86 pages

A slim volume that offers an in-depth study of the vasculature of the lung as it evolves from fetal to neonatal and later postnatal stages, this work from a pediatric pathology laboratory utilizes a combination of microangiographic and histologic techniques to obtain a two- or three-dimensional view of the vascular bed and its interconnections and relationships. Dr. Robertson describes his findings in specimens without disease of the heart or lungs and then contrasts these "normal" findings with those obtained from babies or children who died from conditions such as the idiopathic respiratory distress syndrome or congenital heart disease. He gives details of the methodology of the injection technique and preparation of the block for X-ray exposure and stereomicroscopic analysis. Photographs of the microangiogram are displayed alongside a histologic preparation of a serial section so that the two ways of viewing the structure of the vasculature can be compared.

The author then systematically describes the pulmonary and bronchial arterial systems, the arterial bronchopulmonary anastomoses, the pulmonary and bronchial venous systems and the system of pulmonary arteriovenous anastomoses. He begins each section with a brief historical re-

view of previous workers' attempts at visualization of the different components of the vascular bed and then presents his original observations using his combined methodologic approach. Where pertinent, the author extends his anatomic observations to clinical correlates, although he is careful to point out that this postmortem demonstration of patency or communication of vessels does not necessarily imply that they functioned during life as patent or anastomosing channels. However, he reasonably states that the finding of obliterated channels can be construed to mean nonfunctional.

Examples are given of severe pulmonary stenosis or atresia wherein arterial bronchopulmonary anastomoses do not become obliterated, as is usual, but remain patent and are present in large numbers. The author likens the "pruning" of the pumonary arterial tree that is observed in roentgenograms of patients with pulmonary hypertension and vascular obstruction to the plexiform lesions he found at perpendicular branch points of the pulmonary arterial system. He also comments on the natural collateral venous path of the neonatal lung whereby true bronchial veins communicate with pulmonary veins and serve to decompress the pulmonary venous system of the neonate by draining the blood into the azygos system; this may be the explanation for the usual absence of rales in the lungs of a young baby with left-sided cardiac failure. The monograph concludes with an extensive and comprehensive list of references.

Dr. Robertson accomplishes his objective of summarizing the contributions of microangiography to the field of pulmonary vascular morphology in a way that should prove interesting and helpful to pediatric cardiologists, neonatalogists, pulmonary physiologists and pathologists.

New York, New York

ADVANCES IN CARDIOLOGY: THE MYOCARDIUM, edited by Ralph Reader. Basel, Switzerland, S. Karger, 1974, 364 pages, $41.85

The proceedings of a conference on the myocardium organized by the National Heart Foundation of Australia in 1973 form the basis of the text. The presentations are by laboratory research workers and clinicians from Australia and other overseas nations who have contributed significantly to their respective areas of endeavor. The keynote address by Dr. P. I. Korner provides a succinct review of the salient points in the papers, which concern cardiac structure, excitation and conduction, contraction, muscle mechanics, myocardial metabolism, hypertrophy, coronary blood flow, clinical assessment of cardiac function, arrhythmias and coronary vein bypass surgery. The papers are well organized and the authors often present their most recent work and current theories in addition to reviewing their field of research. The photomicrographs are highly detailed, the diagrams denoting mechanisms of action are usefully designed and the presentations are selectively referenced.

This volume represents an up-to-date source of material in basic and clinical modern cardiology and will be of interest to basic researchers, clinicians and students. Although the price may reflect the inflated cost of medical research as well as devaluation of the U.S. dollar, the text is highly recommended.

Charles E. Rackley, MD, FACC
Birmingham, Alabama

MECHANISMS OF HYPERTENSION, edited by Mohinder B. Sambhi. New York, American Elsevier, 1973, 389 pages, $57.70

This volume, a record of a workshop conference on hypertension that took place in Los Angeles in 1973, is characterized by an unusually wide variation in quality, from very good to mediocre. For the internist, cardiologist or any practicing physician, the book confuses rather than clarifies the subject of hypertension. Some aspects, such as renin, angiotensin, aldosterone and prostaglandin, are overemphasized, whereas "benign" essential hypertension and its treatment are underemphasized, making much of the book irrelevant to the clinician, since 90 percent of the hypertensive patients he sees have "benign" essential hypertension. The price of the volume seems somewhat excessive since the workshop was supported by several drug companies.

The clinician will find the book confusing and unrewarding, but it will undoubtedly be of value to scientists interested in the chemistry of the hypertensive process although it contains little that is not published elsewhere.

Milton Mendlowitz, MD
New York, New York

7TH EUROPEAN CONFERENCE ON MICROCIRCULATION. PART I: METHODOLOGY ON MICROCIRCULATION, edited by J. Ditzel, MD and D. H. Lewis, MD. Basel, S. Karger, 546 pages, $104

This book comprises 80 papers presented at the 7th European Congress on Microcirculation. Part I contains a detailed explanation of methods used in the study of microcirculation and reviews the experience of internationally known pioneers in this field. The book is divided into seven chapters. The first chapter extensively discusses methods utilized for assessment of microcirculation within various organ tissues. The second deals with rheology and the influence of different physical properties of blood cells and components on microcirculation; there is a good discussion of methods and results for each study. The third chapter discusses myocardial blood flow and effects of various factors on regional coronary and collateral blood flow. The effects of intramyocardial pressure on subendocardial blood flow and the effects of clinical disease states such as left ventricular hypertrophy and acute myocardial infarction on microcirculation and coronary collateral vessels are also discussed. Other chapters deal with the use of the light microscope and electron microscope in the study of red cell agglutination and cell aggregation and general aspects of the study of microcirculation and their application in clinical states, emphasizing methods. The table of contents is somewhat limited but does not distract from the value of the book. Printing style and editing are excellent; there is sufficient information within every paper to explain its purpose, methods and conclusions.

This volume is a compendium of the study of microcirculation and is a highly specialized book of great importance to the students of this field; it is not intended for general cardiologists or clinically oriented students of cardiology. However, the highly sophisticated methods utilized and the results obtained are of value to any academician's general knowledge of microcirculation within various tissues.

Hooshang Bolooki, MD
Miami, Florida

REVIEWS IN CARDIOLOGY*

A Cooperative Program of the American College of Cardiology and the National Library of Medicine

ANEURYSM

Renal artery aneurysm. Polyaneurysmal lesion of kidney. Charron Jules, et al. **Urology** 5(1):1-11, Jan 75 (54 ref.)

ANGIOGRAPHY

Coronary arteriography. A review (first part). Johnson CD. **Bol Asoc Med PR** 65(7):158-66, Jul 73 (91 ref.)

Coronary arteriography: a review (second part). Johnson CD. **Bol Asoc Med PR** 65(10):239-45, Oct 73 (98 ref.)

AORTA

Immunologial aspects of atherosclerosis. Hollander W, et al. **Adv Cardiol** 13:192-207, 1974 (31 ref.)

ARRHYTHMIA

Electrophysiology and pharmacology of cardiac arrhythmias. V. Cardiac antiarrhythmic effects of lidocaine. Rosen MR, et al. **Am Heart J** 89(4):526-36, Apr 75 (61 ref.)

Electrophysiology and pharmacology of cardiac arrhythmias. IV. Cardiac antiarrhythmic and toxic effects of digitalis. Rosen MR, et al. **Am Heart J** 89(3):391-9, Mar 75 (44 ref.)

ARTERIES

Calendar of Continuing Medical Education Programs

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists, educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the National Committee of Continuing Education assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The National Program Committee for Continuing Medical Education of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Borys Surawicz, MD, FACC, Chairman
National Program Committee

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

1975

To be arranged individually — **Preceptorships in Cardiology.** Arthur Selzer, FACC, director. Pacific Medical Center, San Francisco, Calif.

SEPT. 8–9 — **Stress Electrocardiography.** Borys Surawicz, FACC, and Paul L. McHenry, FACC, directors. University of Kentucky Medical Center, Lexington, Ky.

SEPT. 22–26 — **Core Curriculum: Mechanisms and Therapy of Cardiac Arrhythmias.** Leonard S. Dreifus, FACC, director and Albert N. Brest, FACC and Yoshio Watanabe, FACC, co-directors. The Lankenau Hospital, Philadelphia, Pa.

SEPT. 30–OCT. 2 — **Advanced Echocardiography.** Harvey Feigenbaum, FACC, director and Betty C. Corya and James C. Dillon, FACC, co-directors. Indianapolis Hilton Hotel, Indianapolis, Ind.

OCT. 6–15 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC, director. University of Missouri—Kansas City School of Medicine, Kansas City, Mo.

OCT. 8–9 — **Louis N. Katz Symposium—Coronary Artery Disease 1975: Dilemma, Dialogue and Decision.** Sylvan Weinberg, FACC, Leonard S. Dreifus, FACC, Herman Hellerstein, FACC, directors and Homer D. Cassel, FACC, honorary program director. Good Samaritan Hospital, Dayton, Ohio

OCT. 9–11 — **New Techniques and Concepts in Cardiology: Pathogenesis, Diagnosis and Treatment of Coronary Atherosclerosis.** Stephen E. Epstein, FACC, director. Washington Hilton Hotel, Washington, D.C.

OCT. 14–16 — **Ischemic Heart Disease: Current Concepts.** William J. Grace, FACC, director and Richard J. Kennedy, FACC and James T. Mazzara, FACC, co-directors. St. Vincent's Hospital and Medical Center of New York, New York, N.Y.

NOV. 6–8 — **Core Curriculum: Phonocardiography and Pulse Recording—Workshop.** Morton E. Tavel, FACC, director. The Methodist Hospital Graduate Medical Center, Indianapolis, Ind.

NOV. 12–14 — **Core Curriculum: Echocardiography, Phonocardiography and Pulse Tracings—A Basic Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

DEC. 7–9 — **Advances in Heart Disease 1976.** Dean T. Mason, FACC, director. Fairmont Hotel, San Francisco, Calif.

DEC. 7–10 — **Structure—Function Correlations in Cardiovascular Disease.** William C. Roberts, FACC, director. Williamsburg Conference Center, Williamsburg, Va.

DEC. 10 — **Colloquia in Cardiology—Number 8: Stress and the Heart: The Influence and Management of Stress in Heart Disease.** Robert W. Oblath, FACC and Ronald Danzig, FACC, directors. Ambassador Hotel, Los Angeles, Calif.

DEC. 12–14 — **The Dwight E. Harken Symposium: Advances in the Prophylaxis and Therapy of Cardiovascular Disease.** Henry I. Russek, FACC, director. Americana Hotel, New York, N.Y.

1976

JAN. 11–13 — **Future Directions in the Management of Cardiac Disease: A Bicentennial Viewpoint.** John H. K. Vogel, FACC, director and Bruce C. Paton, FACC and James S. Forrester, co-directors. Snowmass-at-Aspen, Aspen, Colo.

JAN. 19–22 — **Core Curriculum: Pediatric Echocardiography.** Richard A. Meyer, director and Samuel Kaplan, FACC, co-director. Children's Hospital, Cincinnati, Ohio

FEB. 23–26 — **Twenty-fifth Annual Scientific Session.** Charles Fisch, FACC, president. Marriott Motor Hotel, New Orleans, La.

NEW MEMBERS

The following individuals were elected to membership in the American College of Cardiology on May 22, 1975, in the category indicated.

25th ANNUAL SCIENTIFIC SESSION
AMERICAN COLLEGE OF CARDIOLOGY

New Orleans, Louisiana **February 23–26, 1976**

- **Abstracts**
  Entries must be postmarked no later than September 22, 1975
- **Technical Exhibits**
  Deadline for requests for space: October 13, 1975
- **Scientific Exhibits**
  Deadline for requests for space: October 13, 1975
- **Young Investigators' Awards Competition**
  Entries must be postmarked no later than October 31, 1975

For application forms, write Patrick A. Ziarnik, Director, Annual Scientific Session Department, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Number pages in sequence after last page of references.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals; Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS:

31. Bellet S, Feinberg LJ, Sandberg H, et al: The effects of caffeine on free fatty acids and blood coagulation parameters of dogs. J Pharmacol Exp Ther 159: 250-254, 1968

(Author: please note that no periods are used after authors' initials.)

For books (edited by other than author of article):

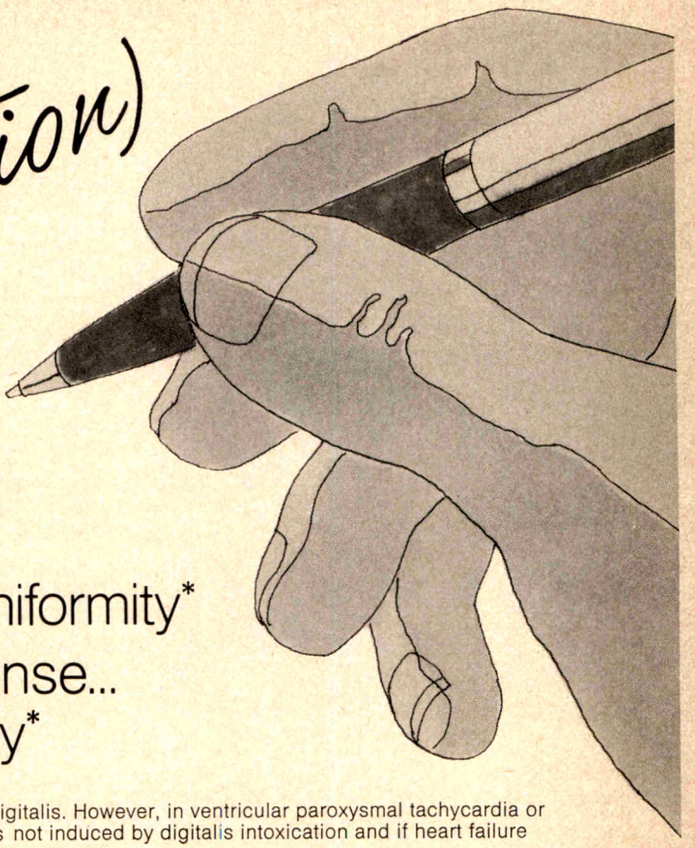
28. Schiebler GL, Van Mierop LHS, Krovetz LJ: Diseases of the tricuspid valve, chap 20. In, Heart Disease in Infants, Children and Adolescents (Moss AJ, Adams F, ed). Baltimore, Williams & Wilkins, 1968, p 134

For books (with identical author and editor):

36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)

Lanoxin
[digoxin]
(no substitution)



write it

precision quality control...
- assured tablet content uniformity*

predictable patient response...
- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

Lanoxin® digoxin

Principles of oral anticoagulation

Practical Considerations

Identifying your patient at risk of thromboembolic complications

While every MI patient is not a candidate for oral anticoagulation therapy, a history of previous infarct or angina, persistent atrial fibrillation or congestive failure, severe hypotension or shock or serious arrhythmia may increase risk of thromboembolic complications.

In addition, certain procedures often place your surgical patient, particularly if he's over 40 years of age, in the high risk category—cup arthroplasty or pelvic surgery, heart valve replacement, reparative vascular surgery.

Your geriatric patient, too, is at high risk of thromboembolism if he's suffered a fracture—especially of the hip, pelvis or a lower extremity—or if his history includes venous insufficiency.

For any of these individuals, obesity, previous episodes of venous thrombosis or pulmonary embolism and a future including prolonged bed rest all increase the risk of thromboembolic complications, and make him a candidate for oral anticoagulation.

Laboratory monitoring

For every patient receiving COUMADIN® (*crystalline* sodium warfarin), frequent laboratory monitoring is a key to effective therapy. Determine prothrombin time daily until results stabilize in the therapeutic range —1½ to 2½ times normal. Individualize dosage and administration as indicated by prothrombin time results. Determine subsequent prothrombin times periodically throughout the course of therapy.

Educating your patient

Because a patient is generally more reliable if he understands his condition and his medication, he should be made aware of the factors that may influence his prothrombin time and, therefore, his response to COUMADIN®—dietary change, travel, other medication, change in physical condition and abrupt environmental change. What's more, he should know the importance of regularly taking the exact dosage of COUMADIN® prescribed and of keeping every appointment with you and with the laboratory.

COUMADIN® is an Endo U.S. registered trademark.

Therapeutic principles put into practice

COUMADIN®

(CRYSTALLINE SODIUM WARFARIN*)

INDICATIONS Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN® is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1) central nervous system; (2) eye; (3) traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1) gastrointestinal, genitourinary or respiratory tracts; (2) cerebrovascular hemorrhage; (3) aneurysms–cerebral, dissecting aorta; (4) pericardial effusions; (5) subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis; or lack of patient cooperation. **Miscellaneous:** polyarthritis, vitamin C deficiency, major regional and lumbar block anesthesia.

WARNINGS Sodium warfarin is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN® are given together, a period of 4 to 5 hours should elapse after the last intravenous dose and 12 to 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when sodium warfarin is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Pregnancy–COUMADIN® passes through the placental barrier, and the danger of hemorrhage to the fetus exists even to the point of fatal hemorrhage **in utero,** even in the accepted therapeutic range of maternal prothrombin level. Close observation and laboratory control are essential. The newborn may be particularly sensitive to sodium warfarin. There have been reports of birth malformations in children born to mothers who have been treated with warfarin during the first trimester of pregnancy. Whether warfarin was in fact the responsible agent has not been established. Therefore, women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed. If COUMADIN® must be used during pregnancy, or if the patient becomes pregnant while taking this drug, the patient should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks. **Lactation**–coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Prolonged dietary deficiency** (cachexia, vitamin K). **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**–sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Spinal puncture. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, menometrorrhagia, allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN® , thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN® .

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders–infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency–steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cinchophen; clofibrate; COUMADIN® overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methylphenidate; monoamine oxidase inhibitors; nalidixic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates (in excess of 1 Gm/day); sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; unreliable prothrombin time determinations.

†Increased and decreased prothrombin time responses have been reported.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN® underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN® . Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (diphenylhydantoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN® (crystalline sodium warfarin) include:

1. Minor or major hemorrhage from any tissue or organ–which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and an extremely rare reaction consisting of hemorrhagic infarction and necrosis of the skin.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN® patient aids are available to physicians on request.

The administration and dosage of COUMADIN® must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K-dependent factors, namely Factors VII, IX, X and II, the factors affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN® should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic prothrombinopenia are 1½ to 2½ times the normal prothrombin time (e.g. 21 to 35 seconds, with a control of 14 seconds).

Induction–40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Maintenance–Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy–The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery–The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN® be adjusted to maintain the prothrombin time at approximately 1½ to 2 times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN® with Heparin–Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in situations of great emergency to administer sodium heparin initially along with COUMADIN . The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe. It should be noted that heparin may affect the prothrombin time; and therefore, when patients are receiving both heparin and COUMADIN® , the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, and preferably 4 to 5 hours after the last intravenous injection or 12 to 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN® (crystalline sodium warfarin), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN® may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN® administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN® (crystalline sodium warfarin). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white, 25 mg red. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous sodium warfarin lyophilized for intravenous or intramuscular use in a box of 6 units. 50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide, accompanied by a 2 ml ampul Sterile Water for Injection. 75 mg: Unit consists of 1 vial, 75 mg; sodium chloride, 15 mg; thimerosal, 0.3 mg. pH is adjusted with sodium hydroxide, accompanied by a 3 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Rev. April, 1975

*Present as crystalline sodium warfarin isopropanol clathrate.

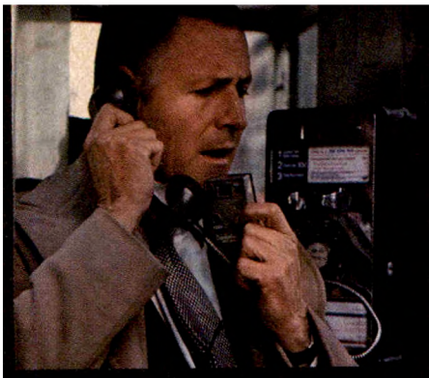
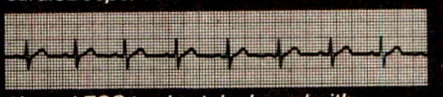
This is the heart of the new CardioBeeper® system.
TEST
BEEP
ECG
CardioBeeper® PM
PACER MONITOR
It can change your concept of patient care.



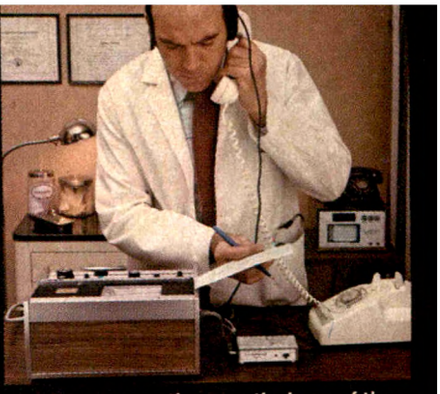
The CardioBeeper® heart monitor and CardioBeeper®-PM pacer monitor are unlike any heart monitoring instruments now in use. They're five ounces, pocket-sized and relatively inexpensive. Yet they are unparalleled in electronic sophistication. The CardioBeeper monitors are engineered to permit your coronary patient, within seconds, to telephonically transmit his heart rate and rhythm or ECG. And to allow your pacemaker patient to transmit pacemaker rate interval and artifact, as well as confirmation of battery integrity and ventricular capture. At any time. From any conventional telephone. If indicated, you are then able to institute immediate, often life-sustaining action.

Pacemaker tracing telephoned with CardioBeeper-PM.



Normal ECG tracing telephoned with CardioBeeper.

The CardioBeeper system is simple to use. Your patient need not undress. Or be bothered with paste, gels or straps. He simply places a reusable electrode in each bare armpit. And to transmit, he merely holds the CardioBeeper



monitor next to the mouthpiece of the phone while touching a button. *Physician and patient stay in constant voice contact while sending and receiving.*

You can immediately receive the telephoned data as a series of audible "beeps" indicating each QRS complex or pacemaker spike. To receive a permanent record of ECG or pacemaker artifact, just connect a CardioBeeper® ECG Decoder to your telephone and to any conventional ECG machine. Or instead, connect a CardioBeeper® Decodalyzer to your phone to obtain a visual readout of heart rate or pacemaker rate in BPM, interval count in msec. or a direct ECG tracing for your records.

In life-threatening emergencies or routine checks, no remote cardiac monitoring instruments available today at any cost can rival the revolutionary CardioBeeper system. For further information, simply contact your Wyeth representative or Wyeth Laboratories, Box 8299, Philadelphia, Pa. 19101.

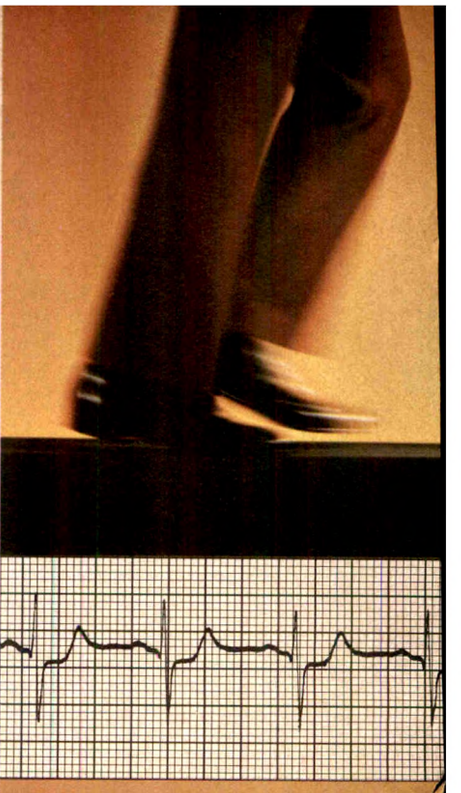
Standing, at rest, V-5, HR-74. American's Stress Test Electrode supplies immediate base line stability. Testing with a narrow, drift free base line can begin as soon as the self-adhering, silver/silver chloride electrodes have been applied to the patient and connections made to your monitoring equipment.

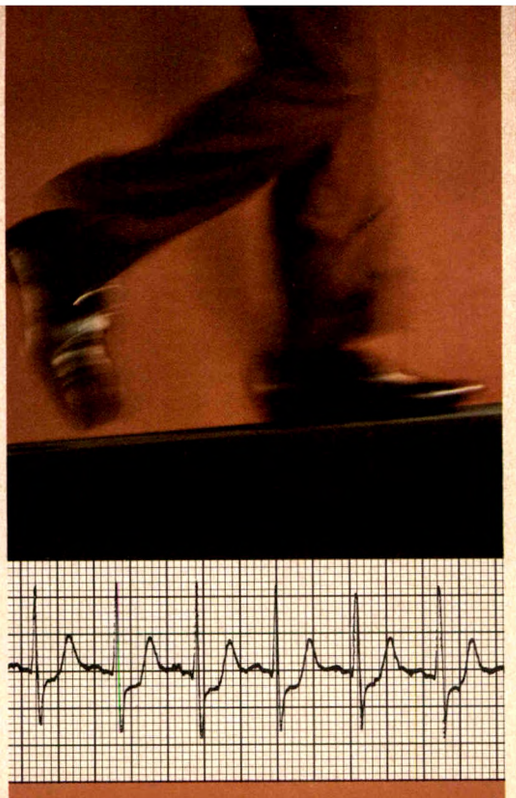
4th Minute at 2 mph, 0% Grade, V-5, HR-75. Base line stability is maintained because of the electrode's gel retaining cup and gel impregnated foam pad; the gel pad is slightly oversize to assure positive, continuous pressure at the electrode-skin interface. The result: virtual elimination of base line instability and motion artifact.



4th Minute at 3 mph (8th minute of test), 0% Grade, V-5, HR-83. (The patient's ECG indicates 1 mm of S-T depression.) Fully shielded cable and leadwire provide an effective barrier to the electrical interference that might otherwise mask small amounts of S-T depression.

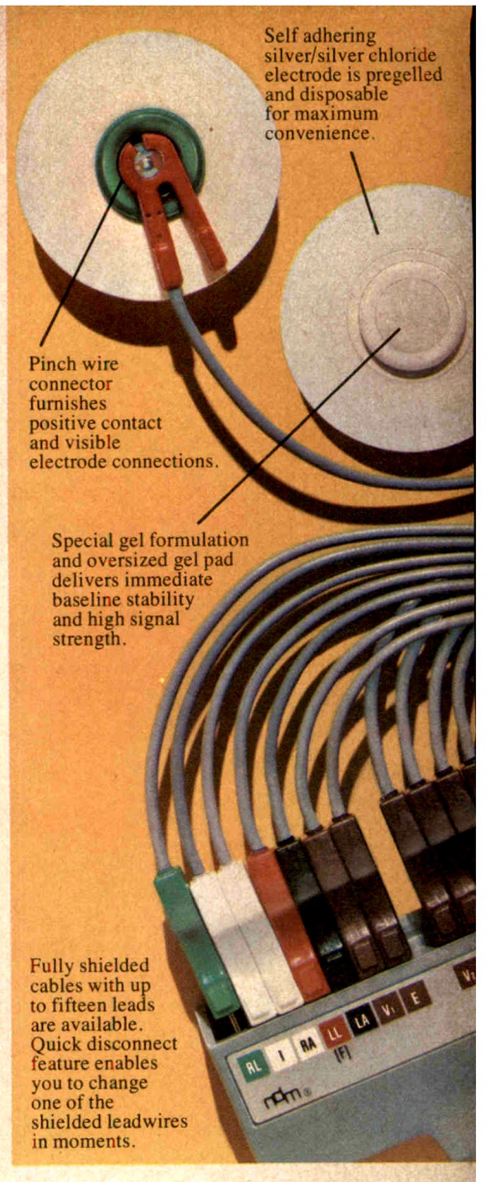
Do your stress test ECGs show everything you need to see?

n Minute at 3 mph (12th minute test), 5% Grade, V-5, HR-117. -T depression increases to 2.5 mm.) en at high work loads, the Ameri- n Stress Test Electrode and fully ielded cable system delivers a stable se line and noise-free signal.



4th Minute at 3 mph (16th minute of test), 7.5% Grade, V-5, HR-135. (S-T depression drops to 2.0 mm.) Long test procedures seldom affect the electrode's contact with a patient's skin; trace quality remains high, even with patients who perspire heavily.

(Because of this electrode's special gel formulation, application periods of longer than four hours are not recommended.)



Compare the stress test electrocardiograms you have been getting with those reproduced above.* There's a reason for the unusually high quality of the ECG traces shown: The patient was being monitored with American's Stress Test Electrode and fully shielded cable system.

If you've been diagnosing from stress test electrocardiograms that display wide or unstable base lines, severe motion artifact or possible hidden S-T depression, please contact us. We think we can help.

*Examples shown were produced under clinical conditions during an actual stress test procedure using the American Stress Test Electrode system.

We invite you to try the first electrode/leadwire/cable system designed to match the "no-compromise" nature of exercise stress testing. The fully shielded patient cable is adaptable to your present monitoring equipment, regardless of its make.

Please contact your American Hospital Supply or NDM representative to arrange a no obligation clinical trial, including a total inservice for your staff. American will supply electrodes, fully shielded cables and fully shielded, quick disconnect leadwires adaptable to your present monitoring equipment during the trial period.

For more information and a complimentary copy of our stress test technician's primer *How to Take the Strain out of Stress Testing,* write to: NDM, Department J, 3040 East River Road, Dayton, Ohio 45439.

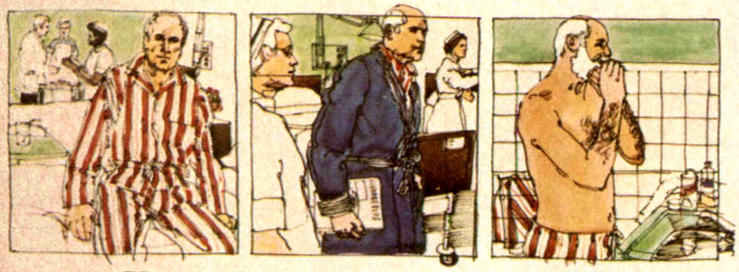
If psychic tension interferes with cardiac rehabilitation, here's how Valium® can help.
(diazepam)



During hospitalization, Valium (diazepam) can relieve psychic tension that can disrupt bed rest and interfere with the rehabilitation program.

After the MI patient is stabilized, a certain amount of psychic tension is to be expected. Your reassurance, counseling and enlistment of family support can often minimize its effects. However, in some instances, the patient's thoughts may dwell constantly on his condition and how it will affect his life, thus producing excessive psychic tension that may present special problems. He may feel overwhelmed and be so burdened by these tensions that he is unable to rest and unable or unwilling to begin a program of rehabilitation. Under these circumstances, Valium® (diazepam) can often be a beneficial adjunct.

Valium can calm the cardiac patient and help reduce his psychic tension to appropriate levels. Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticoagulants, anticholinergics and antacids. Careful consideration should be given to the pharmacology of agents used with Valium, particularly those which may potentiate its action.

During convalescence at home, Valium (diazepam) can reduce excessive anxiety that may hinder participation in active rehabilitation.

Your counseling and the family's support do much to control the anxieties that may interfere with this stage of convalescence—a time when you may wish to encourage a gradual increase in activity. But in some patients, excessive anxiety may retard general progress. For them, Valium can be beneficial during the post-hospital transition to full ambulation. And, because the convalescent cardiac patient may be particularly prone to excessive tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *b.i.d.* or *t.i.d.* schedule can reduce these symptoms and thus may encourage sleep. Therapy with Valium should be discontinued when symptoms have been reduced to tolerable levels.

What an informed cardiac patient should know about Valium therapy.

The cardiac patient should know that he can generally expect Valium to help relax and calm him so that he won't feel so overwhelmed by his tension and anxiety. An explanation of the importance of the dosage regimen you prescribe may go a long way to ensure his cooperation. As with all CNS-acting agents, the patient taking Valium should be cautioned against driving or operating dangerous machinery.

Valium® (diazepam)

2-mg, 5-mg, 10-mg tablets can relieve the cardiac patient's undue psychic tension

ROCHE

For a summary of product information, see the following page.

Valium® (diazepam)
2-mg, 5-mg, 10-mg tablets

can relieve the cardiac patient's undue psychic tension

Prompt and Effective Response Valium acts promptly to help relieve psychic tension in the cardiac patient.

Wide Margin of Safety At recommended dosages, oral Valium is generally well tolerated and does not significantly affect respiration, pulse or heart rate.

Flexible Dosage Available as *scored* tablets, oral Valium allows dosage to be easily readjusted to suit patients' changing needs.

Predictable Pharmacokinetically Pharmacokinetic studies of Valium demonstrate a highly predictable pattern of absorption, distribution, metabolism and excretion.

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

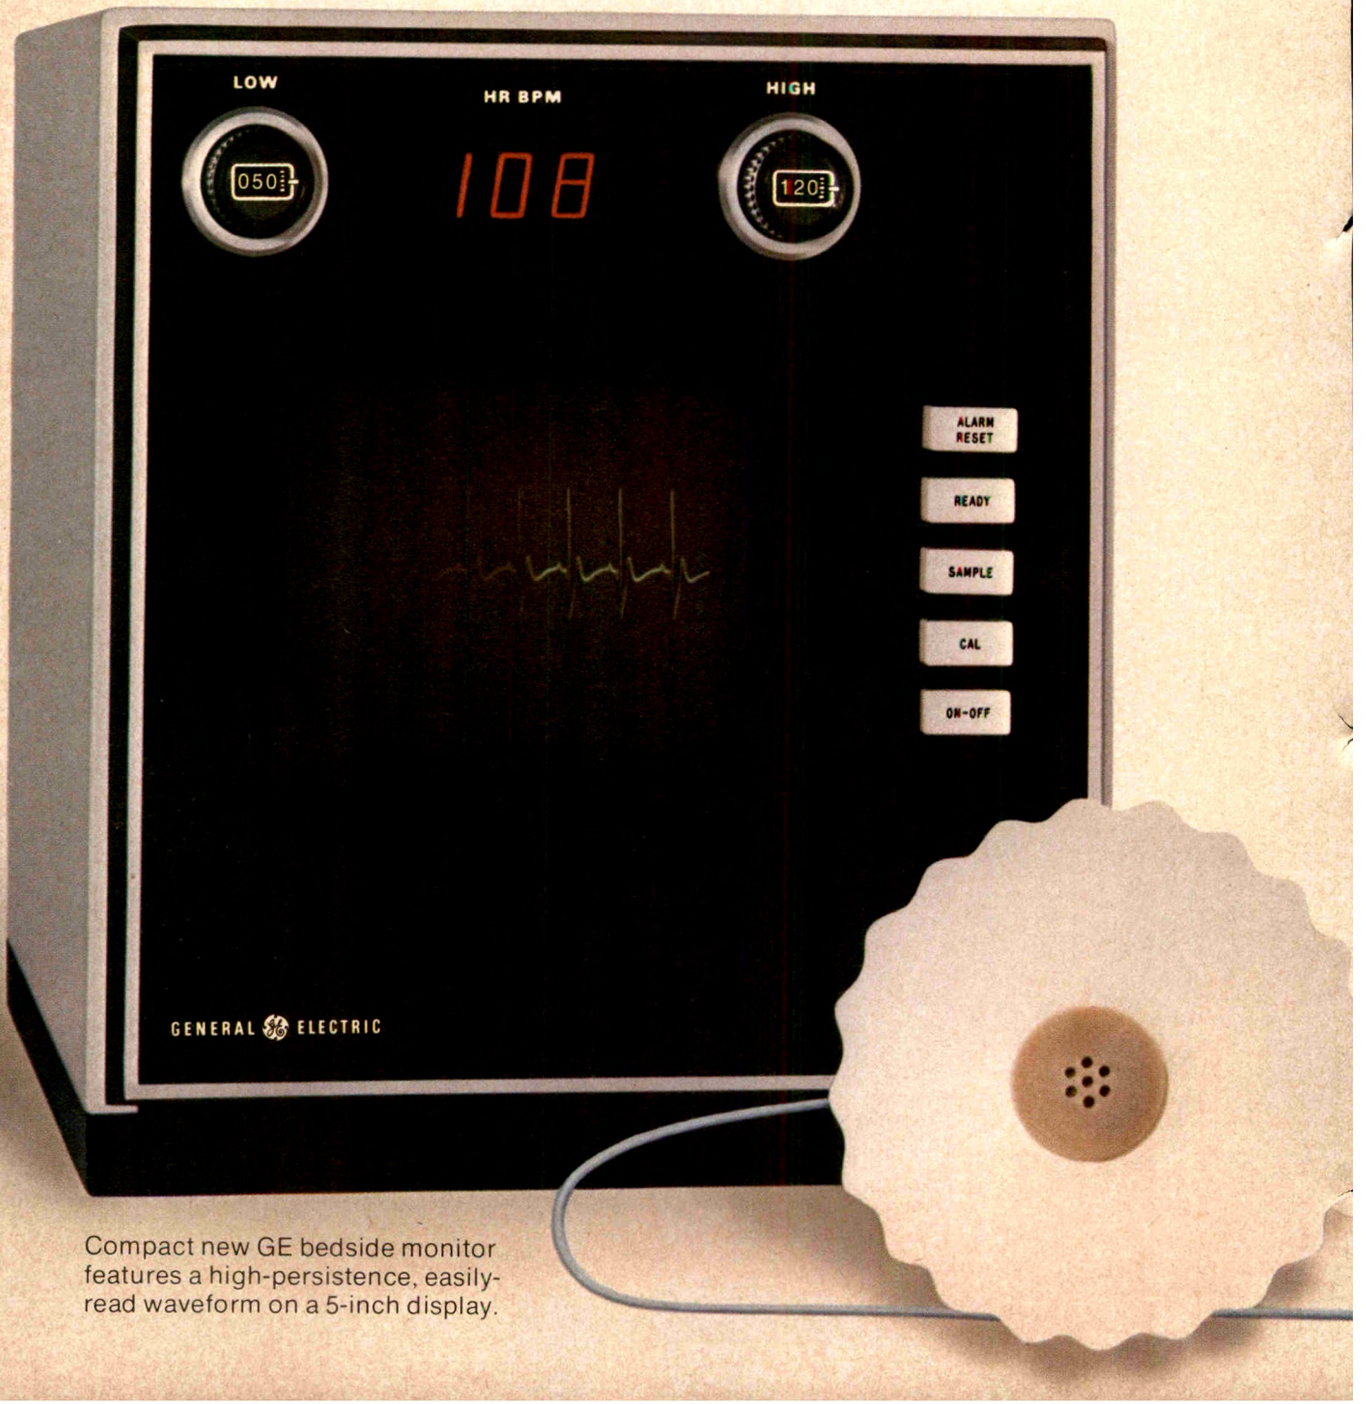
How to get less for your money in monitoring equipment...



Compact new GE bedside monitor features a high-persistence, easily-read waveform on a 5-inch display.

1. Less signal drift.

Accurate patient monitoring begins with signal capture, and only General Electric offers Daisy™ electrodes, recognized by the industry for long-term monitoring effectiveness. Silver-silver chloride sensing element minimizes offset potentials and drift.

2. Less noise.

GE's sophisticated signal recognition circuitry and artifact rejection separate the signal from the noise, presenting meaningful ECG complexes and digitally displayed data necessary for patient management.

3. Fewer false alarms.

Because GE compensates for T waves, noise, and shifts in signal level, you're not plagued by false alarms. Should a lead fail, you're told just that, so you know it's not a patient problem.

4. Fewer missed signals.

Automatic gain control adjusts to the R waves as they decrease or increase in size, thus accurate heart rates are provided without constant adjustment.

5. Fewer controls.

Many functions such as g
detection, graph recordir
overload recovery are aut
Fewer adjustments. Easie
minimum staff training.

Peritrate® SA Sustained Action
(pentaerythritol tetranitrate) 80mg

CAUTION: Federal law prohibits dispensing without prescription.

Description: Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.

(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop.

(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later. Tablets should not be chewed.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 (N 0047-0004-51) and 1000 (N 0047-0004-60). Also in unit dose—package of 10 x 10 strips (N 0047-0004-11).

Additional Dosage Forms: Peritrate 20 mg—light green, scored tablets in bottles of 100 (N 0047-0001-51) and 1000 (N 0047-0001-60). Also in unit dose—package of 10 x 10 strips (N 0047-0001-11). Peritrate 10 mg—light green, unscored tablets in bottles of 100 (N 0047-0007-51) and 1000 (N 0047-0007-60).

Full information is available on request.

Defense against attack.

For over 22 years, Peritrate® has been considered by many physicians as one of the top defensive measures for patients with angina pectoris. In many patients Peritrate used prophylactically helps decrease the frequency and severity of angina attacks.* With minimal side effects.

Peritrate can also help reduce nitroglycerin requirements and, therefore, nitroglycerin side effects. Is it any wonder so many physicians continue to prefer Peritrate prophylaxis for their angina patients?

LONG-ACTING PROTECTION AGAINST ANGINA PAIN*

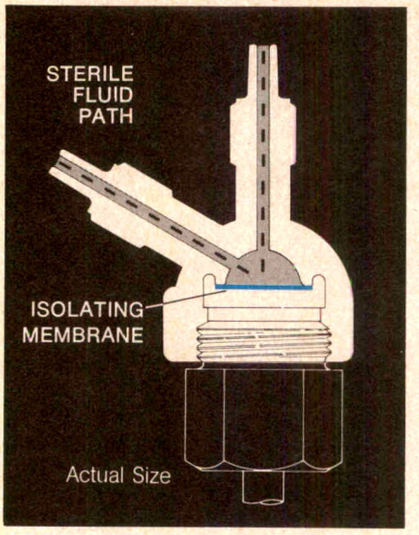
The Great Wall of China, an immense 1,400-mile-long man made barrier 20 to 30 feet high and 15 to 20 feet thick, helped defend China from the attack of Mongol hordes for more than 2,000 years.

*The drug has been evaluated as possibly effective for this indication.
See brief summary.

With the introduction of the new Sterile Disposable Domes, Bentley Trantec offers safety, convenience and economy, previously unavailable. This has been accomplished by designing an isolating polycarbonate membrane into the dome itself. *Only* this membrane touches the transducer sensing surface, isolating the fluid in the dome from the non-sterile surface. It does not affect the sensitivity or fidelity of the transducer and the possibility of cross-contamination is completely eliminated.

Bentley Trantec Domes also allow immediate and continuous use of the transducer. With each patient, simply change domes – no further need for time consuming cleaning, wrapping, sterilizing or storing.



With the purchase of a Bentley Trantec Pressure Transducer and the coupon below, we'll give you a carton of six individually packaged domes. If you already have a Bentley Trantec Pressure Transducer we'll send you six domes free *without* an additional purchase. Fill out and send today; this offer is limited.

BLOOD FLOW

for clinical applications

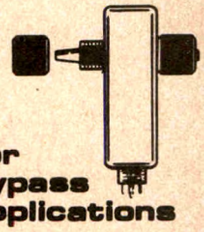
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

New books from Lea & Febiger . . . have you sent us the order for your copies?

SURGICAL TREATMENT OF CONGENITAL HEART DISEASE, 2nd ed.

Cor triatriatum, scimitar syndrome, parachute mitral valve and other anomalies are detailed by history, clinical and laboratory diagnosis, surgical indications, operative technique, complications and results. Emphasis is on operative procedure with all variations thoroughly described.

By **GRADY L. HALLMAN, M.D.** and **DENTON A. COOLEY, M.D.,** both of The Texas Heart Institute, Houston, Texas. *204 pp. (8½ x 11), numerous illus., 1975, Ready Soon.*

CARDIAC EMERGENCY CARE

A complete summary discussing acute pulmonary edema, pulmonary embolism and infarction, cardiogenic shock, pre-hospital management of acute myocardial infarction, coronary care unit, intermediate coronary care unit, tachyarrhythmias, bradyarrhythmias, direct current shock, and other important topics.

Edited and with contributions by **EDWARD K. CHUNG, M.D.,** Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania. (18 Contributors). *347 pp., 88 illus., 1975, $14.50.*

PROGRESS IN CARDIOLOGY. 4

Discussed here is the role of echocardiography in explaining heart sounds and murmurs, prolapse of the mitral leaflet syndrome, mechanism and recognition of digitalis toxicity, pediatric coronary artery disease, and prevention of heart cell death.

Edited by **PAUL N. YU, M.D.,** University of Rochester School of Medicine and Dentistry, Rochester, New York; and **JOHN F. GOODWIN, M.D.,** Royal Postgraduate Medical School, London, England. (17 Contributors). *224 pp. (7 × 10), illus., 1975, Ready Soon.*

CARDIAC CATHETERIZATION AND ANGIOGRAPHY

This text begins with a clearly written and well illustrated section on catheter placement. Subsequent sections cover basic knowledge in areas of hemodynamic principles and angiographic techniques.

Edited by **WILLIAM GROSSMAN, M.D.,** Peter Bent Brigham Hospital, Boston, Massachusetts. (24 Contributors). *339 pp. (7 x 10), 152 illus., 1974, $24.50.*

INDEX OF SUSPICION IN TREATABLE DISEASES

This is a unique book providing a listing of disorders in which it is imperative to administer a particular form of early treatment. Brevity, practicality and unique form of presentation make this an excellent source of information.

Edited and with contributions by **ORVILLE HORWITZ, M.D.** and **JOSEPH H. MAGEE, M.D.,** both of the University of Pennsylvania School of Medicine, Philadelphia. (65 Contributors). *574 pp. (7 × 10), 66 illus. (1 in color), 1975, $29.50.*

GUIDELINES FOR GRADED EXERCISE TESTING AND EXERCISE PRESCRIPTION

Details safe and effective graded exercise testing, exercise prescription and exercise programs for patients with cardiopulmonary disease. Exercise risk, screening and supervision, drugs and emergency procedures, and intensity and duration of exercise are thoroughly covered.

Edited by the **AMERICAN COLLEGE OF SPORTS MEDICINE,** Madison, Wisconsin. Prepared by the Task Force of the Postgraduate Education Committee. *116 pp. (5¼ x 7¾), paperback, 1975, $4.00.*

A PRIMER OF WATER, ELECTROLYTE AND ACID-BASE SYNDROMES, 5th ed.

In this extensively revised new edition, Dr. Goldberger maintains the clinical approach to these disorders and describes them in terms of pathophysiology, etiology, symptoms, signs, laboratory findings, and diagnosis and treatment.

By **EMANUEL GOLDBERGER, M.D.,** Albert Einstein College of Medicine, New York, New York. *604 pp. (5¼ x 7¾), illus., 1975, Ready Soon.*

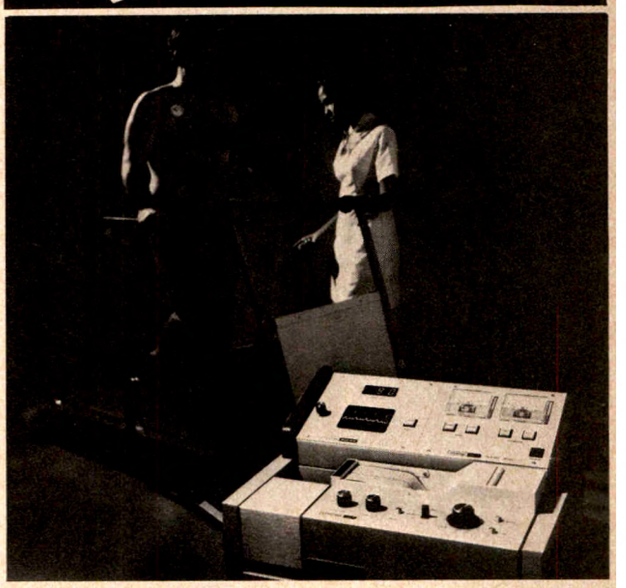
Cambridge STS STRESS without strain



A new, easy-to-operate exercise electrocardiography system designed to stress the patient without straining the physician or the budget.

Cambridge STS is an integrated, easy-to-use system intended for hospital, health care, and athletic facilities, as well as for the practitioner with a limited budget. STS reliably produces exercise test results of excellent quality. It is designed to function superbly as a multistage exercise test system in office or hospital, as a standard, mobile electrocardiograph, or as a rate meter/monitor in the ER, ICU, or CCU.

- Strip chart recorder, ECG monitor, heart rate meter, and optional treadmill meters and controls all located in single mobile console where entire test protocol is controlled, monitored, and recorded.
- **Digital** heart rate meter and **non-fade** ECG monitor for easy daylight viewing.
- Optional recorder-programmer helps automate graded testing.
- Patient cable and electrodes specially designed for dynamic ECGs.
- VS-4S electrocardiograph meets all AHA specs.
- Existing VS-4 electrocardiographs easily retrofitted for inexpensive upgrading for exercise **and** rest electrocardiography.

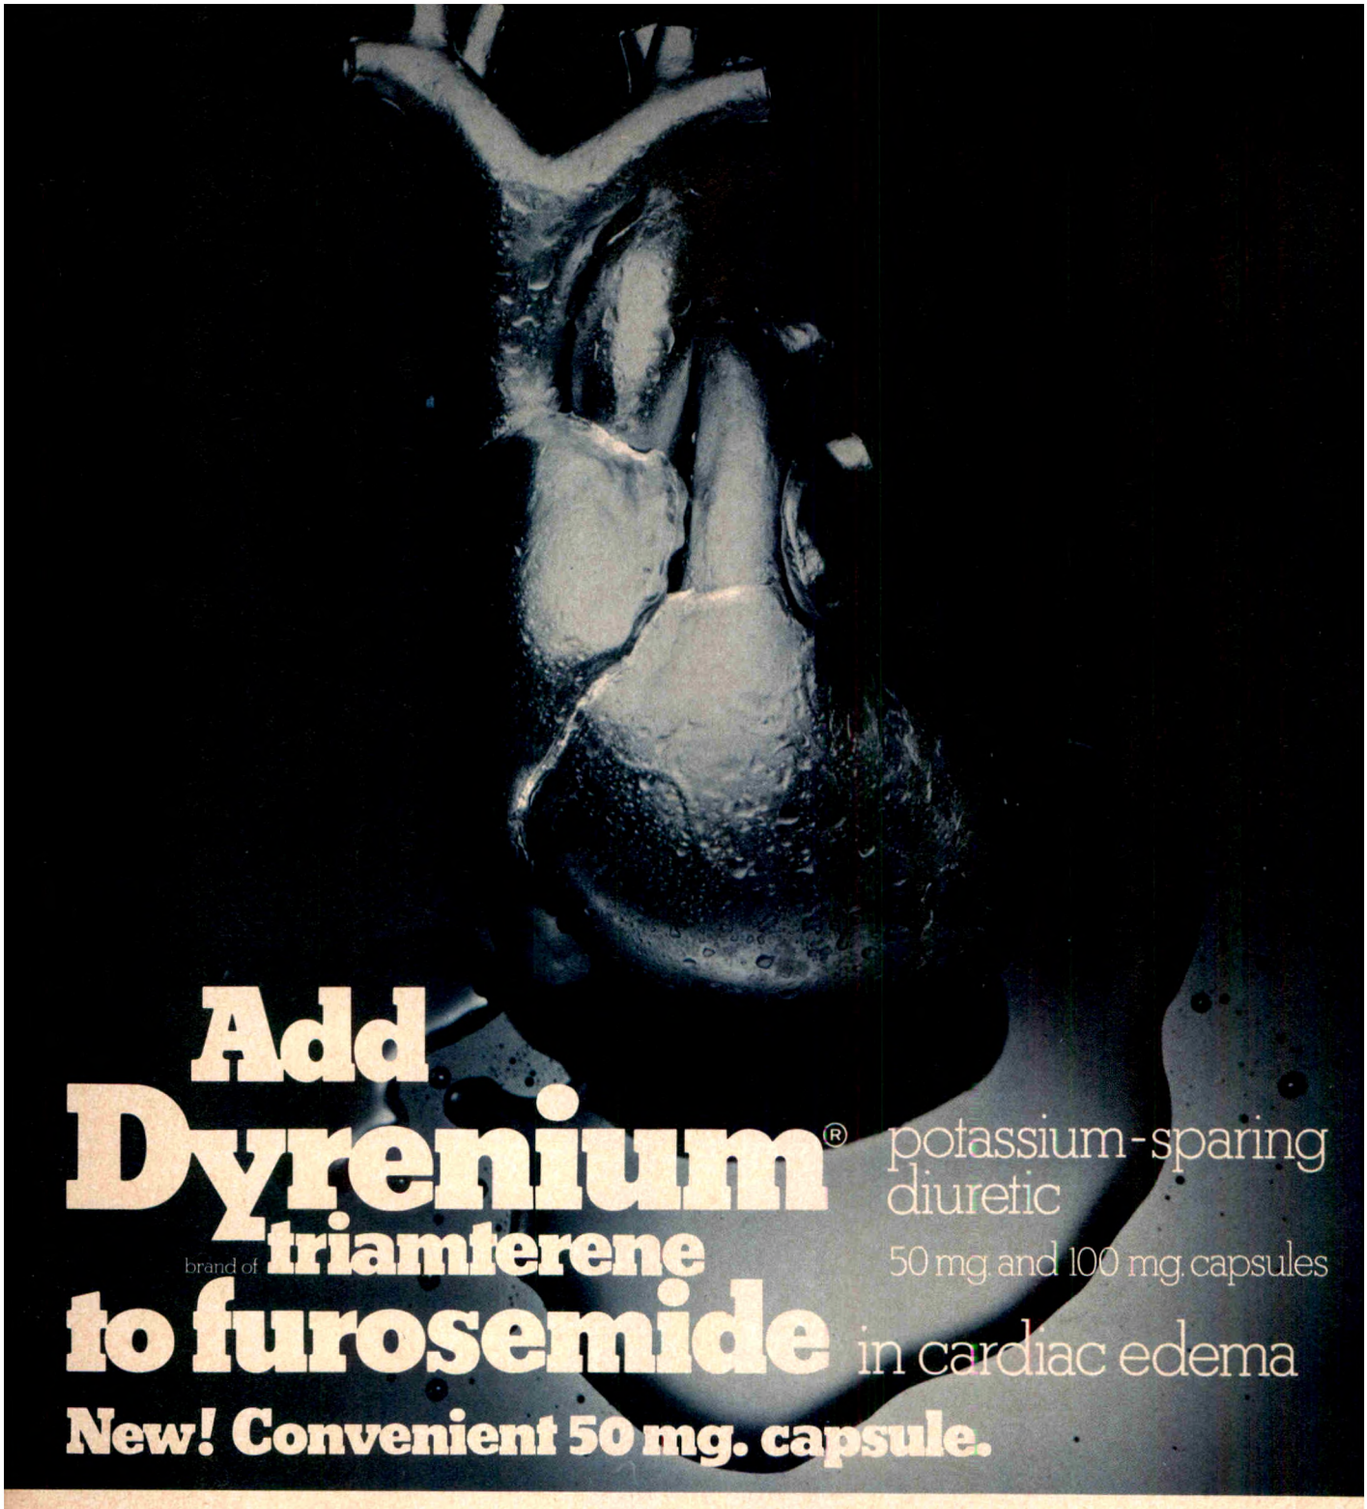
Cambridge *first in electrocardiography*



"First dose" natriuretic effect of concomitant 'Dyrenium' (50 or 100 mg.) and furosemide (40 mg.) was up to four times as great as that of furosemide (40 mg.) alone, compared to baseline values, in 10 normal volunteers.[1] 'Dyrenium' (50 or 100 mg.) blocked the kaliuretic effect of furosemide in 7 subjects. Patients with fluid overload and abnormal physiology may respond differently from volunteers; therapy should be titrated to the individual.

1. Stote, et al.: Effect of Triamterene on Furosemide Induced Kaliuresis in Normal Volunteers, J. Int. Med. Res. 2:379-83, 1974.

Hyperkalemia can occur with any K^+-sparing agent, but it is rare if urinary output is adequate. Serum K^+ and BUN should be checked periodically; elderly, diabetics, or patients with suspected or confirmed renal insufficiency should be observed closely. When 'Dyrenium' is given with furosemide, K^+ supplements should be discontinued, and not given unless hypokalemia develops or dietary potassium intake is markedly impaired.

See facing page for indications and brief summary of prescribing information.

Dyrenium®

brand of **triamterene**

Potassium-sparing adjunct to furosemide in cardiac edema.

Now in 50 mg. and 100 mg. capsules.

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: Edema associated with congestive heart failure, cirrhosis and nephrotic syndrome; steroid-induced edema, idiopathic edema, edema due to secondary hyperaldosteronism and edema resistant to other diuretic therapy.

Contraindications: Severe or progressive kidney disease or dysfunction (possible exception: nephrosis). Severe hepatic disease. Pre-existing elevated serum potassium. Hypersensitivity to the drug. Continued use in developing hyperkalemia. Do not give potassium supplements, either by drug or by diet.

Warnings: Observe regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Blood dyscrasias have been reported. Check BUN and serum potassium periodically, especially in the elderly, diabetics, and those with suspected or confirmed renal insufficiency. Use in pregnancy only when essential to patient welfare.

Dyrenium (triamterene, SK&F) and spironolactone are not usually used concurrently; if they are, however, frequent serum potassium determinations are required.

Precautions: If hyperkalemia develops, withdraw the drug. The following may also occur: electrolyte imbalance, low-salt syndrome (with low salt intake), reversible mild nitrogen retention, decreasing alkali reserve with possible metabolic acidosis. Do periodic hematologic studies in cirrhotics with splenomegaly. Concomitant use with antihypertensive drugs may result in an additive hypotensive effect. When 'Dyrenium' is to be discontinued after intensive or prolonged therapy, withdraw gradually because of possible rebound kaliuresis.

Adverse Reactions: Diarrhea, nausea and vomiting (may indicate electrolyte imbalance), other gastrointestinal disturbances, weakness, headache, dry mouth, anaphylaxis, photosensitivity, elevated uric acid, rash.
Note: When combined with another diuretic, the initial dosage of each agent should be lower than recommended.

Supplied: 50 mg. capsules, in bottles of 100; 100 mg. capsules in bottles of 100, in Single Unit Packages of 100 (intended for institutional use only).

Now there's another way
Emergency treatment for life-threatening ventricular arrhythmias.

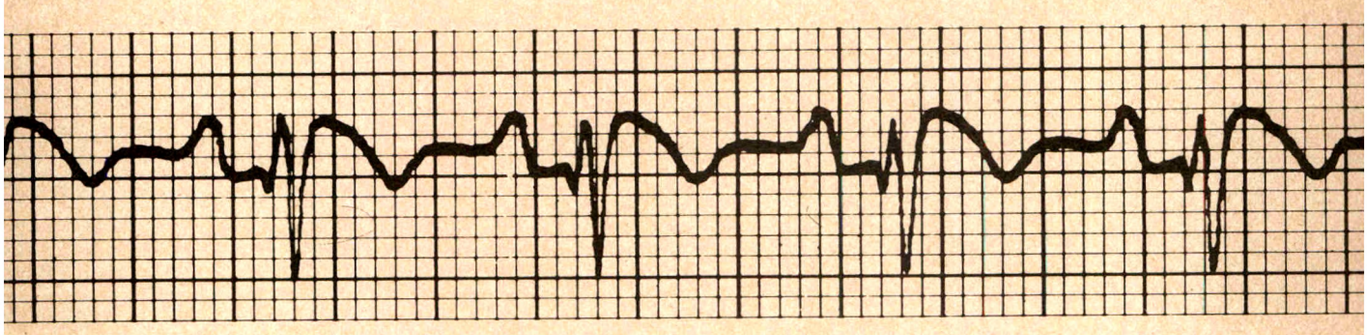
When an appropriate dose of Xylocaine is administered by the intramuscular (deltoid) route, effective antiarrhythmic blood levels are usually attained within 5-15 minutes and may persist for 60-90 minutes. Xylocaine Intramuscular is specifically indicated in the acute management of life-threatening ventricular arrhythmias when justified:

- by a physician when ECG equipment is not available to verify diagnosis, but potential benefits may outweigh possible risks
- by a physician when IV facilities are not available
- by paramedical personnel in a mobile coronary care unit directed by a physician viewing a transmitted ECG

New Xylocaine® (lidocaine) HCl

Intramuscular injection for cardiac arrhythmias

Usual dosage: For the average 150 lb man, 3 ml (300 mg) injected in deltoid muscle. See complete instructions in package insert.



Before prescribing or administering, please consult complete product information, a summary of which follows:

Contraindications: Patients with known hypersensitivity to local anesthetics of the amide type, and patients with Adams-Stokes syndrome or severe degrees of sinoatrial, atrioventricular or intraventricular block.

Warnings: ASPIRATE FREQUENTLY TO AVOID INADVERTENT INTRAVASCULAR ADMINISTRATION.

ECG monitoring is recommended. However, in emergency situations when a physician suspects ventricular arrhythmia and ECG equipment is not available, a single dose may be administered when the physician determines potential benefits outweigh possible risks. If possible, have emergency resuscitative drugs and equipment immediately available to manage potential adverse reactions involving cardiovascular, respiratory, or central nervous systems.

Intramuscular use of Xylocaine® may result in increased creatine phosphokinase levels and compromise the use of this enzyme determination, without isoenzyme separation, in diagnosing acute myocardial infarction.

Pediatric use is not recommended.

Precautions: Observe usual precautions in the presence of impaired renal or hepatic function, hypovolemia and shock, and all forms of heart block.

Adverse Reactions: Although serious adverse reactions to Intramuscular Xylocaine have been rare, the following previously have been reported following lidocaine administration:

1. Central Nervous System—lightheadedness; drowsiness; dizziness; apprehension; euphoria; tinnitus; blurred or double vision; vomiting; sensations of heat, cold, or numbness; twitching; convulsions; unconsciousness; respiratory depression and arrest.
2. Cardiovascular System—hypotension; cardiovascular collapse; bradycardia which may lead to cardiac arrest.

Cross-sensitivity with procainamide or quinidine has not been reported.

Soreness at injection site, occasionally.

Supplied in 5 ml ampules, in cartons of 10. Each ml contains 100 mg of Xylocaine HCl and sodium hydroxide to adjust pH. A 3 ml injection provides the recommended dose.

FOR INTRAMUSCULAR USE ONLY.

Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

Sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release

In titrating dosage, availability of different strengths "... is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg) Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg) Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12 hour intervals.
Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

NOW-ACCURATE AND COMPLETE CARDIAC MONITORING DURING EXERCISE!

The Collins HEART RATE MONITOR SYSTEM is ideal for patient monitoring during exercise on Treadmills or Ergometers. It is a Modular System which offers any combination of available components. One large, modern console houses all of the components and provides panel mounted jacks for all patient pickup leads. Hand held remote Treadmill controls allow for operator mobility during testing. The Collins Heart Rate Monitor System can be comprised of any or all of these Modules:

EKG MODULE
LVET (Left Ventrical Ejection Time) MONITOR MODULE
RECORDER MODULE
TREADMILL/ERGOMETER CONTROL MODULE
PROGRAMMER MODULE

Designed for use with either Collins Treadmills or Ergometer, the Heart Rate Monitor System is a giant step toward providing investigators with the necessary sophisticated tools they require. Write for a complete detailed brochure to Warren E. Collins, Inc., 220 Wood Road, Braintree, Mass. 02184.

Unique long-acting nitrate formulation. proved in years of practice

Nitrol® Nitroglycerin Ointment 2%

1955 "Because of the ineffectiveness of the conventional measures, it was suggested that a 2% nitroglycerin ointment [Nitrol] be applied to the skin....It is the authors' impression that there has been definite benefit from this therapy, when used together with all other measures for the treatment of angina pectoris....The principle of slower absorption with resulting prolonged action of an effective coronary vasodilator would seem to deserve further trial in this condition."[1]

1974 "...nitroglycerin ointment [Nitrol] exhibited a consistently prolonged beneficial influence that, in practice, has never been demonstrated for any other nitrate used in the therapy of angina."[2]

Composition: Nitroglycerin 2% in lanolin-petrolatum base. **Administration:** From 1/2 to 2 inches applied to desired skin area by means of Appliruler supplied. Adjust to individual need, starting in lower range. **Side effects:** Headache indicates overdose. Dizziness on standing may be the result of postural hypotension. **Contraindications:** Marked anemia, increased intraocular pressure or increased intracranial pressure. **Supplied:** 1-oz. or 2-oz. tubes. **Caution:** Federal law prohibits dispensing without prescription.

City/State/Zip_____

AJC875

New! Ambulatory Blood Pressure Recorder.

Smaller, lighter compact one-piece unit weighs 25 ounces.

The Remler patented Ambulatory Blood Pressure Recorder has been in use for more than ten years by leading physicians and research institutions throughout the world.

Now, by miniaturizing circuits and components, we have produced a smaller and easier to wear single-unit version that weighs only 25 ounces.

This new Model M-2000 records blood pressures during the wearer's working or leisure day. Wearing this unobtrusive, lightweight device on a belt, any patient can easily record blood pressure data onto the micro-cassette as many as fifty times daily. This method eliminates the pressor effect of an observer's presence.

The compact recording unit plugs into the physician's corresponding decoder for quick direct decoding on a permanent paper transcript which can be evaluated by the physician for indications of varying systolic and diastolic pressures and heart rate. The decoder's headphones aid in interpretation of Korotkoff sounds in the area of diastolic pressures.

The Remler system is especially useful in determining the efficacy of medication in the treatment of hypertension.

Please return the coupon for complete information.

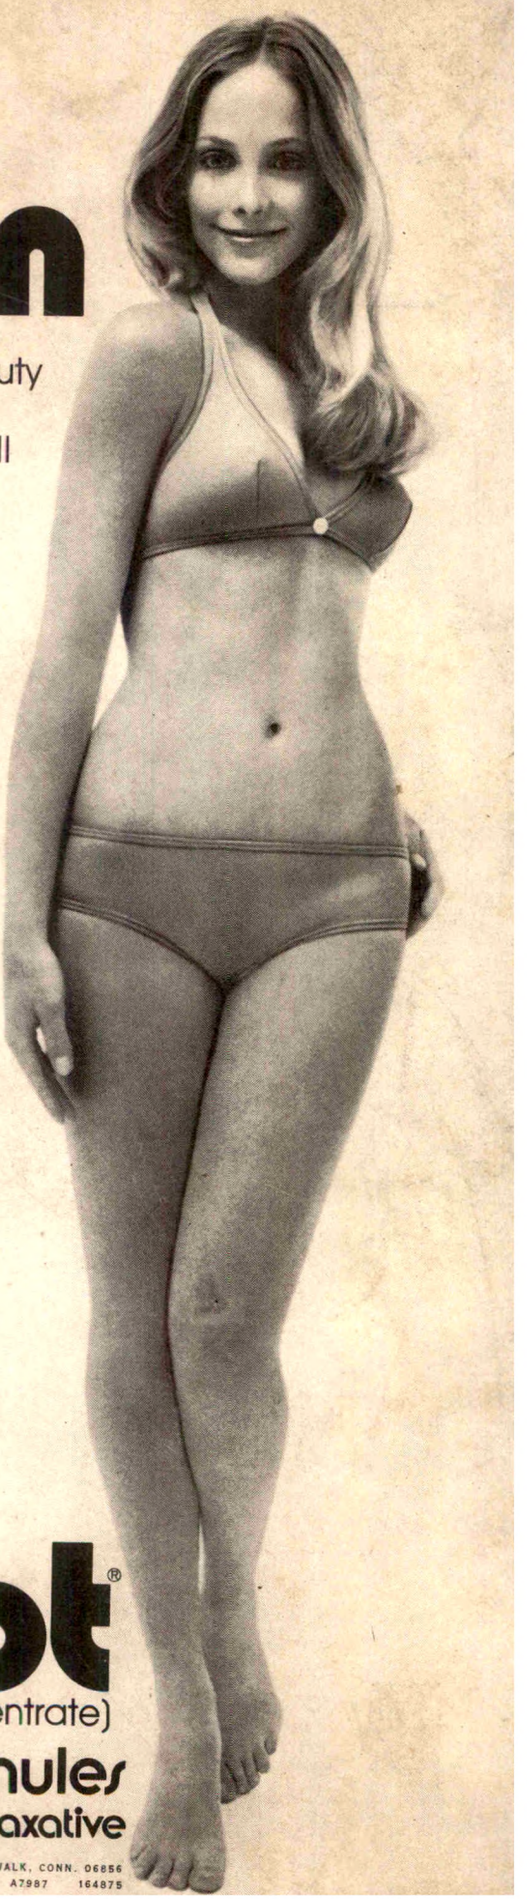
Natural distinction



Wholesome and unadorned young beauty impresses the eye with its natural distinction. Among medicinals, such natural distinction will be found in SENOKOT Tablets/Granules.

Standardized senna concentrate has two claims to natural distinction. In SENOKOT Tablets/Granules, it is standardized for uniform action. And it is prepared from the deseeded pod of Cassia acutifolia, discarding the leaves that contain coarse resins.

Virtually colon-specific, SENOKOT Tablets/Granules provide gentle, predictable overnight laxation...usually without side effects at recommended dosage levels. As regular elimination is established, dosage can be reduced gradually and eventually discontinued.

In hypertension—
Once you have found him...

TABLETS, 25 mg and 50 mg

HydroDIURIL®

(HYDROCHLOROTHIAZIDE | MSD)

a basic therapeutic approach to hypertension

The importance of early diagnosis in hypertension, so that appropriate treatment can be initiated promptly, has been well established.

Authorities in cardiovascular medicine have come more and more to favor the thiazides as initial drug therapy in early essential hypertension—for several important reasons.

initial medication that is often effective when used alone

The thiazides are well-established baseline therapy. Their effectiveness in lowering blood pressure has been thoroughly documented, and this effectiveness fits the needs of most patients with mild hypertension. Many hypertensives can be maintained for years on thiazide therapy.

suitable when used with other agents

Equally important is the usefulness of the thiazides in combination with other antihypertensive agents, when they are indicated. This retention of the thiazide in the regimen provides a useful baseline upon which the physician may build a therapeutic program. Since thiazides may add to or potentiate the action of other antihypertensive drugs, careful observation for changes in blood pressure must be made.

HydroDIURIL
(HYDROCHLOROTHIAZIDE, MSD)
often an excellent choice

HydroDIURIL is highly effective antihypertensive therapy, initially and over the long term—the results it has helped achieve over many years with many patients make it especially worth your consideration in the early treatment of hypertension.

Contraindications include anuria and hypersensitivity to hydrochlorothiazide or other sulfonamide-derived drugs. Use with caution in patients with severe renal disease, impaired hepatic function, or progressive liver disease.

For a brief summary of prescribing information,

MSD
MERCK SHARP &

Once you have found him...

HydroDIURIL®

(HYDROCHLOROTHIAZIDE | MSD)

in the management of hypertension

Contraindications: Anuria; hypersensitivity to this or other sulfonamide-derived drugs; routine use in an otherwise healthy pregnant woman with or without mild edema.

Warnings: Use with caution in severe renal disease since thiazides may precipitate azotemia. Cumulative effects may develop in patients with impaired renal function. Use with caution in patients with impaired hepatic function or progressive liver disease, since minor alterations of fluid and electrolyte balance may precipitate hepatic coma. May add to or potentiate action of other antihypertensive drugs; potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Use in pregnancy: Thiazides cross placental barrier and appear in cord blood; in pregnancy or in women of childbearing potential, weigh anticipated benefit against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions that have occurred in adults.

Nursing mothers: Thiazides appear in breast milk; if use of drug is deemed essential, patient should stop nursing.

Precautions: Perform periodic determination of serum electrolytes to detect possible electrolyte imbalance. Observe all patients for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Warning signs, irrespective of cause, are dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Hypokalemia may develop, especially with brisk diuresis, in severe cirrhosis, with concomitant corticosteroid or ACTH therapy, or with inadequate oral electrolyte intake. Hypokalemia can sensitize or exaggerate response of heart to toxic effects of digitalis (e.g., increased ventricular irritability). Hypokalemia may be avoided or treated by use of potassium supplements, such as foods with a high potassium content. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather; appropriate therapy is water restriction, rather than administration of salt except in rare instances when the hyponatremia is life threatening. In actual salt depletion, appropriate replacement is the therapy of choice.

Hyperuricemia may occur or frank gout may be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged; latent diabetes mellitus may become manifest. Thiazides may increase responsiveness to tubocurarine. Antihypertensive effects of the drug may be enhanced in postsympathectomy patients. May decrease arterial responsiveness to norepinephrine; this diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. If progressive renal impairment becomes evident, consider withholding or discontinuing diuretic therapy. Thiazides may decrease serum PBI levels without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Pathological changes in the parathyroid gland with hypercalcemia and hypophosphatemia have been observed in a few patients on prolonged therapy; thiazides should be discontinued before testing for parathyroid function.

Adverse Reactions: *Gastrointestinal System*—Anorexia; gastric irritation; nausea; vomiting; cramping; diarrhea; constipation; jaundice (intrahepatic cholestatic jaundice); pancreatitis; sialadenitis.

Central Nervous System—Dizziness; vertigo; paresthesias; headache; xanthopsia.

Hematologic—Leukopenia; agranulocytosis; thrombocytopenia; aplastic anemia.

Cardiovascular—Orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Hypersensitivity—Purpura; photosensitivity; rash; urticaria; necrotizing angiitis (vasculitis) (cutaneous vasculitis); fever; respiratory distress including pneumonitis; anaphylactic reactions.

Other—Hyperglycemia; glycosuria; hyperuricemia; muscle spasm; weakness; restlessness; transient blurred vision.

Whenever adverse reactions are moderate or severe, thiazide dosage should be reduced or therapy withdrawn.

Note: When used with other antihypertensive drugs, careful observations for changes in blood pressure must be made, especially during initial therapy. Dosage of other antihypertensive agents must be reduced by at least 50 percent as soon as this drug is added to the regimen. As blood pressure falls under the potentiating effect of this agent, further reduction in dosage, or even discontinuation, of other antihypertensive drugs may be necessary.

How Supplied: Tablets containing 25 mg hydrochlorothiazide each in bottles of 100 and 1000 and single-unit packages of 100; Tablets containing 50 mg hydrochlorothiazide each in bottles of 100, 1000, and 5000 and single-unit packages of 100; Tablets containing 100 mg hydrochlorothiazide each in bottles of 100.

MERCK SHARP & DOHME

"Required Reading" For Your Hypertensive Patients

Because of the importance of patient motivation, Merck Sharp & Dohme offers "High Blood Pressure," a concise, pocket-sized booklet that defines the patient's own role in the management of hypertension. This booklet is available for you to give to your patients. It is designed to reinforce your explanation of hypertension and it emphasizes the importance of patient understanding in adhering to the regimen you prescribe.

Please ask your Merck Sharp & Dohme Professional Representative or write Professional Service Department, West Point, Pa. 19486 for a supply of this booklet.

IN ANGINA*: ACTS WITH SUBLINGUAL SPEED

CHEWABLE SORBITRATE® 5MG.
ISOSORBIDE DINITRATE

As with sublingual ISDN:
acts in 2 minutes for therapeutic use...
acts up to 2 hours for prophylaxis.

In addition:
chewing action helps distribute nitrate over a larger mucosal area.

SUMMARY OF
PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE (isosorbide dinitrate) is unknown, although the basic pharmacologic action is to relax smooth muscle. Isosorbide dinitrate reduces in number and severity the incidence of angina pectoris attacks, with concomitant reduction in nitroglycerin intake.

* **Indications:** Based on a review of this drug by The National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Probably" effective: Sublingual and chewable dosage forms of SORBITRATE are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: A history of sensitivity to the drug.
Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety. Phenobarbital may be habit forming.
Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.
Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.
Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.
This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.
Dosage and Administration: Route: Sublingual, oral and chewable tablets.
Individual Dose: To minimize hypotensive responses, which may occasionally be severe with chewable doses as low as 5 mg., the smallest effective dose should be employed. Chewable tablets are generally given in doses of 5 mg. Sublingually or orally, 5 to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.
Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Sublingual SORBITRATE may be taken p.r.n. or at 4 to 6 hour intervals; Oral SORBITRATE may be taken 3 to 4 times daily. CHEWABLE SORBITRATE may be taken for prompt relief of anginal pain 3 or 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:
Onset of Effect: Sublingual and Chewable: 2 to 5 minutes. Oral: 15 to 30 minutes.
Duration of Effect: Sublingual and Chewable: 1 to 2 hours. Oral: Estimated to be 4 to 6 hours.
It is recommended that the oral dosage be taken on an empty stomach.

Wilmington, Delaware 19897

to help increase blood supply in treatable vasospastic disorders*

Brief Summary

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified this drug as "possibly" effective for peripheral vascular disease and circulatory disturbances of the inner ear. Final classification of the less-than-effective indications requires further investigation.

Contraindications: Acute myocardial infarction, paroxysmal tachycardia, progressive angina pectoris and thyrotoxicosis. **Warnings:** In patients with cardiac disease such as tachyarrhythmias and uncompensated congestive heart failure, the benefit/risk ratio should be weighed prior to therapy and reconsidered at intervals during treatment. **Adverse Reactions:** Trembling, nervousness, weakness, dizziness (not associated with labyrinthine artery insufficiency), palpitations, nausea and vomiting may occur. Postural hypotension, while not reported, may also occur. **Dosage:** Orally, 3 to 12 mg. three or four times a day. **How Supplied:** White, scored tablets, 6 mg. and 12 mg. Bottles of 100 and 1000; single-dose blister packs, boxes of 100 (10 x 10 strips).

Long before
facing the
"ultimate" test
of stability...

Nitrostat has shown proof of stability

There are a lot of ways to say "stable" when you're dealing with nitroglycerin. Some more meaningful than others.

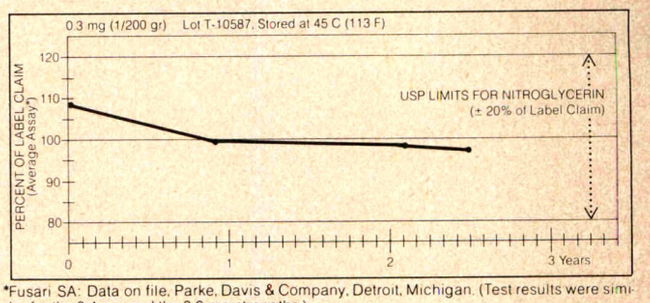
That's why the testing of Nitrostat *includes* tests to simulate, as closely as possible, the actual conditions of use.

For example, we test for **wickability** — a Parke-Davis test (the time in seconds required for water to wet the tablet completely by capillary action under controlled conditions) — to simulate under-the-tongue conditions.

Heat-stable? Yes. Up to 45 C (113 F) (considerably higher than your patient's pocket temperature). See graph.

What's more, the crucial question of maintenance of content uniformity of nitroglycerin is answered by Nitrostat as proved by assay.

Potency? The average assay still shows almost 100% of label claim more than 30 months after manufacture: less chance of your patient taking a superpotent or, more important, a subpotent tablet.



*Fusari SA: Data on file, Parke, Davis & Company, Detroit, Michigan. (Test results were similar for the 0.4-mg and the 0.6-mg strengths.)

Disintegration? We test it using the USP test in 800 ml of water — all tablets usually disintegrate within 30 seconds (USP limit — two minutes).

Dissolution? Using NF Method II, we show greater than 90% dissolution in 30 seconds.

Now, each factor taken by itself may not be decisive. But taken together, they add up to a good reason to specify Nitrostat.

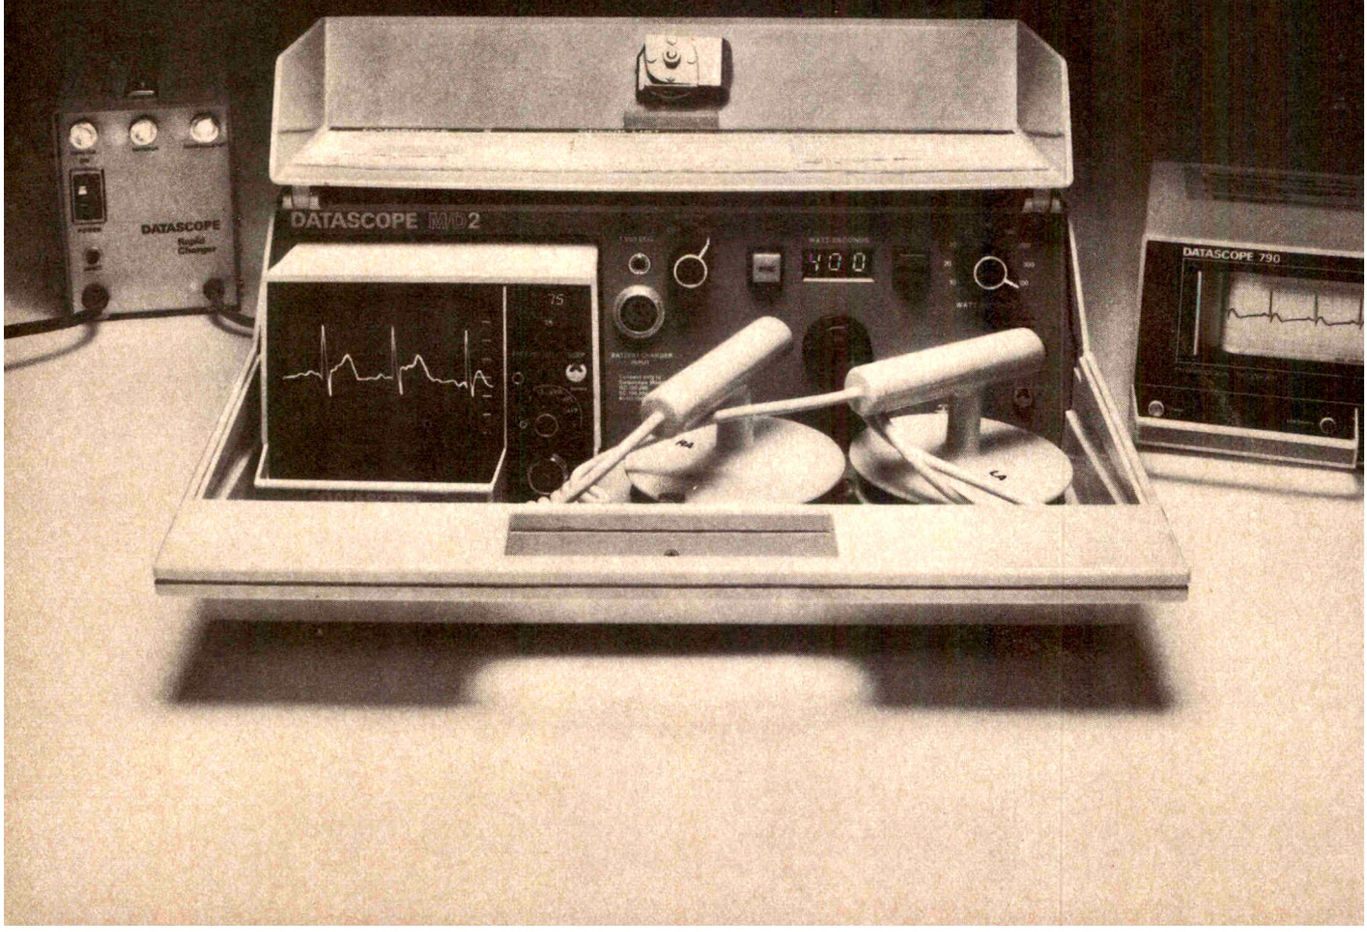
THE DATASCOPE M/D2 SYSTEM THE FIRST RESCUE SYSTEM AS FLEXIBLE AS THE PEOPLE WHO USE IT.



If there's one thing you can
sure of in cardiac rescue, it's
at you can't be sure of anything.

Every situation, either in the
spital or in the field, presents
w problems, and requires new
lutions.

At Datascope, we've been in
nergency medicine since its
ception.

Our equipment has faced just
out everything. And from that
perience we've put together a
stem that's prepared to face
ything: the M/D2 System.

The M/D2 System is built on
e very simple principle. *Every
strument in the system must be
dependent and not compro-
ised by any other instrument.*

In keeping with this philoso-
y, our monitor, our defibrillator
d our strip-chart recorder each
ve a separate battery source.
ne unit never puts a drain on
other.

But to see its flexibility, let's
ke our system apart, instrument
/ instrument.

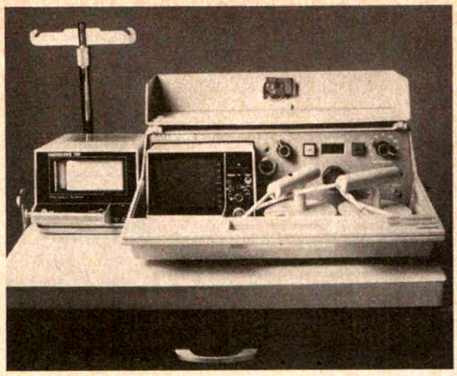
OUR MONITOR.

The monitor in the M/D2
stem nests inside the defibril-
tor. You can carry the monitor
d defibrillator, use it, and store
as one unit.

But the monitor pulls out* of
e M/D2 case and works as a
parate unit as well. So it can be
aced right on a patient's stretcher
the field. Or put in the most
lvantageous viewing position at
e bedside.

In addition to being so flex-
ible, our monitor outperforms any
monitor in emergency medicine.

It has a 5-inch scope with a
8 x 11 cm. viewing area.



It has a memory which pro-
vides a bright, non-fade display
that's remarkably clear even in
strong sunlight.

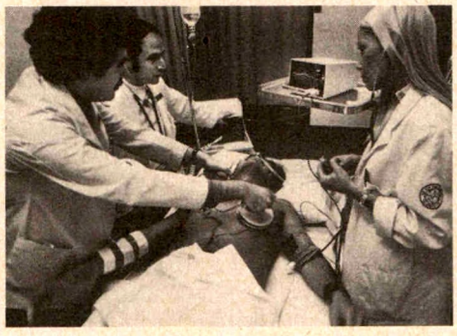
It has a freeze button which
lets you stop the ECG for closer
study.

It's the only emergency moni-
tor with a digital heart rate read-
out. And because the readout is
an LED display, you can even read
it in the dark.

OUR DEFIBRILLATOR.

Like our monitor, our defib-
rillator has its own battery-pack.

It's the only defibrillator made
that gives you a *digital* energy
meter. Which displays both stored
energy and the results of delivered
energy tests.



The defibrillator is exception-
ally safe. A warning tone sounds
when the selected energy level is
reached.

Energy cannot be delivered
unless the push-button switch
on each paddle is actuated
simultaneously.

The energy within the defib-
rillator is automatically discharged
when the unit is turned off.

For paramedic use, the M/D2
is available completely shielded
against RF interference across
the entire communications band.

OUR RECORDER.

Our recorder is flexible as
well. It's carried separately and
powered separately. (For good
reason. A recorder powered by a
common battery puts an enormous
drain on the other instruments in
the system.)

Our recorder weights only 11
pounds. And when you're using
our monitor outside the M/D2
case, our recorder fits right into
the space the monitor vacated.
Which allows even easier transport.

OUR RAPID CHARGER.

Although the M/D2 comes
with a standard battery recharger,
we offer the first rapid recharging
unit as part of our system. Our
Rapid Charger allows you to de-
fibrillate with just 60 seconds of
recharge. And in just 10 minutes
it will recharge the defibrillator to
at least 60% of total capacity.

THE SYSTEM. IT'S MORE THAN ANY OF ITS PARTS.

Three independent units.
Three independent battery-packs.
And a Rapid Charger. They work
together, or apart. They give you
more ability to react than any
single unit ever could.

For more information on the
M/D2 System, write: Datascope
Corp., 580 Winters Avenue,
Paramus, N.J. 07652.

THE DATASCOPE M/D2

Why not have a CCU on every floor?

No matter where a cardiac emergency occurs, the problem is: Deliver the same skilled care the patient would get in the CCU . . . and just as quickly. The answer is a crash cart on every floor, manned by trained personnel and equipped with a LIFEPAK® portable defibrillator/cardioscope from PHYSIO-CONTROL®.

For more information about Physio-Control defibrillators and their various applications, write for our 24-page, full-color brochure to: Physio-Control Corporation, 11811 Willows Road, Redmond, Washington 98052.
Phone (206) 883-1181. Cable: Physio-Red. Telex: 32-0166.

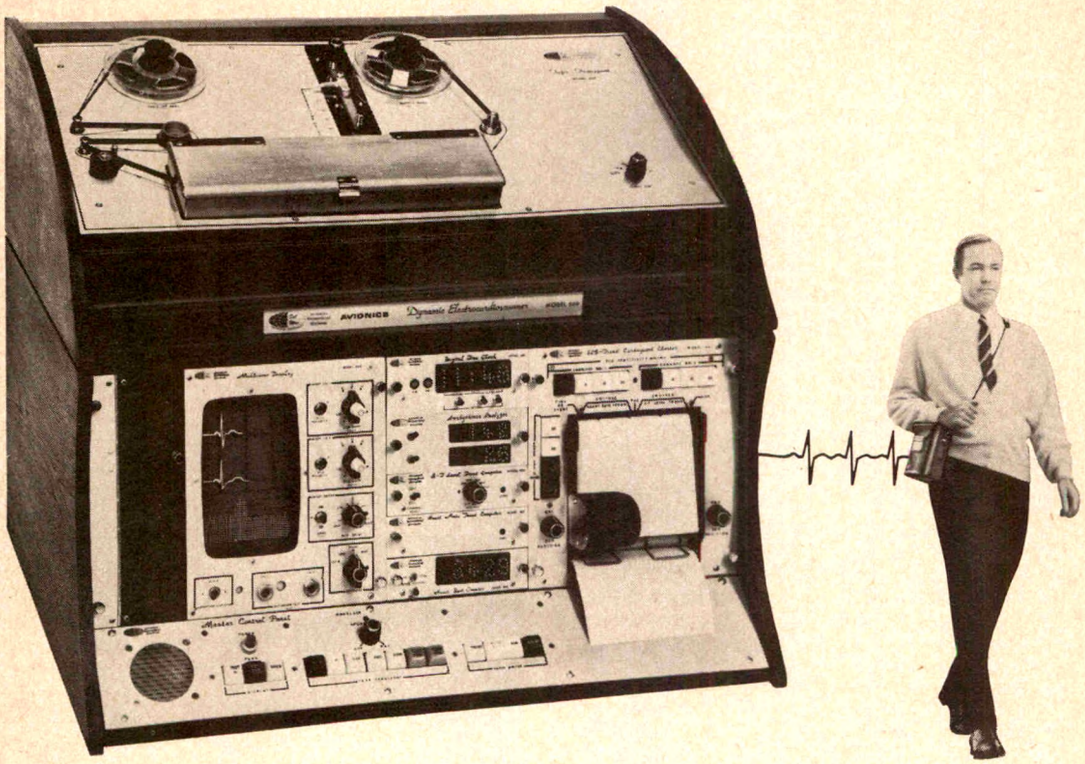
THE NEW 660 A DRAMATIC LEAP FORWARD IN DYNAMIC ELECTROCARDIOGRAPHY!



Model 660 Features:

- **2-channel playback of Holter recordings**
- **2-channel paper writer**
- **120:1 playback ratio (24-hour recording scanned in 12 minutes)**
- **Trend recording of S-T segment and heart rate**
- **Digital display and chart recording of ventricular and supraventricular ectopic beats**
- **Total heart beat counter**
- **Digital display clock**
- **Automatic time print-out on ECG write-out**
- **Adjustable delay loop for tape deck**
- **Solid state, modular design**

Now available to every physician . . . an advanced ECG system for post MI follow-up, pacemaker evaluation, evaluation of drug administration, and detecting the causes of such fleeting symptoms as phantom chest pains and dizziness.

Model 425 Holter Monitor
Provides a 2-channel, 24-hour ECG recording of ambulatory patients.

Model 660 Electrocardioscanner®
Performs a 12-minute scan of the 24-hour, 2-channel tape recording and provides standard ECG documentation of abnormalities and quantification of arrhythmia and ischemic data.

AVIONICS

☐ Please send me the literature. I would like to know more about Holter monitoring and the Avionics Dynamic Electrocardiographic Systems.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

VOLUME 36

NUMBER 3

CONTENTS

CLINICAL STUDIES

281 **New Observations on the Effects of Atropine on the Sinoatrial and Atrioventricular Nodes in Man**

GOPAL DAS, FREDERICK N. TALMERS and ARNOLD M. WEISSLER

In normal volunteers the response of the sinoatrial (S-A) node to various doses (0.1 to 0.8 mg) of atropine was bimodal, slowing at smaller doses and accelerating at larger doses. The atrioventricular node showed accelerated conduction at all dosage levels. These observations suggest caution in the use of atropine in patients with acute myocardial infarction. Smaller doses may paradoxically aggravate bradycardia and larger doses may precipitate tachyarrhythmias.

286 **Induction of Atrioventricular Nodal Reentrant Tachycardia After Atropine. Report of Five Cases**

MASOOD AKHTAR, ANTHONY N. DAMATO, WILLIAM P. BATSFORD, ANTONIO R. CARACTA, JEREMY N. RUSKIN, GERALD M. WEISFOGEL and SUN H. LAU

The intravenous administration of 0.5 mg of atropine provided the necessary balance of conduction and refractoriness within the atrioventricular (A-V) nodal reentrant pathways to produce and sustain A-V nodal reentry in five patients with no history of supraventricular tachycardia. This effect may help to explain the success of digitalis and propranolol in the management of supraventricular tachycardia, since these agents prolong refractoriness of the A-V node and abolish A-V nodal reentry.

292 **Quantitative Study of the Supernormal Phase of Ventricular Excitability in Man**

MASAO IGARASHI and TAKAO AYABE

Ten of 11 patients with acute and chronic bradyarrhythmias studied by fixed rate endocardial pacing manifested a supernormal phase of excitability either early or late in diastole. Its duration depended on the intensity of subthreshold stimuli. Ventricular excitability was not uniform throughout diastole and could be enhanced unexpectedly late in diastole by summation of impulses. This could be the basis for the Wedensky facilitation phenomenon.

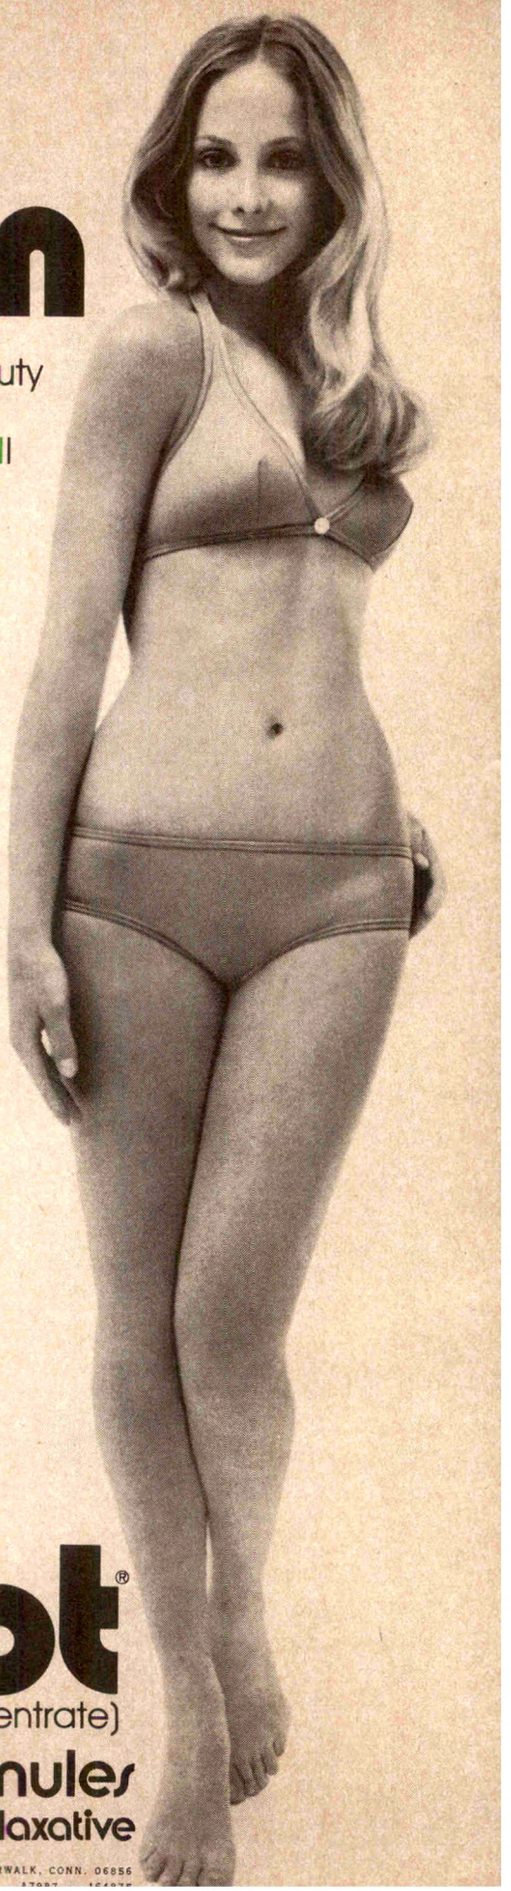
297 **Hereditary Progressive Atrioventricular Conduction Defect**

HENRY T. LYNCH, SYED MOHIUDDIN, JANE MORAN, ARNOLD KAPLAN, MICHAEL SKETCH, ALAN ZENCKA and VINCENT RUNCO

Concordance analysis of the hereditary progressive atrioventricular conduction defect in the affected parents and offspring of Family S (a kindred of 1,067 members) suggests a Mendelian autosomal dominant factor is responsible for transmission of the diathesis for the defect. The empiric risks for heart block in offspring of affected parents range from 0.16 to 0.31 and in siblings from 0.01 to 0.50. The pathogenesis of the syndrome is unknown.

Continued on page A15

Natural distinction



Wholesome and unadorned young beauty impresses the eye with its natural distinction. Among medicinals, such natural distinction will be found in SENOKOT Tablets/Granules.

Standardized senna concentrate has two claims to natural distinction. In SENOKOT Tablets/Granules, it is standardized for uniform action. And it is prepared from the deseeded pod of Cassia acutifolia, discarding the leaves that contain coarse resins.

Virtually colon-specific, SENOKOT Tablets/Granules provide gentle, predictable overnight laxation...usually without side effects at recommended dosage levels. As regular elimination is established, dosage can be reduced gradually and eventually discontinued.

Purdue Frederick

Senokot®

(standardized senna concentrate)

Tablets/Granules

a natural vegetable laxative

CONTENTS

302 **Abnormalities of Left Ventricular Function and Geometry in Adults with an Atrial Septal Defect. Ventriculographic, Hemodynamic and Echocardiographic Studies**

KENNETH A. POPIO, RICHARD GORLIN, LOUIS E. TEICHHOLZ, PETER F. COHN, DAVID BECHTEL and MICHAEL V. HERMAN

The left ventricle in 12 adults with an ostium secundum atrial septal defect was subnormal in volume, abnormal in sequence of contraction of the septum (early systolic bulging toward right ventricle), and characterized by apparent decreased distensibility. These findings suggest that the superimposition of a mild degree of stress, such as hypertension, age, atrial fibrillation or mitral regurgitation, may precipitate clinical heart failure.

309 **Phasic Left Ventricular Blood Velocity Alternans in Man**

KENNETH B. DESSER and ALBERTO BENCHIMOL

Direct measurement of the blood cell velocity in the left ventricle of conscious man by Doppler catheter velocimetry relates alternans of phasic left ventricular blood velocity to an altered inotropic state during cardiac acceleration or to beat to beat variations in end-diastolic fiber length. Critical right atrial or ventricular pacing rates required to produce blood velocity alternation ranged from 100 to 160 beats/min.

315 **The Coronary Arteries in Marfan's Syndrome. A Morphologic Study**

ANTON E. BECKER and JAN-PAUL van MANTGEM

In four of the five hearts in these cases of Marfan's syndrome studied microscopically, the extramural coronary arteries showed accumulations of acid mucopolysaccharides and concomitant disruption of the connective tissue elements. The intramural coronary arteries were generally unaffected. The possibility of such coronary arterial involvement should be considered in all patients with Marfan's syndrome.

METHODS

322 **Clinical Applications of the Threshold Tracking Pacemaker**

THOMAS A. PRESTON and DAVID L. BOWERS

Limited clinical testing of the threshold tracking pacemaker indicates its potential effectiveness and safety in patients requiring temporary pacing for acute cardiac problems. This new generation fully automatic pacemaker searches for and finds the threshold level and adjusts its stimulus to just above this level. It ensures an adequate safety margin of stimulation but reduces the stimulus level to the lowest safe level possible.

PEDIATRIC CARDIOLOGY

327 **Tricuspid Atresia: Clinical Course in 101 Patients**

MACDONALD DICK, DONALD C. FYLER and ALEXANDER S. NADAS

Fifty percent of 101 patients with all forms of tricuspid atresia survived to 15 years of age. Although the overall surgical mortality rate was 23 percent, surgical intervention in those with decreased pulmonary vascularity improved the prognosis from a 10 percent chance to survive the first year of life to a 50 percent chance to survive to 15 years of life. Early surgical palliation appears to be promising.

2. BETTER SERVICE— full service and maintenance contracts available...

Compare the quality and performance of our system with all others. We'll bring the entire system, including the treadmill, to your hospital, clinic, or office and conduct an actual stress test under your control. You can prove the superior performance and diagnostic quality of our system to your own satisfaction.

Ask any competitor to bring and demonstrate his complete system to you, including treadmill exercising. If he refuses, that should tell you something! If you want the best, we've got it and we're ready to bring it to you.

For action, just use the coupon below.

REPORTS ON THERAPY

338 Surgical Experience in Patients with Marfan's Syndrome, Ascending Aortic Aneurysm and Aortic Regurgitation

ANTOINE T. NASRALLAH, DENTON A. COOLEY, YOUSSEF GOUSSOUS, GRADY L. HALLMAN, ROBERTO LUFSCHANOWSKI and ROBERT D. LEACHMAN

The 5 year survival rate of 42.8 percent following surgical treatment of aortic insufficiency and ascending aortic aneurysm in 30 patients with Marfan's syndrome indicates that surgical treatment should not be withheld despite the underlying biochemical defect and potential future catastrophic complications in such subjects.

342 Coronary Artery Bypass in Patients Over 70 Years of Age: Indications and Results

JOSEPH MEYER, DON C. WUKASCH, WALTER SEYBOLD-EPTING, LUIGI CHIARIELLO, GEORGE J. REUL, Jr., FRANK M. SANDIFORD, GRADY L. HALLMAN and DENTON A. COOLEY

Improved surgical technique and postoperative care as detailed in this report are responsible for the reduced hospital mortality rate of only 4.8 percent in 21 patients operated upon during the first 6 months of 1974 compared with the overall mortality rate of 22.1 percent in all 95 patients over the age of 70 undergoing aortocoronary bypass. Such reduced mortality makes such operations in this age group less controversial.

DIAGNOSTIC SHELF

346 Echocardiographic Findings of Ventricular Septal Rupture in Acute Myocardial Infarction

ROBERT L. DeJOSEPH, STUART F. SEIDES, ANTON LINDNER and ANTHONY N. DAMATO

In an 80 year old man with a ventricular septal defect after acute myocardial infarction, the major echocardiographic change occurred in the upper portion of the septum. This area, showing only slight anterior motion during systole before the rupture, demonstrated, after rupture, a marked posterior motion with the onset of ventricular diastole, presumably representing passive motion of a flail dyskinetic septum.

349 Echocardiographic Findings in Uhl's Anomaly. Demonstration of Diastolic Pulmonary Valve Opening

JAMES W. FRENCH, DAVID BAUM and RICHARD POPP

Echocardiography helps differentiate Uhl's anomaly (congenital hypoplasia of the right ventricular myocardium) from Ebstein's disease of the tricuspid valve. Diastolic opening of the pulmonary valve was demonstrated by echocardiography in this 14 year old girl with Uhl's anomaly. Increased right ventricular dimension, delayed tricuspid valve closure and prolapse of the mitral valve were also observed.

354 Echocardiogram in Calcified Mitral Anulus

DAVID S. HIRSCHFELD and BIANKA B. EMILSON

These two case reports indicate that the echocardiogram of calcified mitral anulus mimics that of pericardial effusion but may be differentiated by demonstrating the abrupt termination of mitral ring echoes during sweep from the left ventricle to the left atrium. In contrast, there is a gradual diminution of the posterior or echo-free space in true pericardial effusion.

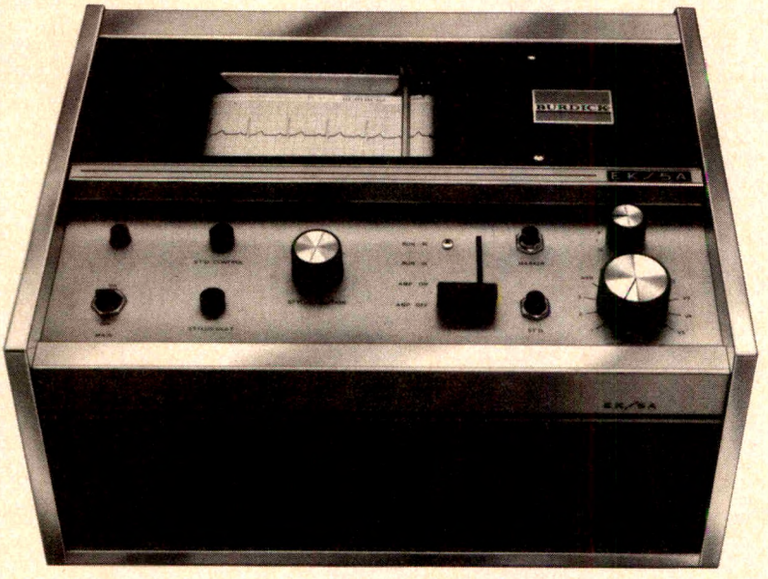
These free supplies



will pay for this EK-5A.

Now through October 31st, order a new Burdick EK-5A electrocardiograph, and we'll give you enough Lectro-pads, paper, and mounts for 100 ECGs. And 100 are more than enough to cover the cost of your EK-5A.

The Burdick EK-5A is an instant-on solid-state electrocardiograph with a coveted reputation for accuracy, definition, and dependability. It exceeds the minimum American Heart Association frequency-response recommendations, is Data-Phone-compatible, and is backed by our there-when-you-need-us service.

How often is there a pay-for-itself opportunity like this on something there's really reason to have? Take advantage of this, before the October 31st deadline, by calling toll-free 800-356-0701. In Wisconsin: (608) 868-7631. Or write to The Burdick Corporation, Milton, Wisconsin 53563.

CASE REPORTS

357 Reticulum-Cell Sarcoma with Intracardiac Metastases. Case with Angiocardiographic Improvement After Chemotherapy

CESAR A. CONDE, JOSE MELLER, JOHN PANTAZOPOULOS, EPHRAIM DONOSO and SIMON DACK

This is the first report of a case in which angiography demonstrated resolution of an intracardiac metastatic tumor after chemotherapy. This 66 year old man with reticulum-cell sarcoma eventually died from progressive multiorgan involvement.

363 Echocardiographic Diagnosis of Right Atrial Extension of Wilms' Tumor

ZIA Q. FAROOKI, JAMES G. HENRY and EDWARD W. GREEN

This report describes the fourth instance of direct propagation of a Wilms' tumor to the right atrium through the inferior vena cava and the first echocardiographic diagnosis of such extension in a child. This case differs from the others in that there was invasion of the surrounding structures and the tumor metastasized to the liver, rendering the condition inoperable.

SYMPOSIUM ON REPERFUSION DURING ACUTE MYOCARDIAL INFARCTION—PART II

368 Revascularization After 3 Hours of Coronary Arterial Occlusion: Effects on Regional Cardiac Metabolic Function and Infarct Size

COSTANTINO COSTANTINI, ELIOT CORDAY, TZU-WANG LANG, SAMUEL MEERBAUM, JOHN BRASCH, LEO KAPLAN, STEVEN RUBINS, HERBERT GOLD and JULES OSHER

In closed chest dogs two beneficial effects of revascularization after 3 hours of occlusion included significant reduction of average infarct size and restoration of cardiac function by the 7th day. Adverse effects included swelling of the ischemic myocardium and abnormal cardiac metabolic and mechanical function for at least 1 hour after reperfusion. This confirmed the unstable character of the early phase of reperfusion resulting in inadequate coronary reflow and metabolic derangements whereas prolonged reperfusion for 7 dogs reversed these adverse effects.

385 Consequences of Coronary Arterial Occlusion on Remote Myocardium: Effects of Occlusion and Reperfusion

ELIOT CORDAY, LEO KAPLAN, SAMUEL MEERBAUM, JOHN BRASCH, COSTANTINO COSTANTINI, TZU-WANG LANG, HERBERT GOLD, STEVEN RUBINS and JULES OSHER

Microinfarcts and regional lactate derangements were observed in the remote segments of the right and left ventricles of closed chest, normotensive dogs after acute occlusion of the proximal left anterior descending coronary artery. These changes, often irreversible, are attributed to ischemia of the remote myocardium that accompanies an acute coronary occlusion.

ACCEPTED CONCEPTS IN ANGINA THERAPY*

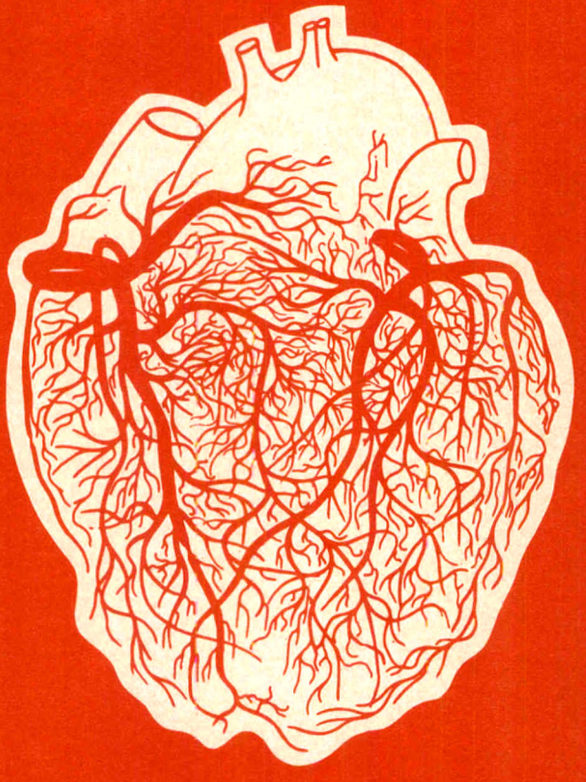
- Nitrates are the first line of defense against angina pectoris
- The therapeutic goal of oral nitrate therapy is an angina-free patient

When higher dosage is necessary in the prophylaxis of angina

prescribe

ISORDIL®
(isosorbide dinitrate)
20 mg.

Scored, oral tablets



Fewer tablets for patients on 80 mg. or more per day (up to a maximum of 120 mg./day)
To provide prophylaxis against anginal attacks often caused by unavoidable everyday stress.
To reduce the frequency and severity of angina pectoris attacks. (Not intended to abort the acute episode.)

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

395 Myocardial Revascularization After Acute Infarction

HOOSHANG BOLOOKI *with the assistance of* MICHAEL D. KOTLER, LAWRENCE LOTTENBERG, STEPHEN DRESNICK, ROBERT C. ANDREWS, STEVEN KIPNIS and RICHARD M. ELLIS

Reperfusion of an area of myocardium ischemic for less than 2 hours in dogs or less than 4 hours in man may significantly reduce the extent of infarction and improve cardiac function as measured by cardiac catheterization and angiography. However, the revascularized area remains angiographically dyskinetic and electrocardiographically abnormal. This difference in time suggests a greater tolerance of the human myocardium to ischemia, most likely due to the presence of numerous intercoronary collateral communications and the insidious onset of coronary obstruction. This study emphasizes that the duration of ischemia before reestablishment of blood flow in an acutely occluded coronary artery in man must be limited to 4 hours.

CMS. It gives mor

CMS — Clinical Monitoring Systems — is an advanced, computerized monitoring system developed by B-D Electrodyne, a medical instrumentation division of Becton, Dickinson and Company.

It provides more meaningful information more quickly, and in a more easily assimilated form, than conventional or even other computerized systems.

For example:

Status. Composite, moment-to-moment status displays of each patient for each variable. Easily visible, even at a distance.

Rhythm history. 8 or 24 hour history of each patient. Large-screen graphic display.

Trend graphs of any monitored variable.

Alarm limits individually selected for each variable, for each patient.

Alphanumeric-labeled ECG strips. Each automatically labeled with time, date, bed number, patient name, status, beat classification.

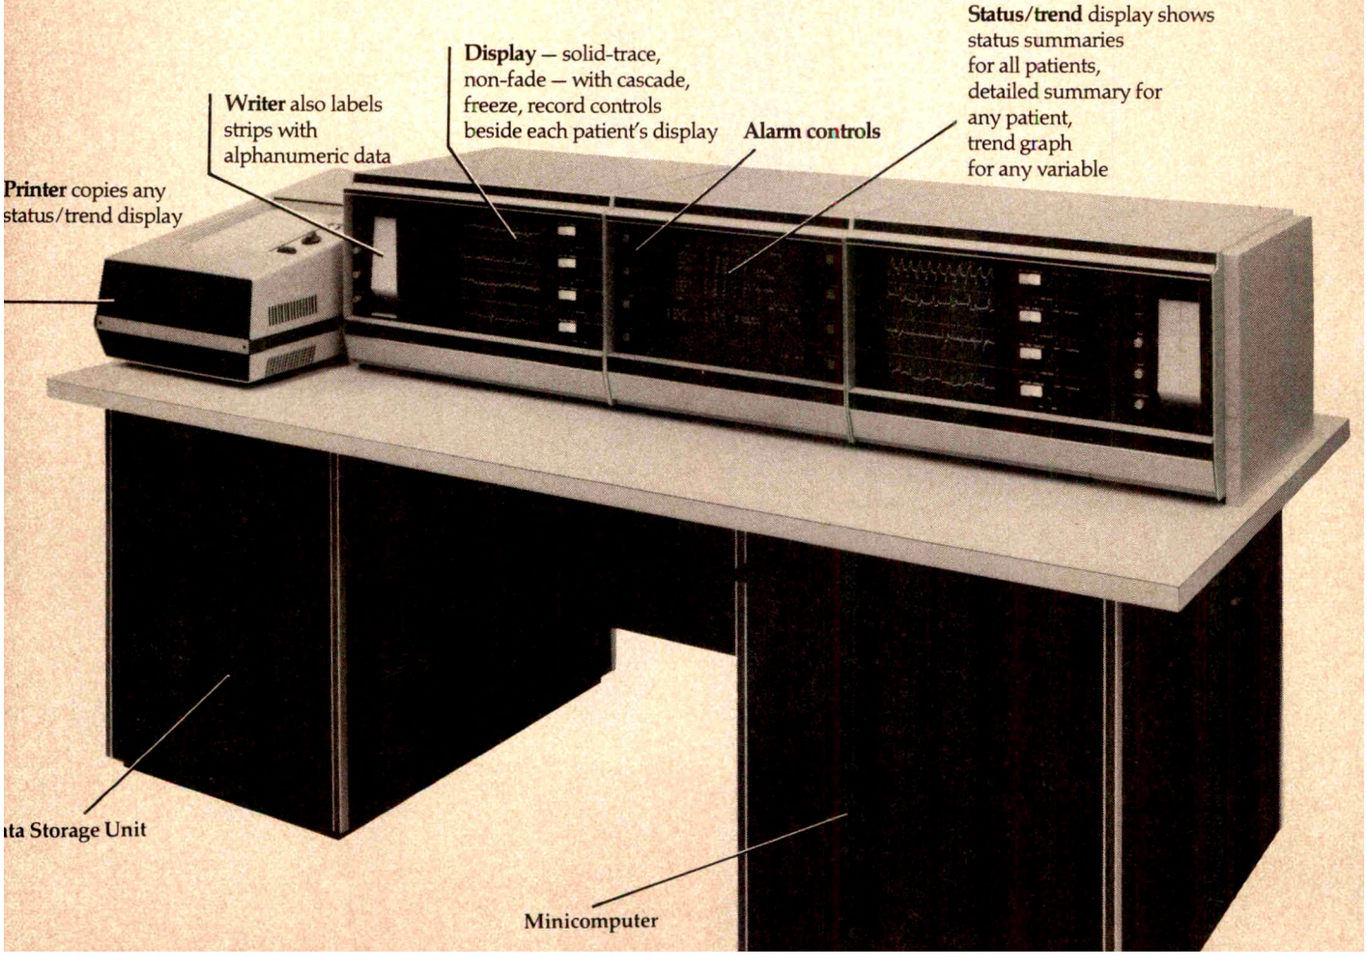
Hard copies of any display at any time.

Medication report. Type, amount, time.

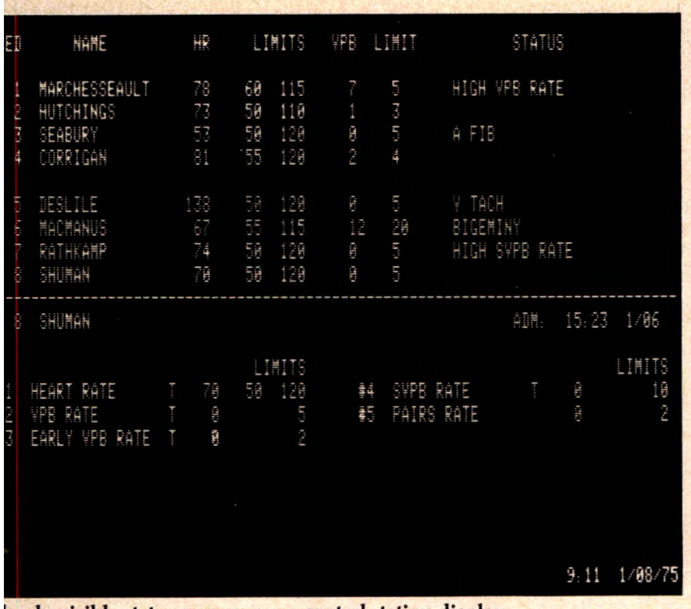
In addition, CMS can be added t any existing solid-trace B-D Electr dyne system, and may be purchase leased.

Obviously, there is much more t CMS than can be described in this space. To get details, send for CMS Booklet and abstract of an indepen ent clinical evaluation. B-D Electro dyne, Division of Becton, Dickinso and Company, Sharon, MA 02067. 617-828-9080.

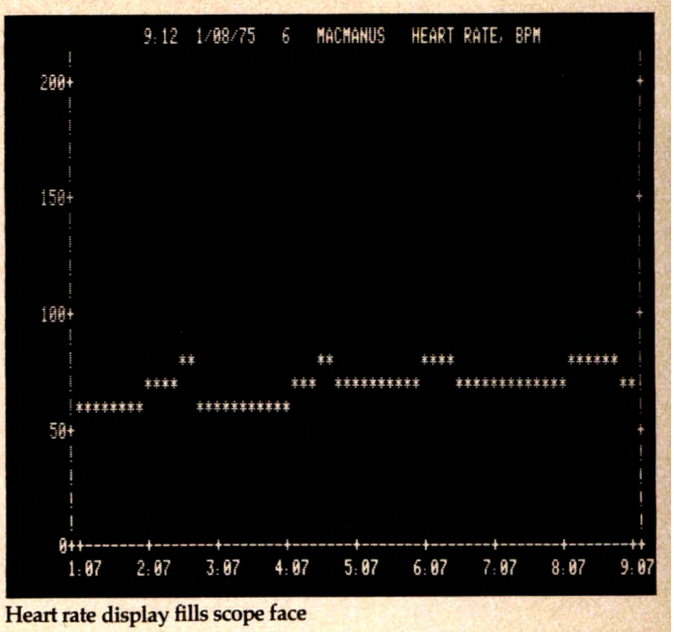
B-D **ELECTRODYNE**
Division of Becton, Dickinson and Company



neaning to monitoring.

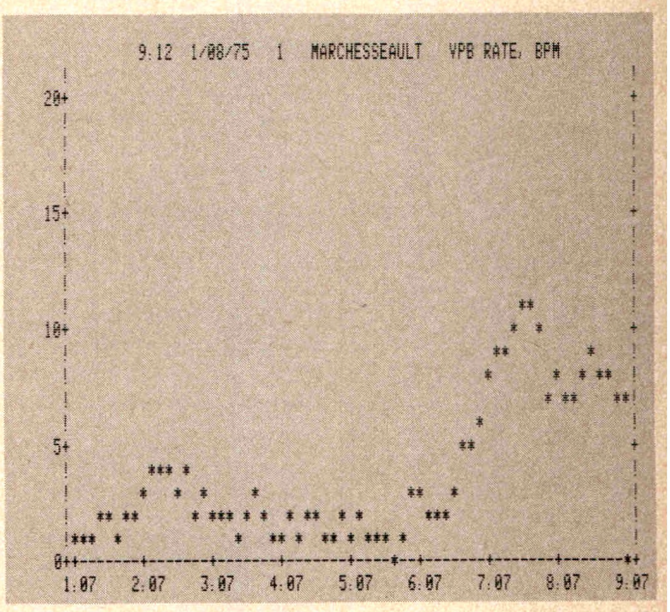


learly visible status summary on central station display



Heart rate display fills scope face

Ongoing record of status, trends
Large, easily readable displays for any variable being monitored. Can also be printed for permanent record.



Hard-copy printout of displayed VPB trend graph

Automatically labeled stripchart
ECG or blood pressure waveform and alphanumeric patient information. Automatically initiated at alarm condition. Can also be manually controlled.

Peritrate® SA Sustained Action

(pentaerythritol tetranitrate) 80mg

CAUTION: Federal law prohibits dispensing without prescription.

Description: Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.

(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop.

(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later. Tablets should not be chewed.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 (N 0047-0004-51) and 1000 (N 0047-0004-60). Also in unit dose—package of 10 x 10 strips (N 0047-0004-11).

Additional Dosage Forms: Peritrate 20 mg—light green, scored tablets in bottles of 100 (N 0047-0001-51) and 1000 (N 0047-0001-60). Also in unit dose—package of 10 x 10 strips (N 0047-0001-11). Peritrate 10 mg—light green, unscored tablets in bottles of 100 (N 0047-0007-51) and 1000 (N 0047-0007-60).

Defense against attack.

For over 22 years, Peritrate® has been considered by many physicians as one of the top defensive measures for patients with angina pectoris. In many patients Peritrate used prophylactically helps decrease the frequency and severity of angina attacks.* With minimal side effects.

Peritrate can also help reduce nitroglycerin requirements and, therefore, nitroglycerin side effects. Is it any wonder so many physicians continue to prefer Peritrate prophylaxis for their angina patients?

LONG-ACTING PROTECTION AGAINST ANGINA PAIN*

Peritrate® SA
Sustained Action

The Great Wall of China, an immense 1,400-mile-long man made barrier 20 to 30 feet high and 15 to 20 feet thick, helped defend China from the attack of Mongol hordes for more than 2,000 years.

*The drug has been evaluated as possibly effective for this indication.
See brief summary

now, one station does it all... collects ECG data, computes, analyzes, prints report

in minutes, at bedside, without central computer or telephone tie-ins

The Roche Mobile Computerized ECG Station contains its own minicomputer, recorder, and printer. It can eliminate the routine work associated with the reading of normal ECG's. It is highly accurate, classifying correctly 95-98% of normal ECG's, 85% of abnormals.[1] It is fast, supplying a computer printout based on the widely accepted USPHS program within a minute after readings are taken.

There is a high degree of patient safety. Also, the Roche Station signals the operator immediately when tracings are being taken incorrectly or are of poor quality; it identifies interpretations that may be incomplete or equivocal.

The Roche Mobile Station offers considerable savings over telephone tie-in ECG systems and yet avoids the extensive investment required for a dedicated central computer. Economic feasibility studies and additional information are available from Roche.

Schering

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action **Hyperstat®** I.V.
Brand of DIAZOXIDE
INJECTION
20 ml. ampule
contains 300 mg

"The injection of the [diazoxide] bolus in 10 to 15 seconds results in a prompt blood pressure fall in a high percentage of cases. A maximal blood pressure response usually occurs within 5 to 10 minutes."*

☐ **Rapid reduction to normotensive levels**

Induces rapid reduction of blood pressure generally within 5 minutes... often in 1 or 2 minutes to the lowest level achieved. Blood pressure response facilitated by appropriate diuretic therapy.

☐ **Prolonged activity**

A single injection of HYPERSTAT I.V. generally maintains blood pressure below pretreatment levels for periods up to 12 hours.

☐ **Protective action—helps avert target organ damage**

Cardiac output increases as diastolic pressure is reduced. Coronary and cerebral blood flow maintained. Increased renal blood flow after transient decrease.

☐ **Uncomplicated procedure**

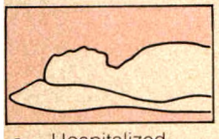
Simple I.V. "push" in a peripheral vein in 30 seconds or less. Close monitoring at frequent intervals is necessary until blood pressure is stabilized (generally 15-30 minutes). Thereafter, hourly measurement should be taken during the balance of effect.

☐ **Stable... convenient... no preparation**

HYPERSTAT I.V. Injection supplied in a 20 ml. ampule containing a stable solution of diazoxide 300 mg. ...ready to use.

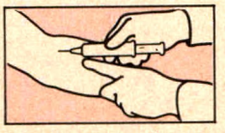
*Marvin Moser, M.D., Assistant Professor of Clinical Medicine, Albert Einstein College of Medicine, and Chief of Cardiology, White Plains Hospital, White Plains, N.Y., in Diazoxide—an effective vasodilator in accelerated hypertension. *Am Heart J* 87(6): 791-795, June 1974.

Administration guidelines



1. Hospitalized patient should be recumbent.

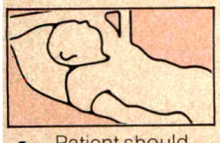
2. Fill dry syringe with appropriate dose of HYPERSTAT I.V. Injection (20 ml. ampule contains 300 mg. diazoxide).



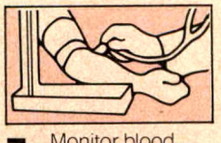
3. Insert needle only into a peripheral vein.

4. Inject entire dose I.V. in 30 seconds or less.

5. Remove needle carefully—avoid extravasation.

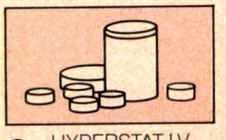


6. Patient should remain recumbent for at least half an hour after injection.



7. Monitor blood pressure closely until stabilized—usually 15-30 minutes.

8. If patient is to be ambulatory, blood pressure should be measured in standing position before surveillance is ended.



9. HYPERSTAT I.V. Injection should be continued until a regimen of oral antihypertensive medication becomes effective—generally within a few days.

Copyright © 1975, Schering Corporation. All rights reserved.

Before prescribing HYPERSTAT I.V. Injection, please consult complete product information on next page.

Stat regimen for rapid reduction of blood pressure in malignant hypertension

direct-action

Hyperstat® I.V.

Brand of DIAZOXIDE

INJECTION
20 ml ampule
contains 300 mg

FOR INTRAVENOUS USE IN HOSPITALIZED PATIENTS ONLY

Description HYPERSTAT I.V. Injection is a rapidly acting antihypertensive agent. Each ampule (20 ml.) contains 300 mg. diazoxide, a nondiuretic benzothiadiazine derivative, in a clear, colorless, aqueous solution; the pH is adjusted to approximately 11.6 with sodium hydroxide. Diazoxide is 7-chloro-3-methyl-2H 1, 2, 4-benzothiadiazine 1, 1-dioxide.

Actions HYPERSTAT I.V. Injection produces a prompt reduction in blood pressure by relaxing smooth muscle in the peripheral arterioles. Cardiac output is increased as blood pressure is reduced by diazoxide; coronary and cerebral blood flow are maintained. Renal blood flow is increased after an initial decrease. Diazoxide has no known direct action on the central nervous system.

Patients refractory to other antihypertensive agents usually remain responsive to diazoxide.

Diazoxide is extensively bound to serum protein (>90%). The plasma half-life is 28 ±8.3 hours; however, the duration of its antihypertensive effect is variable, generally lasting less than 12 hours. Although an antihypertensive response has been obtained with slow intravenous injection, in general, a greater antihypertensive effect is obtained with rapid intravenous administration.

Indications HYPERSTAT I.V. Injection is indicated for the emergency reduction of blood pressure in malignant hypertension in hospitalized patients, when prompt and urgent decrease of diastolic pressure is required. Treatment with orally effective antihypertensive agents should be instituted as soon as the hypertensive emergency is controlled.

HYPERSTAT (diazoxide) I.V. Injection is ineffective against hypertension due to pheochromocytoma.

Contraindications HYPERSTAT I.V. Injection should not be used in the treatment of compensatory hypertension, such as that associated with aortic coarctation or arteriovenous shunt.

The drug should not be used in patients hypersensitive to diazoxide or other thiazides, unless the potential benefits outweigh the possible risks.

Warnings **Usage in Pregnancy:** The safety of HYPERSTAT I.V. Injection in pregnancy has not yet been established.

Information is not available concerning the passage of HYPERSTAT in breast milk. However, it is known that diazoxide crosses the placental barrier and appears in cord blood. Like other thiazides, the drug may produce fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, and possibly other adverse reactions that have occurred in adults.

Usage in Children: The safety of HYPERSTAT I.V. Injection in children has not yet been established.

Hypotension may occasionally result from the administration of HYPERSTAT I.V. If hypotension severe enough to require therapy occurs, it will usually respond to the administration of sympathomimetic agents, such as norepinephrine.

Hyperglycemia occurs in the majority of patients, but usually requires treatment only in patients with diabetes mellitus; it will respond to the usual management, including insulin. Therefore, blood glucose levels should be monitored especially in patients with diabetes or in those requiring multiple injections of diazoxide. Hyperglycemia and hyperosmolar coma associated with transient cataracts developed in one infant receiving repeated daily doses of oral diazoxide. The disturbed carbohydrate metabolism was successfully treated with insulin. Cataracts have been observed in a few animals receiving repeated daily doses of intravenous or oral diazoxide.

Since diazoxide causes sodium retention, repeated injections may precipitate edema and congestive heart failure. This retention responds characteristically to diuretic agents if adequate renal function exists. It should be noted that concurrently administered thiazides may potentiate the antihypertensive, hyperglycemic, and hyperuricemic actions of diazoxide (See Drug Interactions).

Since increased volume of extracellular fluid may be a cause of treatment failure in nonresponsive patients, it may be advisable to reduce this increased volume by means of a diuretic agent.

Although no evidence of excessive anticoagulant effects has been reported, patients, especially those who are hypoalbuminemic and receive HYPERSTAT I.V. Injection and coumarin or its derivatives, may require reduction in dosage of the anticoagulant (See Drug Interactions).

Precautions HYPERSTAT (diazoxide) I.V. Injection is a potent antihypertensive agent requiring close monitoring of the patient's blood pressure at frequent intervals. Its administration may occasionally cause hypotension requiring treatment with sympathomimetic drugs. Therefore, adequate facilities to treat such untoward reactions should be available when HYPERSTAT I.V. Injection is used.

HYPERSTAT I.V. Injection should be administered only into a peripheral vein. Because the alkalinity of the solution is irritating to tissue, extravascular injection or leakage should be avoided; subcutaneous administration has produced inflammation and pain without subsequent necrosis. If leakage into subcutaneous tissue occurs, the area should be treated conservatively.

Maximal antihypertensive effects occur after rapid administration (within 30 seconds) into the vein; a slower injection may fail to reduce blood pressure or produce a very brief response.

As with any potent antihypertensive agent, HYPERSTAT I.V. Injection should be used with care in patients who have impaired cerebral or cardiac circulation, that is, patients in whom abrupt and brief reductions in blood pressure might be detrimental.

Special attention is required for patients with diabetes mellitus and those in whom retention of salt and water may present serious problems (See Warnings). Nondiabetic patients may have a transient, reversible, and clinically insignificant increase in blood glucose following HYPERSTAT I.V. Injection.

Since peritoneal dialysis or hemodialysis can reduce levels of diazoxide in the blood, patients undergoing dialysis may require more than one injection.

Adverse Reactions

Frequent and serious adverse reactions: Sodium and water retention after repeated injections, especially important in patients with impaired cardiac reserve; hyperglycemia frequently requiring treatment in diabetic patients, especially after repeated injections.

Infrequent but serious adverse reactions: Hypotension to shock levels; myocardial and/or cerebral ischemia, usually transient but possibly leading to thrombosis and manifested by angina, atrial and ventricular arrhythmias, and marked electrocardiographic changes; unconsciousness, convulsions, paralysis, or confusion; persistent retention of nitrogenous wastes after repeated injections; sensitivity reactions, such as rash, leukopenia, and fever. Rarely, acute pancreatitis has been reported.

Other adverse reactions: Nausea, vomiting, and/or abdominal discomfort; vasodilative phenomena, such as flushing, generalized or localized sensations of warmth, headache (sometimes throbbing), and sweating; orthostatic hypotension, lightheadedness, and weakness of short duration; supraventricular tachycardia and palpitation; transient hyperglycemia in nondiabetic patients; transient retention of nitrogenous wastes; nonanginal "tightness in the chest"; warmth or pain along the injected vein; cellulitis without sloughing and/or phlebitis at the site of extravasation; anorexia and alteration of taste; ileus; bradycardia; back pain; chest discomfort; dyspnea, choking sensation; apprehension or anxiety, malaise, and blurred vision occurred on single occasions; parotid swelling, salivation, lacrimation; ringing in the ears; diarrhea and constipation; increased nocturia; euphoria.

Drug Interactions Since diazoxide is highly bound to serum protein, it may displace other substances or drugs which are also bound to protein, such as bilirubin or coumarin and its derivatives. These potential interactions must be considered when administering HYPERSTAT I.V. Injection. The concomitant administration of diazoxide with thiazides or other commonly used potent diuretics may potentiate the hyperglycemic, hyperuricemic, and antihypertensive effects of diazoxide.

Overdosage Overdosage of HYPERSTAT I.V. Injection may cause an undesirable hypotension. Usually, this can be controlled with sympathomimetic agents, such as norepinephrine; failure of the blood pressure to rise in response to such an agent suggests that the hypotension may have been caused by something other than diazoxide. Excessive hyperglycemia resulting from overdosage will respond to conventional therapy of hyperglycemia.

Diazoxide may be removed from the blood by peritoneal dialysis or hemodialysis.

Animal Pharmacology and Toxicology In studies involving a number of species, including the rat, cat, dog, and monkey, diazoxide has been shown to exert significant antihypertensive actions through its direct effect on peripheral arterioles, which neither impairs cardiac function nor seriously diminishes perfusion of kidneys. In addition, in each species tested, including the rat, dog, and monkey, diazoxide elicits hyperglycemia, increased serum-free fatty acids and decreased plasma insulin levels by a mechanism thought to involve both suppression of insulin release and enhanced catecholamine action.

Although the data are not conclusive, reproduction and teratology studies in several species of animals indicate that diazoxide, when administered during the critical period of embryo formation, may interfere with normal fetal development, possibly through altered glucose metabolism. Parturition was occasionally prolonged in animals treated at term.

Dosage and Administration HYPERSTAT I.V. Injection is administered undiluted and rapidly by intravenous injection. It should only be given into a peripheral vein. Do not administer it intramuscularly, subcutaneously, or into body cavities. Avoid extravasation of the drug into subcutaneous tissues.

The response to HYPERSTAT I.V. Injection varies from patient to patient. Generally, blood pressure decreases within five minutes, often within one to two minutes, to the lowest level achieved. The blood pressure increases relatively rapidly in the next ten to 30 minutes, and then more slowly over the following two to 12 hours, nearly reaching but rarely exceeding the pretreatment level. The response to successive injections is frequently better than that to the initial injection.

Treatment of hypertensive emergencies with HYPERSTAT I.V. Injection should be limited to a few days and a regimen of oral antihypertensive medications should be instituted as soon as possible.

With the patient recumbent, the contents of one 20 ml. ampule containing 300 mg. of HYPERSTAT I.V. Injection are administered intravenously in 30 seconds or less. Slow intravenous injection may fail to reduce the blood pressure or may produce an exceedingly short response.

Specific dosage is required in children or in unusually large or small patients. This dosage may be calculated on the basis of 5 mg./kg. body weight (0.3 ml./kg.) (See Warnings).

A second administration of HYPERSTAT (diazoxide) I.V. Injection may be required for a satisfactory reduction in blood pressure, if the first injection fails to give an adequate response within 30 minutes.

Repeated administration of HYPERSTAT I.V. Injection at intervals of four to 24 hours usually will maintain the blood pressure below pretreatment levels until a regimen of oral antihypertensive medication becomes effective. The interval between injections may be adjusted by the duration of the response to each injection. It is usually unnecessary to continue treatment with HYPERSTAT I.V. Injection for more than four to five days.

Following the use of HYPERSTAT I.V. Injection, the blood pressure should be monitored closely until it has stabilized. Thereafter, measurements taken hourly during the balance of the effect will indicate any unusual response. A further decrease in blood pressure at 30 minutes or more after injection should be investigated for causes other than the action of HYPERSTAT I.V. Injection. It is preferable that the patient remain recumbent for half an hour after injection. In ambulatory patients, the blood pressure should be measured with the patient standing before surveillance is ended.

Since repeated administration of HYPERSTAT I.V. Injection can lead to sodium and water retention, administration of a diuretic may be necessary both for maximal blood pressure reduction and to avoid congestive failure.

How Supplied HYPERSTAT I.V. Injection is supplied in a 20 ml. ampule containing diazoxide 300 mg. in a clear, colorless aqueous solution; box of one ampule.

Protect from light and freezing.

Store away from heat.

On Reliability and a Pound of Flesh

The life's blood of an electrocardiograph is the chart that flows through it.

Assurance that the recording is totally reliable depends, in part, on the quality of the chart itself.

Charts, as provided by the instrument maker, afford this assurance to a maxima ... because they are designed as an integral part of the instrument.

Charts, as provided by others, are imitations at best. They may save a few pennies, but not without risk of shedding a "drop of reliability".

This message was prepared in the interest of better instrument performance by ...

After the "2-Step" Test, the Third Step in Angina* Therapy Is...

NITRO-BID® 6.5
(nitroglycerin 6.5 mg)
Plateau CAPS®

Comparing electrocardiographic responses to standard exercise following placebo or sustained-release nitroglycerin (NITRO-BID® [nitroglycerin] capsules), "...6.5 mg doses produced a favorable response. Such findings indicate that large doses of nitrate escape degradation in the liver."[1]

In another study,"...over a 4-hour period the average work-induced ischemic area increased after placebo by 25 per cent, whereas over the same period the average work-induced ischemic area decreased after peroral nitroglycerin (NITRO-BID® [nitroglycerin] capsules) by 41 per cent."[2]

Also available when titration is important

NITRO-BID® 2.5
(nitroglycerin 2.5 mg)
Plateau CAPS®

* **Indications**
Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
Possibly effective:
For the management, prophylaxis or treatment of anginal attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy, hypotension.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12-hour intervals.

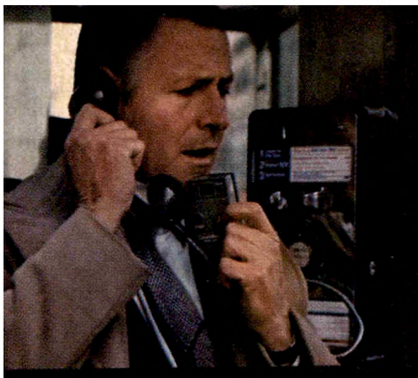
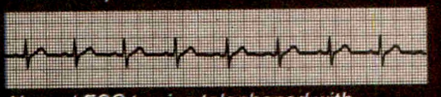
CardioBeeper® PM
PACER MONITOR
It can change your concept of patient care.



The CardioBeeper® heart monitor and CardioBeeper®-PM pacer monitor are unlike any heart monitoring instruments now in use. They're five ounces, pocket-sized and relatively inexpensive. Yet they are unparalleled in electronic sophistication. The CardioBeeper monitors are engineered to permit your coronary patient, within seconds, to telephonically transmit his heart rate and rhythm or ECG. And to allow your pacemaker patient to transmit pacemaker rate interval and artifact, as well as confirmation of battery integrity and ventricular capture. At any time. From any conventional telephone. If indicated, you are then able to institute immediate, often life-sustaining action.

Pacemaker tracing telephoned with CardioBeeper-PM.



Normal ECG tracing telephoned with CardioBeeper.

The CardioBeeper system is simple to use. Your patient need not undress. Or be bothered with paste, gels or straps. He simply places a reusable electrode in each bare armpit. And to transmit, he merely holds the CardioBeeper

monitor next to the mouthpiece of the phone while touching a button. *Physician and patient stay in constant voice contact while sending and receiving.*

You can immediately receive the telephoned data as a series of audible "beeps" indicating each QRS complex or pacemaker spike. To receive a permanent record of ECG or pacemaker artifact, just connect a CardioBeeper® ECG Decoder to your telephone and to any conventional ECG machine. Or instead, connect a CardioBeeper® Decodalyzer to your phone to obtain a visual readout of heart rate or pacemaker rate in BPM, interval count in msec. or a direct ECG tracing for your records.

In life-threatening emergencies or routine checks, no remote cardiac monitoring instruments available today at any cost can rival the revolutionary CardioBeeper system. For further information, simply contact your Wyeth representative or Wyeth Laboratories, Box 8299, Philadelphia, Pa. 19101.

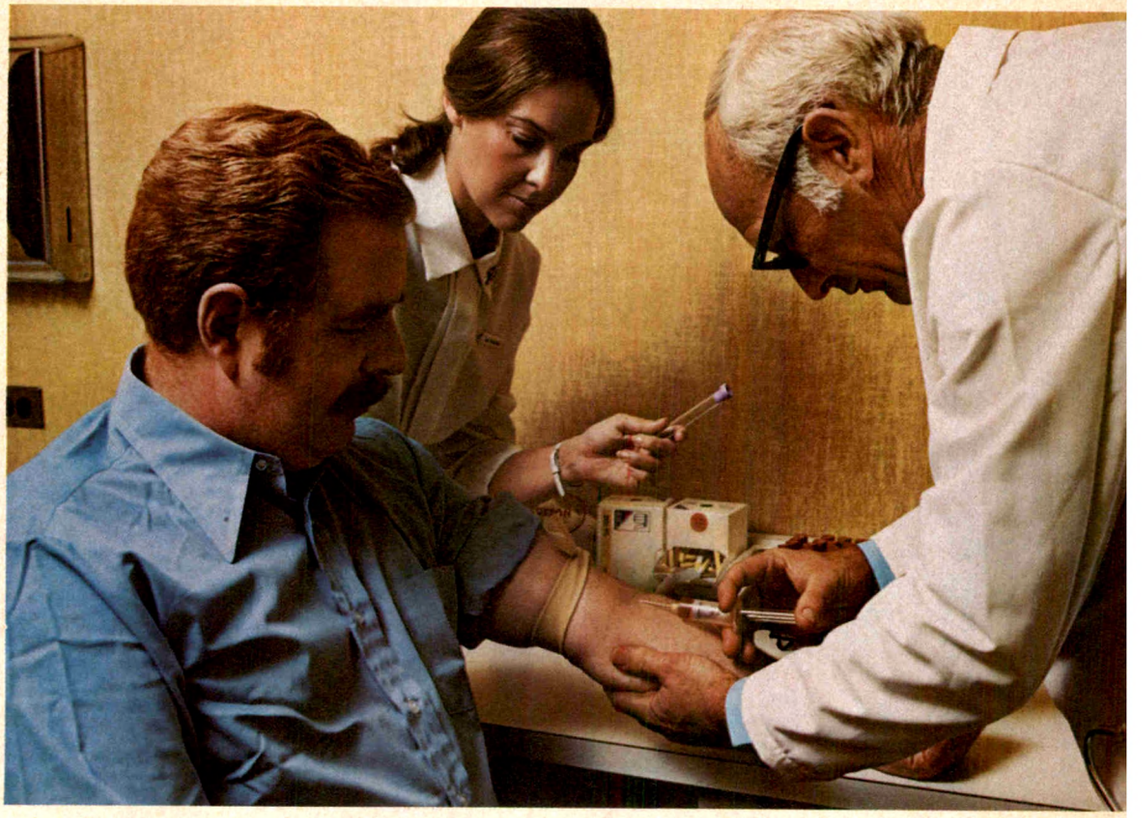
"Hyperlipidemia is one of several factors I sear



(Photographs profession

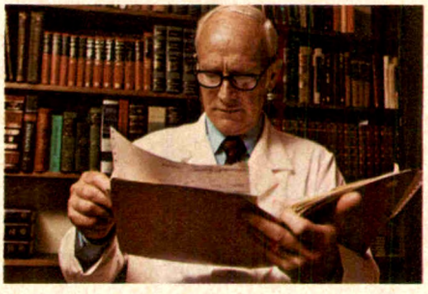
Complete lipid work-up should include both cholesterol and triglyceride determinations

Testing for both lipids—rather than just for cholesterol alone—increases the chances of detecting hyperlipidemia from 60% to over 95%.[2]

Lab results indicate pattern of lipid abnormality

When initial determinations of fasting serum cholesterol and triglyceride levels indicate the presence of hyperlipidemia, the pattern of the lipid abnormality should also be determined.[3]

When lipid elevations are confirmed, underlying disease states that may alter lipid metabolism should be ruled out through history, physical examination, and appropriate laboratory tests. Effective treatment of these pathologic conditions, if they exist, will often return the elevated lipids to a normal range. In the absence of an underlying cause, elevated lipid levels indicate a primary hyperlipidemia.



Therapy begins–but does not necessarily end–with specific dietary recommendations

Diet (specific for the lipid abnormality) is the starting point in the management of primary hyperlipidemia, and in the relatively rare Type I hyperlipop emia it is the *only* therapy since c available drugs are ineffective. B the drug-responsive types (Type IIb, III, IV and V) diet alone may lower lipids adequately.

Drug therapy is often necessary as an adjunct

Convincing the asymptomatic hy demic patient to give up his favo foods for benefits he may not fee best, a difficult task. Even under fully monitored dietary regimens reductions may be inadequate.[4] F reasons it is often necessary to ac antilipemic agent to the dietary r to produce a significant reductior serum lipids.

AN IMPORTANT NOTE: It has not been established whether the drug-induced lowering of serum cholesterol or li levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart dise Several years will be required before current investigations will yield an answer to this question.

or and vigorously treat."[1]

ng with early hypertension, excessive rette smoking and dietary indiscre- s, it is one of the few manifestations nodern society that an individual sician can attempt to control."[1]

his is how one clinician views hyper- lemia—a condition widespread in erica today. The treatment he speaks ften calls for a dietary regimen spe- for the lipid abnormality *plus* an lipemic agent. And since many hy- ipidemic patients exhibit elevations *oth* cholesterol and triglycerides, need a drug such as ATROMID-S fibrate), which has the ability to er *both* lipids.

omid-S significantly reduces lesterol and triglycerides—often in ents unresponsive to diet[5]

ATROMID-S as an adjunct to diet has oven record of effectiveness in lower- serum elevations of both cholesterol triglycerides.[5-8]

lthough most hyperlipidemic pa- ts are asymptomatic, a small number exhibit skin lesions or xanthomas. ression of xanthomatous lesions with OMID-S visually demonstrates the cacy of this lipid-lowering agent. In ie patients xanthomas disappear pletely. In others the size and num- of lesions are reduced.

tinuous treatment, maintenance of y dosage vital to long-term control

eliable cholesterol- and triglyceride-lowering effect is usually sustained as long as ATROMID-S treatment is uninterrupted. This ability to maintain control of serum lipids for extended periods is of primary importance in treating a disorder as persistent as hyperlipidemia.

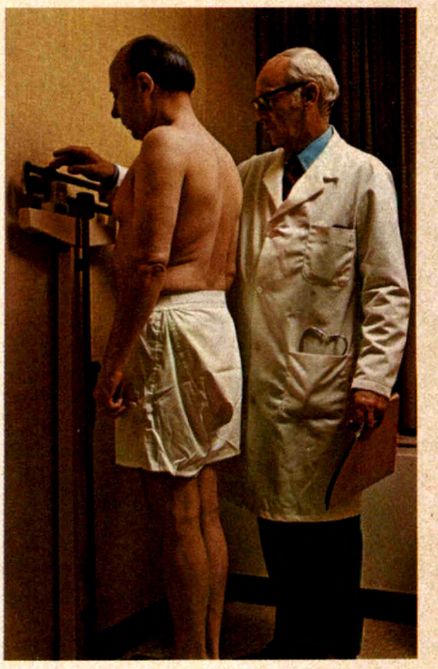
ATROMID-S is effective in a simple, well-accepted regimen that patients can stay with. Initial *and* maintenance dosage is 2 Gm. daily, in divided doses. Some patients may respond to a lower dosage. To maintain continuous control of lipid levels, therapy should be uninterrupted.

The lipid-lowering effect of ATROMID-S is usually noted during the first month of therapy. The higher the initial level, the greater the lipid reduction likely to occur.

If response is inadequate after three months of therapy, the drug should be discontinued. However, if xanthoma tuberosum is present, treatment should continue for longer periods (even up to one year) provided there is a reduction in the size and/or number of the xanthomas.

10 years of successful overall clinical experience with Atromid-S

Throughout more than ten years of widespread use, ATROMID-S has proven to be an effective and very well-tolerated drug. However, before prescribing, you should be thoroughly familiar with the possible adverse reactions as well as with the precautions and warnings described on the last page of this advertisement.



Periodic follow-up important

Once blood lipids have been stabilized at normal levels on a regimen of diet and ATROMID-S, the patient should be examined and his blood lipids tested every two to three months during the first year or so. If stabilization at such lower levels is maintained over this period, the intervals between measurements can be lengthened.

Atromid-S®

Brand of clofibrate

helps control the lipid factor in your patient's profile

Ayerst®

IF GIVEN IN CONJUNCTION WITH ANTICOAGULANTS

WARNING: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

See last page of advertisement for prescribing information.

Atromid-S® (clofibrate)
helps reduce elevated cholesterol and/or triglyceride levels — not just cholesterol alone

Initial and maintenance dosage: 2 Gm. daily (four capsules), in divided doses. Some patients may respond to a lower dosage.

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ATROMID-S® (clofibrate)

Antilipidemic agent for reduction of elevated serum lipids

INDICATIONS: ATROMID-S is indicated as adjunctive therapy to diet and other measures for the reduction of elevated serum cholesterol (especially the beta lipoprotein fraction) and/or triglycerides. Clofibrate appears to have a greater depressant effect on the very low density lipoproteins (S_f 20-400) rich in triglycerides than the low density lipoproteins (S_f 0-20) rich in cholesterol.

ATROMID-S is also indicated for treatment of patients with xanthoma tuberosum associated with hyperlipidemia. The skin lesions frequently regress with clofibrate.

It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

CONTRAINDICATIONS: Clofibrate is contraindicated in pregnant women. While teratogenic studies have not demonstrated any effect attributable to clofibrate, it is known that serum of the rabbit fetus accumulates a higher concentration of clofibrate than that found in maternal serum, and it is possible that the fetus may not have developed the enzyme system required for the excretion of clofibrate.

It is contraindicated in lactating women since it is not known if clofibrate is secreted in the milk.

It is contraindicated in patients with clinically significant hepatic or renal dysfunction.

It is contraindicated in patients with primary biliary cirrhosis since it may raise the already elevated cholesterol in these cases.

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Strict birth control procedures must be exercised by women of childbearing potential. In patients who plan to become pregnant, clofibrate should be withdrawn several months before conception. Because of the possibility of pregnancy occurring despite birth control precautions in patients taking clofibrate, the possible benefits of the drug to the patient must be weighed against possible hazards to the fetus.

PRECAUTIONS: Before instituting therapy with clofibrate, attempts should be made to control serum lipids with appropriate dietary regimens, weight loss in obese patients, control of diabetes mellitus, etc.

Because of the long term administration of a drug of this nature, adequate base line studies should be performed to determine that the patient has significantly elevated serum lipid levels. Frequent determinations of serum lipids should be obtained during the first few months of ATROMID-S administration, and periodic determinations thereafter. The drug should be withdrawn after three months if response is inadequate. However, in the case of xanthoma tuberosum, the drug should be employed for longer periods (even up to one year) provided that there is a reduction in the size and/or number of the xanthomata.

Subsequent serum lipid determinations should be done to detect a paradoxical rise in serum cholesterol or triglyceride levels. Clofibrate will not alter the seasonal variations of serum cholesterol peak elevations in midwinter and late summer and decreases in fall and spring. If the drug is discontinued, the patient should be placed on an appropriate hypolipidemic diet, and his serum lipids should be monitored until stabilized, as a rise in these values to or above the original base line may occur.

During clofibrate therapy, frequent serum transaminase determinations and other liver function tests should be performed since the drug may produce abnormalities in these parameters. These effects are usually reversible when the drug is discontinued. Hepatic biopsies are usually within normal limits. If the hepatic function tests steadily rise or show excessive abnormalities, the drug should be withdrawn. Therefore use with caution in those patients v a past history of jaundice or hepatic disease.

Clofibrate may produce "flu like" symptoms (muscular aching, soren cramping). The physician should differentiate this from actual viral and bacterial disease.

Use with caution in patients with peptic ulcer since reactivation has b reported. Whether this is drug-related is unknown.

Complete blood counts should be done periodically since anemia, and m frequently, leukopenia have been reported in patients who have been tak clofibrate.

Various cardiac arrhythmias have been reported with the use of clofibrate.

Several investigators have observed in their studies that clofibrate may duce a decrease in cholesterol linoleate but an increase in palmitoleate oleate, the latter being considered atherogenic in experimental animals. significance of this finding is unknown at this time.

ADVERSE REACTIONS: Of the pertinent reactions, the most common nausea. Less frequently encountered gastrointestinal reactions are vomit loose stools, dyspepsia, flatulence, and abdominal distress. Reactions repor less often than gastrointestinal ones are headache, dizziness, and fatigue; m cle cramping, aching, and weakness; skin rash, urticaria, and pruritus; brittle hair, and alopecia.

The following reported adverse reactions are listed alphabetically by systems

Cardiovascular
- Increased or decreased angina
- Cardiac arrhythmias
- Both swelling and phlebitis at site of xanthomas

Dermatologic
- Skin rash
- Alopecia
- Allergic reaction including urticaria
- Dry skin and dry brittle hair
- Pruritus

Gastrointestinal
- Nausea
- Diarrhea
- Gastrointestinal upset (bloating, flatulence, abdominal distress)
- Hepatomegaly (not associated with hepatotoxicity)
- Vomiting
- Stomatitis and gastritis

Genitourinary
- Impotence and decreased libido
- Findings consistent with renal dysfunction as evidenced by dysuria, he turia, proteinuria, decreased urine output. One patient's renal biop suggested "allergic reaction."

Hematologic
- Leukopenia
- Potentiation of anticoagulant effect
- Anemia
- Eosinophilia

Musculoskeletal
- Myalgia (muscle cramping, aching, weakness)
- "Flu like" symptoms
- Arthralgia

Neurologic
- Fatigue, weakness, drowsiness
- Dizziness
- Headache

Miscellaneous
- Weight gain
- Polyphagia

Laboratory Findings
- Abnormal liver function tests as evidenced by increased transamina (SGOT and SGPT), BSP retention, and increased thymol turbidity
- Proteinuria
- Increased creatine phosphokinase

Reported adverse reactions whose direct relationship with the drug has r been established: peptic ulcer, gastrointestinal hemorrhage, rheumatoid arth tis, tremors, increased perspiration, systemic lupus erythematosus, blurr vision, gynecomastia, thrombocytopenic purpura.

DOSAGE AND ADMINISTRATION: *Initial:* The recommended dosage adults is 2 Gm. daily, in divided doses. Some patients may respond to a low dosage. *Maintenance:* Same as for initial dosage. **Note:** In children, insufficie studies have been done to show safety and efficacy.

DRUG INTERACTIONS: Caution should be exercised when anticoagulan are given in conjunction with ATROMID-S (clofibrate). The dosage of the ant agulant should be reduced usually by one-half (depending on the individu case) to maintain the prothrombin time at the desired level to prevent bleedi complications. Frequent prothrombin determinations are advisable until it h been definitely determined that the prothrombin level has been stabilized.

MANAGEMENT OF OVERDOSAGE: While there has been no reported ca of overdosage, should it occur, symptomatic supportive measures should taken.

HOW SUPPLIED: ATROMID-S—No. 243—Each capsule contains 500 mg. cl brate, in bottles of 100.

patient care
commitment...
yesterday, today
and tomorrow.

Yesterday. The Honeywell patient care commitment began more than 15 years ago. We recognized that physiological data systems must cons of more than just good hardware, that our commitment to you and better patient care must be total.

Today. Honeywell products for health care can be found in cardiovascular diagnostic, surgical monitoring facilities, hospital data centers and clinical laboratories all over the world.
Our commitment includes six different physiological data systems: phonocardiography, echocardiography, catherization, surgery, surgical intensive care and a G.I. motility system. Each medical-engineered and supported by Honeywell application specialists. Our commitment includ professional training for your people and a choice of several comprehensive service programs.

Tomorrow. Tomorrow's biomedical monitoring systems are being built now in Honeywell R&D facilities . . . to make your job easier, to ma diagnosis more accurate and to help assure the most modern patient ca

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

CLINICAL STUDIES

New Observations on the Effects of Atropine on the Sinoatrial and Atrioventricular Nodes in Man

GOPAL DAS, MD, FACC
FREDERICK N. TALMERS, MD, FACC
ARNOLD M. WEISSLER, MD, FACC

Allen Park and Detroit, Michigan

Previous observations of slowing of the heart rate after administration of atropine in doses smaller than 0.4 mg and recent reports of development of rhythm disorders in patients with acute myocardial infarction given atropine prompted us to evaluate systematically the effects of various doses of atropine (0.1 to 0.8 mg) on the response of the sinoatrial (S-A) and atrioventricular (A-V) nodes in healthy volunteers. The response of the S-A node to atropine was characteristically bimodal, slowing at smaller doses and accelerating at larger doses. In contrast, the A-V node showed acceleration of conduction in response to all doses of atropine used. A hypothesis based on current understanding of the electrophysiologic parameters governing impulse formation and impulse conduction is advanced to explain the apparent paradox in the S-A and A-V nodal responses to small doses of atropine. The results suggest the need for caution and continuous rhythm monitoring when giving atropine to patients with acute myocardial infarction.

The function of the sinoatrial (S-A) and atrioventricular (A-V) nodes is influenced by a balance between parasympathetic and sympathetic control mechanisms. Stimulation of the parasympathetic system causes a decrease in the S-A nodal rate and prolongation of A-V conduction time.[1] On the other hand, blockade of parasympathetic influences results in an increase in the S-A rate and abbreviation of A-V conduction time. Previous observations have shown that atropine, an agent well known for its vagolytic action in usual doses, in fact decreases the cardiac rate in small doses.[2] This study was designed to evaluate the pharmacologic effects of atropine in doses ranging from 0.1 to 0.8 mg on the S-A and A-V nodes in man. Since A-V conduction is influenced by changes in heart rate as such, the effects of atropine on A-V conduction time were further studied in patients whose heart rate was maintained constant by atrial pacing.

Material and Methods

The study was carried out in normal volunteer subjects aged 25 to 35 years and in patients undergoing diagnostic atrial pacing studies. Informed consent was obtained from each person. None of the normal subjects had cardiac ab-

NS = not significant; P = probability.

normalities as detected on physical examination, chest X-ray film or electrocardiogram. The patient studies were carried out from a protocol identical to that for normal subjects except that a bipolar pacing electrode was positioned near the junction of the superior vena cava and right atrium under fluoroscopic monitoring and the right atrium was continuously paced with a 2 msec square wave pulse of twice the threshold amplitude (Medtronic model 5837 pulse generator). The heart rate in these patients was held constant at 100 to 110 beats/min throughout the period of atropine administration.

For all studies, an intravenous infusion with 5 percent dextrose in water was started and surface electrocardiographic leads were applied and connected to a DR-8 (Electronics for Medicine) recorder. Each subject was then allowed to rest for 30 minutes before the study. Three electrocardiographic leads (I, II and aVF) were simultaneously displayed and recorded at a paper speed of 100 mm/sec with time lines at 40 msec intervals. Three control recordings were obtained 10 minutes apart and the results averaged. Placebo (1 ml of normal saline solution) or atropine (diluted in 1 ml of saline solution) was administered by intravenous tubing over a period of 1 minute in a single blind manner. The tracings were then repeated 5 minutes later. The S-A nodal rate was derived from mean P-P intervals and was rounded to the nearest integer, and the A-V conduction time was measured from the beginning of the P wave to the beginning of the QRS complex and was expressed to the nearest 4 msec. Ten to 20 beats were measured and averaged for each determination. Student's paired t test was used to analyze the statistical significance of the data.

Results

The effects of atropine on the S-A nodal rate and A-V conduction time are summarized in Table I and Figure 1. Both were essentially unchanged after administration of placebo. Atropine in doses smaller than 0.4 mg caused slowing of the S-A rate. With increasing doses above 0.4 mg there was a sequential increase in sinus rate. In contrast, A-V conduction time decreased progressively at all dose levels used.

The response of A-V conduction time when the heart rate was held constant by atrial pacing consisted of a progressive abbreviation throughout the range of atropine doses used (Fig. 2).

Discussion

Pharmacology of atropine: Although atropine was isolated by Vaquelin[3] in 1809, it was Bezold and Bloebaum[4] who demonstrated its antivagal properties in 1867. Stimulation of the parasympathetic nervous system leads to release of acetylcholine at postganglionic parasympathetic nerve endings (muscarinic effects) and at preganglionic nerve endings (nicotinic effects).[5] In therapeutic doses (0.4 to 1.0 mg) atropine modifies the muscarinic effects alone,[4,6] whereas in large doses it blocks both the muscarinic and the nicotinic effects of acetylcholine.[7] However, there is a considerable variation in the response to atropine depending on the organ system.[8] Although in therapeutic doses atropine effectively blocks the effects of vagal stimulation on the heart and salivary glands, the effects on the intestinal and urinary bladder musculature remain intact.[8,9] The mechanism of atropine action is not clearly understood although it is widely believed to be the competitive inhibition of the parasympathetic receptors. The secretion of acetylcholine from nerve endings is not affected.[10,11] The effects of atropine begin about 25 seconds after intravenous injection and reach a peak value in 2 to 3 minutes.[12]

Effects of atropine on S-A and A-V nodes: It has been well established that stimulation of the parasympathetic system causes a decrease in S-A

TABLE II

Possible Mechanisms of Slowing of S-A Nodal Rate in Response to Small Doses of Atropine

1. Central stimulation of vagal centers[1,19–23]
2. Peripheral stimulation of parasympathetic receptors[4,26]
3. Inhibition of cholinesterase enzyme[27,29]
4. Effects on sympathetic nervous system[30]
5. Direct effects on the pacemaker cells

rate and a prolongation of A-V conduction time.[1] Pharmacologic blockade, on the other hand, results in an increase in S-A rate and an abbreviation of A-V conduction time. The magnitude of these responses depends upon the degree of endogenous parasympathetic activity at the time of drug administration. Atropine in therapeutic doses induces acceleration of the S-A rate and a decrease in the A-V conduction time as evidenced by the P-R interval. However, as shown herein and by others,[13–18] small doses of atropine (less than 0.4 mg) actually slow the S-A rate whereas, as demonstrated in this study, A-V conduction accelerates consistently (Table I). In normal subjects (Fig. 1) there was a lesser abbreviation of A-V conduction time after administration of 0.8 mg of atropine than after administration of 0.4 mg. We believe that this represents the secondary effects of the acceleration in heart rate induced at the higher dose level (Table I: no significant change in heart rate at 0.4 mg, an increase of 21 beats at 0.8 mg). When heart rate was maintained constant by atrial pacing, A-V conduction time decreased progressively with increasing doses of atropine (Fig. 2), lending evidence that the acceleration of A-V conduction is indeed dose-dependent throughout the range of doses studied.

Mechanism of S-A slowing with small doses of atropine: The explanation for the differential effects of atropine on the S-A and A-V nodes is not clear. In the past, various mechanisms have been proposed to explain the vagotonic effects of small doses of atropine on the S-A node (Table II). Atropine in small doses causes stimulation of the central nervous system,[19,20] particularly of the medulla oblongata,[1] resulting in stimulation of vagal centers. According to Mitchell,[21] Szerb[22] and Polak,[23] the release of acetylcholine within the central nervous system is responsible for the increased central vagal tone. That this mechanism cannot be the sole explanation for the slowing in heart rate is evidenced by the observation of Kottmier and Gravenstein[24] that the bradycrotic response following administration of small doses of atropine persisted after bilateral vagotomy. Furthermore, atropine methylbromide, which does not cross the blood brain barrier, induces cardiac slowing when administered in small doses.[24,25]

In relation to the intrinsic mechanics of atropine at peripheral nerve endings Lullman et al.,[26] Sekiya[27] and Kato[28] demonstrated that atropine inhibits the activity of the enzyme cholinesterase, and they postulated that in small doses this anticholinesterase activity may actually predominate and lead to an increased receptor response to naturally existing acetylcholine.

Another explanation of the slowing of S-A rate is that vagotonic effects of atropine may exert their influence through inhibition of the sympathetic nervous system or beta adrenergic receptors in the heart. Studies by Malhotra and Das[29] revealed increased release of acetylcholine to parasympathetic stimulation in the presence of sympathetic blockade. However, Chamberlain et al.[30] found persistence of cardiac slowing after administration of atropine in volunteers

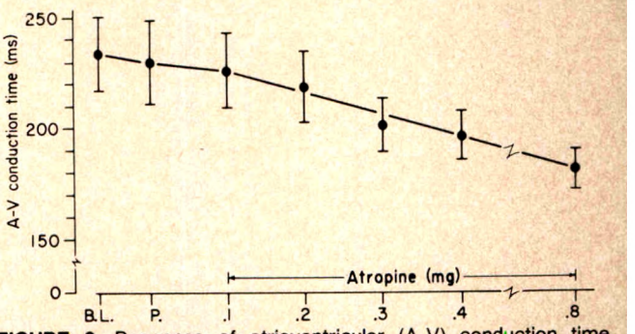

FIGURE 2. Response of atrioventricular (A-V) conduction time, under conditions of constant heart rate produced by atrial pacing, to increasing dosage of atropine. B.L. = base-line (control) value; P. = value with placebo. Data expressed as mean values ± standard error of the mean.

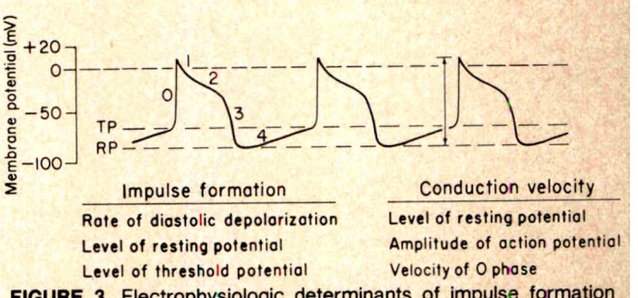

FIGURE 3. Electrophysiologic determinants of impulse formation and impulse conduction. RP = resting potential; TP = threshold potential.

in whom the beta receptors were blocked by propranolol, thus discounting sympathetic inhibition as a mechanism for this cardiac slowing.

According to Patton,[31] most receptor blocking agents in small doses produce brief depolarization of the receptors, resulting in stimulation, whereas large doses, by sustained depolarization, cause receptor blockade. In this respect the receptor stimulation after administration of small doses of atropine is comparable to the actions of ergot alkaloids on alpha adrenergic receptors and of dichloroisoproterenol and propranolol on beta receptors.[4]

Mechanism of effects of atropine on A-V conduction: Although the vagotonic response of the S-A node to small doses of atropine may be attributed to the peripheral mechanisms, the vagolytic response of the A-V node to the same doses of atropine remains unexplained. Recent knowledge of the electrophysiology of the cells in the S-A and A-V nodes and the electrophysiologic variables governing the function of these cells, namely, impulse formation and impulse conduction, may offer an explanation for these differences. According to current concepts (Fig. 3), the rate of impulse formation is related to the rate of diastolic depolarization (phase 4), the level of resting potential and the level of threshold potential.[32] If the difference between the resting potential and the threshold potential is increased either by increased resting potential (more negative) or by decreased threshold potential (less negative), the rate of impulse formation decreases. A decrease in the rate of phase 4 depolarization will also result in slowing of the rate of impulse formation. Impulse conduction, on the other hand, is critically related to the rate of rise of zero phase depolarization and the amplitude of the action potential, both of which are directly related to the magnitude of the resting potential of the cell.[33,34]

The effects of small doses of atropine, either by virtue of direct receptor stimulation or by anticholinesterase activity, would be similar to those of small doses of acetylcholine, namely, hyperpolarization (increased resting potential) of the cells and decreased rate of phase 4 depolarization,[32,35] resulting in a decreased rate of impulse formation (S-A node) and at the same time improved impulse conduction. Thus, one need not postulate actual differences in the actions of atropine on S-A and A-V nodal function; rather, the inherently unique electrophysiologic variables governing the function of these tissues would in themselves result in what appears to be a paradoxical response at small doses.

Clinical implications: One of the principal uses of atropine in cardiovascular practice is in the management of patients with a slow heart rate. Han et al.[36] have shown that excessive slowing of the heart rate results in a greater disparity in the duration of action potentials and the refractory periods of cardiac tissues. This inhomogeneous electrical setting predisposes to reentrant excitation and arrhythmias. Increasing the heart rate, on the other hand, decreases this inhomogeneity and the incidence of arrhythmias. This, along with recent observations emphasizing the high rate of occurrence of atropine-responsive bradycardia in patients with acute myocardial infarction,[37–39] and the high risk of serious arrhythmias and mortality in them,[40,41] has led to widespread recommendations for the use of large doses of atropine (1 to 2 mg) in the management of such patients.[37,42,43] Prophylactic use, including self-medication with atropine in the prehospital care of acute infarction, has been advocated to reduce the risk of these bradyarrhythmias.[44–46]

Although the systematic response of patients with acute myocardial infarction to graded doses of atropine is not known, our observations suggest caution in the use of atropine in such patients. Smaller doses may aggravate bradycardia, and larger doses may actually precipitate tachyarrhythmias.[47,48] We believe that greater vigilance and the titration of individual dosage during rhythm monitoring are mandatory in order to achieve an optimal response to atropine in such patients.

Induction of Atrioventricular Nodal Reentrant Tachycardia After Atropine

Report of Five Cases

After intravenous administration of 0.5 mg of atropine sustained atrioventricular (A-V) nodal reentrant tachycardia could be produced in five patients who had no prior historical or electrocardiographic evidence of supraventricular tachycardia. During the control period single atrial echo beats could be demonstrated in four of the five patients, but no instance of sustained tachycardia occurred. Atropine, known to enhance A-V nodal conduction, allowed achievement of longer A-H intervals (Case 1) and provided the necessary balance of conduction and refractoriness within the A-V nodal reentrant pathways (Cases 1 to 5) to sustain A-V nodal reentry in these patients.

It has repeatedly been observed that a critical degree of atrioventricular (A-V) nodal conduction delay is required for the demonstration of manifest A-V nodal reentry and the initiation of A-V nodal reentrant supraventricular tachycardia.[1–10] This critical degree of A-V nodal delay can be achieved either with appropriately timed premature atrial beats occurring during the relative refractory period of the A-V node or with rapid atrial pacing.[9] Less well appreciated is the fact that sustained A-V nodal reentry requires a critical balance between conduction and refractoriness within the reciprocating limbs of a reentrant circuit.

During the conduct of previous studies[11,12] designed to evaluate the effects of atropine on A-V conduction and refractoriness, we encountered five patients who had only single or no atrial echo beats due to A-V nodal reentry during the control period but who had sustained A-V nodal reentrant tachycardia after administration of small doses of atropine (0.5 mg intravenously). We postulate that atropine, known to enhance A-V nodal conduction, permitted the necessary balance of conduction and refractoriness to allow sustained reentrant tachycardia in these patients. This report deals with the observations made in these five patients.

Methods

Right heart catheterization was performed with patients under local anesthesia and in the postabsorptive, nonsedated state. The nature of the procedure was explained to all patients and signed consent was obtained. Electrode catheters were percutaneously introduced into peripheral veins and fluoroscopically positioned to record atrial and His bundle electrograms as previously described.[13] Atrial pacing was accomplished using a digital stimulator capable of delivering rectangular impulses of 1.5 msec duration at an adjustable milliamperage. The rate of atrial pacing was gradually increased (in increments of 10 beats/min) to rates sufficient to produce A-V nodal Wenckebach cycles. During pacing-induced A-V nodal Wenckebach cycles, the stimulator was periodically turned off to permit observation of subsequent spontaneous events. The atrial extrastimulus technique was employed to determine refractory periods of the A-V conduction system.[14] A premature

atrial beat (A_2) was introduced after every eighth sinus or paced beat (A_1-A_1) until atrial refractoriness occurred.

Standard electrocardiographic leads I, II, III and V_1, intracardiac electrograms and time lines generated at 10 and 100 msec were displayed on a multichannel oscilloscope and recorded on magnetic tape. The records were subsequently recorded on photographic paper at a speed of 150 mm/sec. After completion of the control studies 0.5 mg of atropine was given intravenously and the studies were repeated 10 minutes after drug administration. All equipment was carefully grounded. The procedure was well tolerated by all patients.

Definition of Terms[15,16]

The A-H interval was measured from the onset of the low atrial electrogram (on the recording of the His bundle electrogram) to the beginning of the His bundle deflection and was used as an approximation of A-V nodal conduction time (normal for our laboratory 60 to 140 msec).

The H-V interval was similarly measured from the onset of the His bundle deflection to the beginning of ventricular activation and was taken as an approximation of His-Purkinje conduction time (normal for our laboratory 30 to 55 msec).

The effective refractory period of the atrium is defined as the longest S_1-S_2 interval in which S_2 fails to depolarize the atrium, S representing the artificial stimulus.

The effective refractory period of the A-V node is the longest atrial coupling interval (A_1-A_2 interval) in which A_2 blocks in the A-V node.

The functional refractory period of the A-V node is the shortest H_1-H_2 interval in response to a full range of A_1-A_2 intervals to the point of atrial refractoriness.

Atrial echo beat (A-V nodal reentrant atrial echo beat, Ae) is the reentrant atrial beat with a low to high sequence of atrial activation following induced atrial beats associated with a critical degree of A-V nodal conduction delay (A-H interval).

Results

Clinical and electrophysiologic data are summarized in Tables I and II. None of the patients had a history suggestive of tachycardia or electrocardiographic evidence of a supraventricular tachyarrhythmia or the Wolff-Parkinson-White syndrome. No patient was taking any cardioactive medications. The well known effects of atropine on sinus rate and A-V nodal conduction were observed in all five patients. The average decrease in sinus cycle length after administration of atropine was 164 msec (range 60 to 300 msec), representing an average decrease of 21 percent from control values. All patients manifested a decrease in the sinus A-H interval after administration of atropine (average decrease 28 msec). Results obtained in individual patients are as follows:

Case 1 (Fig. 1 and 2): In this 15 year old boy with first degree heart block of uncertain origin neither atrial echo beats nor A-V nodal reentrant tachycardia could be elicited during control studies but could readily be induced after administration of 0.5 mg of atropine. During control studies (Fig. 1, panels A and B) the longest A-H interval that could be achieved during premature atrial stimulation was 280 msec (panel A). The effective refractory period of the

	A	600	90	500	500–600	600	300

A-V node was determined to be 580 msec (panel B). After administration of atropine (panels C and D) the effective refractory period of the A-V node significantly shortened, thereby permitting more premature atrial beats to be conducted with longer A-H intervals. Sustained A-V nodal reentrant tachycardia consistently occurred after A-H intervals of 440 to 575 msec. Termination of tachycardia by a single properly timed premature atrial depolarization is illustrated in Figure 2.

Case 2 (Fig. 3): In the control period, only infrequent single atrial echo beats occurred after A-H intervals of 370 to 390 msec induced by premature atrial stimulation; these beats did not occur at similar A-H intervals during pacing-

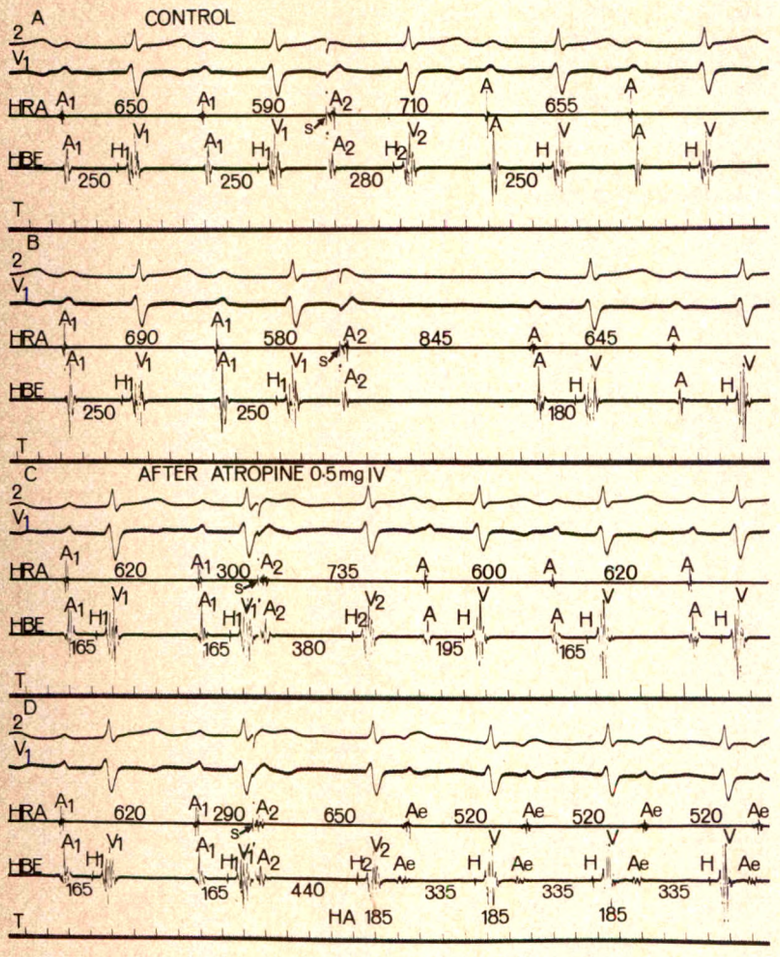

FIGURE 1. Case 1. Supraventricular tachycardia after administration of atropine. Tracings in each panel **(from top to bottom)** are: electrocardiographic leads II (2) and V_1, a high right atrial electrogram (HRA), His bundle electrogram (HBE) and time lines (T) at 10 and 100 msec. S denotes stimulus artifact. During sinus rhythm the A-H interval is abnormally prolonged at 250 msec and the sequence of atrial activation is from the high to the low atrium. In the control period a premature atrial beat (A_2) coupled to a preceding sinus beat (A_1) at an interval of 590 msec is conducted with an A_2-H_2 interval of 280 msec. At a slightly closer A_1-A_2 interval of 580 msec **(panel B),** A_2 is blocked in the A-V node and a sinus escape beat follows. Administration of atropine resulted in shortening of the sinus cycle length and the A-H interval and a marked decrease in the effective refractory period of the A-V node as evidenced by the ability of relatively earlier premature atrial beats to conduct to the bundle of His **(panels C** and **D).** The decrease in the A-V nodal effective refractory period after administration of atropine is accompanied by achievement of longer A-H intervals **(panels C** and **D).** At critically long A-H intervals a sustained supraventricular tachycardia occurred **(panel D).** Note the low to high sequence of atrial activation (Ae) and the inverted P wave in lead II during supraventricular tachycardia. Ae = atrial echo beat.

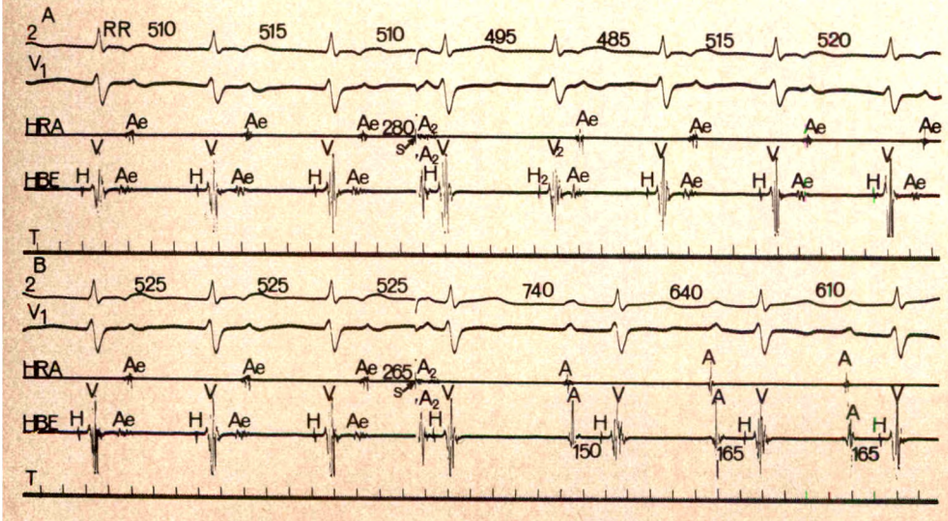

FIGURE 2. Case 1. Termination of supraventricular tachycardia. In **panel A,** a premature atrial beat is delivered at an Ae-A_2 interval of 280 msec and does not terminate the tachycardia. At a closer coupling interval of 265 msec **(panel B),** A_2 successfully terminates the tachycardia and sinus rhythm is restored.

induced A-V nodal Wenckebach cycles. After administration of atropine, sustained A-V nodal reentrant tachycardia regularly occurred at similar or shorter A-H intervals produced either by premature atrial depolarizations or by pacing-induced A-V nodal Wenckebach cycles.

Case 3 (Fig. 4): During control studies in this patient, A-V nodal reentry, as manifested by single or two consecutive atrial echo beats, could easily be elicited, but sustained A-V nodal reentrant tachycardia never occurred. After administration of atropine, sustained reentrant tachycardia was regularly initiated at the same A-H intervals that produced only one or two echo beats in the control period.

Cases 4 and 5: A-V nodal Wenckebach cycles induced by atrial pacing after administration of atropine resulted in sustained supraventricular tachycardia at the same period of A-V nodal conduction delay (A-H interval) that gave rise to only single atrial echo beats during the control period (Table II). The critical A-H intervals necessary for demonstration of A-V nodal reentry, although obtained with rapid atrial pacing, could not be attained during atrial premature coupling in these two patients.

Discussion

Mechanism of reentrant phenomenon in each case: It has been well established that A-V nodal reentry in the form of atrial echo beats requires a critical range of antegrade A-V nodal delay, most often elicited by premature atrial stimulation. Within the context of our present limited understanding of the reentrant phenomenon it is postulated that a requisite antegrade delay is necessary to allow recovery of the retrograde limb of the reentrant circuit, which may lead to reexcitation of the atrium. Within the limits of this currently accepted concept the following explanations are offered for the results obtained in these cases.

In Case 1, a prolonged effective refractory period of the A-V node prevented closely coupled atrial premature beats from being conducted with sufficiently long antegrade A-V nodal conduction time (A-H intervals) to permit recovery of the retrograde limb. This situation was reversed by atropine, which decreased the effective refractory period of the A-V node so that more closely coupled atrial premature beats could be conducted. These beats were associated with critically long A-H intervals and the necessary balance between conduction and refractoriness within the limbs of the reentrant circuit was achieved.

In Cases 3 to 5, most often only single and occasionally two consecutive atrial echo beats were elicited in the control period within a critical zone of

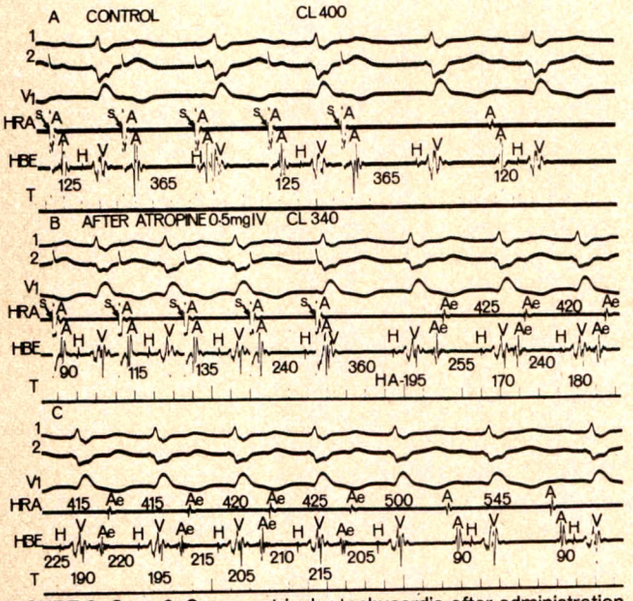

FIGURE 3. Case 2. Supraventricular tachycardia after administration of atropine. **Panel A** shows 3:2 A-V nodal Wenckebach cycles at a paced atrial cycle length of 400 msec. The A-H intervals of the first and second conducted beats measure 125 and 365 msec, respectively, and the third atrial beat blocks in the A-V node. The atrial stimulus is omitted after the last conducted beat of the second Wenckebach cycle following which a sinus escape beat occurs. After administration of atropine A-V nodal conduction of the Wenckebach type occurred at a paced atrial cycle length of 340 msec (**panel B**). The last (fifth) atrial paced beat conducts with an A-H interval of 360 msec and is followed by a sustained A-V nodal reentry. This figure also demonstrates spontaneous termination of supraventricular tachycardia. From the onset of the tachycardia there is a progressive decrease in the Ae-H interval (**panels B** and **C** are continuous) from 255 msec to 205 msec. There is a corresponding increase in the H-Ae interval and a final block of the impulse in the retrograde limb of the reentry circuit, and sinus rhythm ensues.

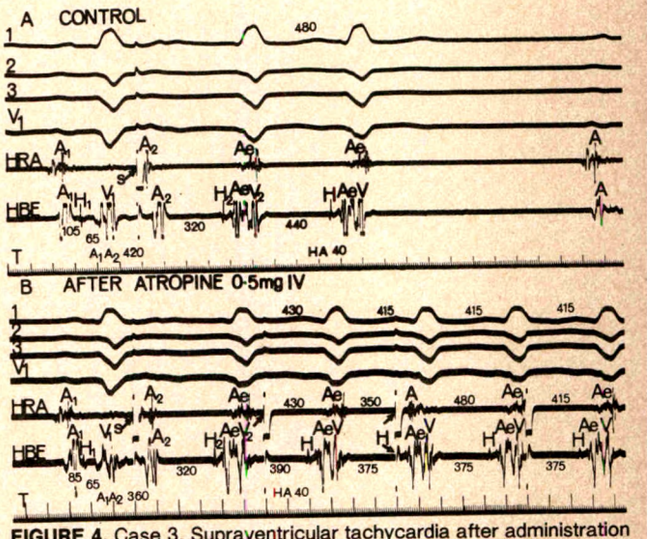

FIGURE 4. Case 3. Supraventricular tachycardia after administration of atropine. In **panel A** a premature atrial beat (A_2) is coupled to the preceding sinus beat at an A_1-A_2 interval of 420 msec. A_2 conducts with an A_2-H_2 interval of 320 msec and initiates unsustained A-V nodal reentry. The reentrant impulse conducts in antegrade fashion to the bundle of His with an Ae-H interval of 440 msec, then conducts back to the atrium and finally blocks in the antegrade limb. The H-Ae interval for the two reentrant beats is constant at 40 msec. After administration of atropine **(panel B)** sustained A-V nodal reentry is initiated at a similar degree of A-V nodal delay (A_2-H_2 interval 320 msec) as in the control period. After an initial variation, the Ae-H interval stabilizes at 375 msec. The H-Ae interval remains unchanged at 40 msec. Subsequent atrial stimuli **(panel B)** are for the most part ineffective and were delivered inadvertently. The third stimulus captures the high right atrium and results in fusion activation of the right atrium (low atrial electrogram; that is, Ae occurs at the expected time) (A-Ae interval 480 msec). This has no effect on the supraventricular tachycardia.

A-H delay. Failure of the atrial echo beats to conduct to the His-Purkinje system suggests that the antegrade limb of the A-V nodal reentrant pathway was refractory to the reciprocating impulse and therefore sustained reentry did not occur. The occurrence of sustained reentry after administration of atropine, which was initiated at levels of A-H delay comparable to those of the control period, implies that atropine decreased refractoriness of the antegrade limb to a degree that permitted continuous reciprocation. A decrease in A-V nodal refractoriness is a well known effect of the drug. Whether the retrograde limb was equally or unequally affected by atropine can only be conjectured. However, atropine did bring about the necessary balance between conduction and refractoriness within the reentrant circuit.

In Case 2, sustained supraventricular tachycardia occurred after administration of atropine at A-H intervals significantly shorter than those that in the control period resulted in either single or no atrial echo beats. Since sufficient antegrade A-V nodal delay (that is, longer A-H intervals) was achieved during the control period, it appears that improved conduction and shortening of refractoriness of only the crossover or retrograde pathway, or both, after administration of atropine were responsible for creating the balance necessary for the occurrence of sustained reentry. This possibility is also suggested by the mechanism of spontaneous termination of supraventricular tachycardia (Fig. 3). The initiation of sustained reentry at shorter A-H intervals after administration of atropine further attests to the importance of a balance between conduction and refractoriness in the limbs of a reentrant circuit.

Atropine and reentry: The possibility that atropine caused sustained reentry by changing atrial refractoriness can be summarily dismissed for the following reasons:

1. Small doses of atropine, as used in this study, produced no significant changes in atrial refractoriness as tested by the extrastimulus method.[11] After administration of atropine the effective refractory period of the atrium increased by 10 msec in Cases 1 and 3, decreased by 10 msec in Cases 2 and 5 and did not change in Case 4.

2. In four of five cases (Cases 2 to 5) atrial echo beats did occur in the control period and in Cases 3 to 5 the atrial echo beats were not followed by His bundle potentials, thus suggesting that the A-V node, not the atria, was refractory.

Although administration of small doses of atropine resulted in sustained A-V nodal reentry in these 5 patients, findings were not similar in the other 17 patients[11,12] who received the same amount of drug. There are several possible explanations for these differences: (1) Only 5 patients had the potential for development of reentrant supraventricular tachycardia that was unmasked by atropine; (2) in the other 17 patients the dose of atropine was either too small or too large; or (3) atropine simply did not produce the necessary balance of conduction and refractoriness between the antegrade and retrograde limbs of the reentrant circuit in these 17 patients.

Clinical implications: The results of this study help to elucidate some underlying mechanisms responsible for the success of therapeutic agents, such as digitalis and propranolol, in the management of patients with supraventricular tachycardia. Both digitalis and propranolol are known to prolong refractoriness of the A-V node and therefore may totally abolish manifestations of A-V nodal reentry.[17–19] These changes could result from prolongation of A-V nodal conduction and refractoriness in one or more sites in the reentrant circuit—the antegrade or retrograde limbs or crossover tracts—so that the premature atrial beats fail to induce the echo response. In some patients single or multiple atrial echo beats may still be demonstrable after administration of these drugs although sustained A-V nodal reentry may not occur if the necessary balance between conduction and refractoriness within the various limbs of the reentrant circuit is sufficiently altered by the therapeutic agents. Finally it must be pointed out that at times, these and other drugs may show what appear to be paradoxical effects on the reentrant phenomenon. We have observed in some patients A-V nodal reentrant atrial echo beats occurring only after administration of digitalis or propranolol whereas none were seen during the control period (unpublished observations). Likewise, it is conceivable that atropine may prevent sustained reentry in some patients with supraventricular tachycardia by altering the critical balance of conduction and refractoriness within the A-V node.

Quantitative Study of the Supernormal Phase of Ventricular Excitability in Man

MASAO IGARASHI, MD
TAKAO AYABE, MD*

Tokyo, Japan

The supernormal phase of excitability of the human heart was studied by means of fixed rate endocardial pacing in 11 patients with acute and chronic bradyarrhythmias. Ten of the eleven patients manifested a supernormal phase. The duration of the phase increased with increasing intensity of subthreshold stimuli and ranged from 91 to 148 percent of the Q-T interval. Subthreshold stimuli of a wide range of intensity could elicit a full response. Two types of supernormal phase, early and late in relation to the cardiac cycle, were observed. The latter was attributed to the summation of subthreshold stimuli with either spontaneous phase 4 depolarization of a ventricular ectopic pacemaker or atrial depolarization potentials. Its possible connection with Wedensky facilitation was suggested. The ventricle was less excitable after an ectopic beat than after a normally conducted beat.

Since Adrian[1] introduced the term supernormal excitation to denote a particular type of ventricular response to a subthreshold stimulus, the occurrence of this response in the mammalian[2–4] and human[3–10] heart has been repeatedly discussed. Nevertheless, few quantitative studies of the phenomenon have been performed and little is known about its mechanism. This study was designed to define quantitatively a supernormal phase of excitability in the human heart in terms of intensity of the effective subthreshold stimuli required to evoke it and its temporal relation to the cardiac cycle. The physiologic implications of the phenomenon and its bearing on Wedensky facilitation are also discussed.

Material and Methods

Eleven patients requiring temporary transvenous pacing for acute and chronic bradyarrhythmias were studied (Table I). Fixed rate endocardial pacing was performed in each case using a bipolar electrode catheter positioned at the apex of the right ventricle (Medtronic 5880A demand pacemaker and 5821 bipolar electrode catheter for endocardial pacing). This method enabled the pacemaker stimuli to fall at various portions of the cardiac cycle. After the diastolic threshold was determined, pacing was attempted with subthreshold stimuli at various levels of current intensity. A decrement of less than 0.1 milliampere between two consecutive levels of current intensity could not be used because of the technical properties of our pulse generators. The duration of the period of supernormal excitability was expressed as percent of the Q-T interval or as the time interval in seconds after the onset of the Q wave. The effectiveness of subthreshold stimuli was expressed as a percent of all stimuli administered at a given time.

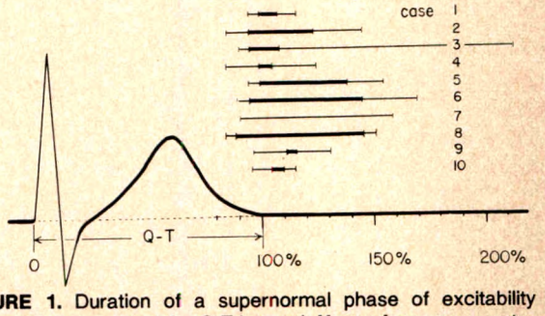

FIGURE 1. Duration of a supernormal phase of excitability expressed as percent of the Q-T interval. **Heavy bars** represent zones in which every subthreshold stimulus could produce an effective ventricular response.

Results

A supernormal phase of excitability was found in 10 of 11 patients studied (Table I).

Duration of the supernormal phase of excitability: A supernormal phase was observed not only at the end of the T wave but also at various points well after the T wave (Fig. 1, Table I). In five cases the supernormal phase measured 150 percent of the Q-T interval and in one case (Case 3) 91 to 213 percent of the Q-T interval.

In four cases a study of the duration of this supernormality at different current levels of subthreshold stimuli (Table II) revealed that the duration depended on the intensity of the subthreshold stimuli: Stronger subthreshold stimuli produced a longer supernormal phase. For example, in Case 8 (Fig. 2 and 3), the duration of the supernormal phase was 0.25, 0.16 and 0.08 second at respective current levels of 3.5, 2.5 and 1.5 ma. The lowest effective current of 1.0 ma could elicit a ventricular response only 0.40 second after the Q wave. In each case stronger stimuli extended the supernormal phase further into the late than into the early portion of diastole with an increment in the latter of up to 0.04 second.

Relative effectiveness of subthreshold stimuli: A subthreshold stimulus that could produce a full response in the midportion of the supernormal phase sometimes failed to do so near the beginning and end of the phase. The zone of 100 percent effectiveness usually occurred during a period constituting 100 to 125 percent of the Q-T interval (Fig. 1, Table I).

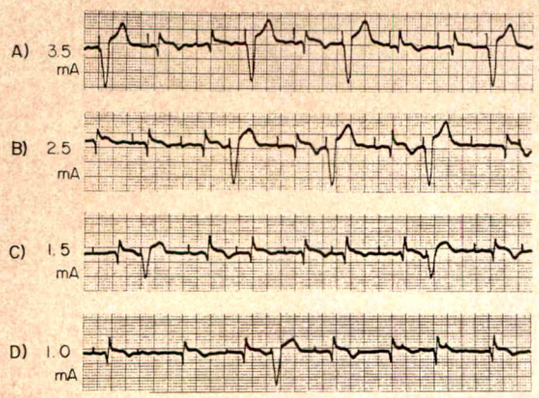

FIGURE 2. Case 8. The ventricular response to various levels of current intensity of subthreshold stimuli. Note longer duration of supernormal phase with stronger subthreshold stimuli (**A** and **B**). mA = milliamperes.

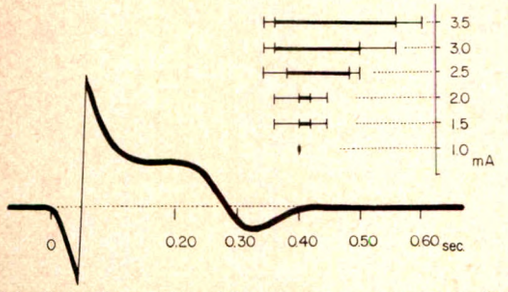

FIGURE 3. Case 8. Duration of the supernormal phase at different levels of subthreshold stimulus intensity. The duration increased with increasing strength of the stimuli. The horizontal axis represents time intervals after onset of the Q wave.

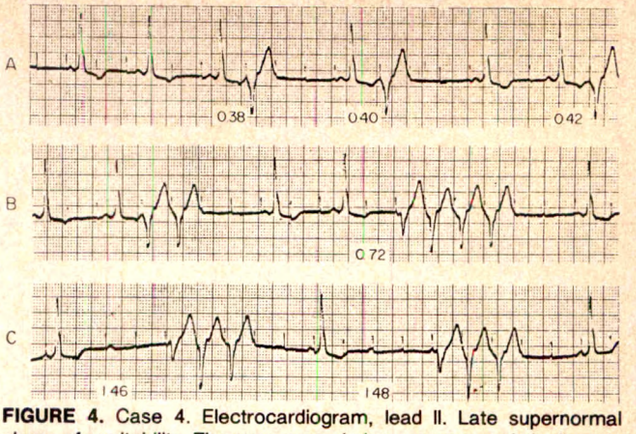

FIGURE 4. Case 4. Electrocardiogram, lead II. Late supernormal phase of excitability. The supernormal phase occurs early in diastole in **A**, both early and late in **B** and only late in **C**. Numbers at the bottom of each tracing represent time intervals after onset of the Q wave in seconds. Note that the two longer intervals in **C** (1.46 and 1.48 seconds) are approximately twice as long as the interval (0.72 second) in **B**.

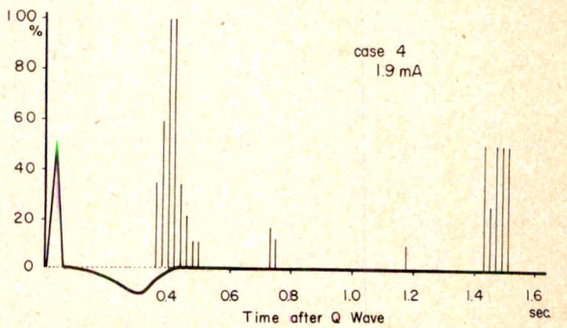

FIGURE 5. Case 4. Effectiveness of subthreshold stimuli at different time intervals after onset of the Q wave. Effectiveness is expressed in percent with reference to all the stimuli delivered at a given time interval in seconds after the Q wave.

Late supernormal phase: Unexpectedly, late occurrence of a supernormal phase was noted in five cases (Cases 2, 4, 6, 8 and 10). Figure 4 (Case 4) shows the occurrence of this late supernormal excitability in two ranges, namely, 0.72 to 0.76 second and 1.44 to 1.52 seconds after the Q wave. In each instance the first of the several consecutive supernormal responses differed in contour from the others. Figure 5 (Case 4) illustrates diagrammatically the frequency of late supernormal excitation at various points in the cardiac cycle. Figure 6 (Case 10) shows that an otherwise ineffective subthreshold stimulus could evoke and share ventricular depolarization with a sinus impulse giving rise to a beat analogous to a fusion beat only if the stimulus fell shortly after a P wave. A similar effect occurred with blocked atrial depolarization potentials in Case 2 (Fig. 7). However, in this case neither P waves nor subthreshold stimuli, occurring at the same time interval *after* the onset of spontaneous automatic beats, could by themselves produce a full response.

Supernormal phase after an ectopic beat: Figure 8 demonstrates in a case of atrial fibrillation the difference in ventricular excitability after a supraventricular and a ventricular ectopic beat. The subthreshold stimulus (ST 1) falling 0.44 second after an ectopic ventricular complex beat failed to elicit a response whereas the one after a conducted beat at the same time interval (ST 2) was able to do so. Although a similar phenomenon was noted in other cases in our study a quantitative analysis was not performed.

Discussion

Duration and location of supernormal phase: In contrast to our observations, the supernormal phase of excitability has been believed to take place within a fixed and narrow range of the cardiac cycle. Most previous studies performed in the human heart have defined the supernormal phase as a period in the cardiac cycle ranging between 80 and 120 percent of the Q-T interval,[4] for example, between the beginning of the downstroke of the T wave and the inscription of the U wave,[5] on the descending branch of the T wave,[9] or at the terminal portion of the T wave.[10] An experimental study[11] using a single fiber of isolated papillary muscle found supernormality of short duration at the end of phase 3 depolarization. By contrast, our results have demonstrated that the du-

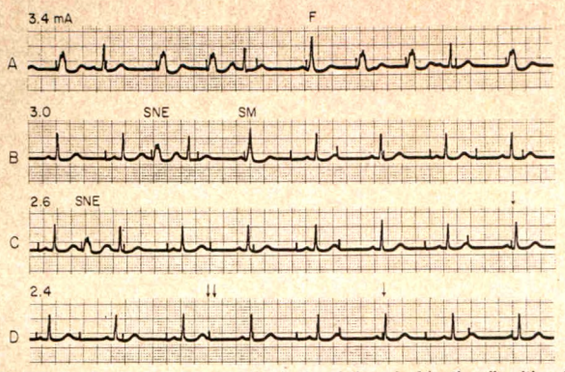

FIGURE 6. Case 10. Summation of subthreshold stimuli with atrial depolarization potentials. In **A,** a suprathreshold impulse precedes a normally conducted beat, giving rise to a fusion beat (F). Subthreshold stimulation is shown in **B** to **D.** SM = summation of a subthreshold stimulus with atrial depolarizing potentials. Note occasional failure of summation (↓) and absence of a supernormal phase of excitability (↓↓). SNE = supernormal phase of excitability.

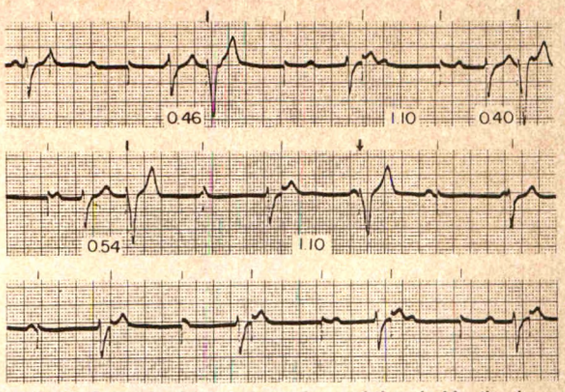

FIGURE 7. Case 2. Summation of a subthreshold stimulus with blocked atrial depolarization potentials in a case of complete A-V block. The **thick arrow** indicates summation, the **thick bars** an effective subthreshold stimulus and **thin bars** an ineffective stimulus. Figures at the bottom of each tracing represent time intervals of subthreshold stimuli from preceding spontaneous QRS complexes.

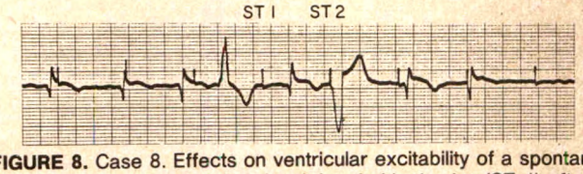

FIGURE 8. Case 8. Effects on ventricular excitability of a spontaneous ventricular ectopic beat. A subthreshold stimulus (ST 1) after a ventricular premature beat could not evoke a response in contrast to one (ST 2) occurring after a conducted beat (in atrial fibrillation).

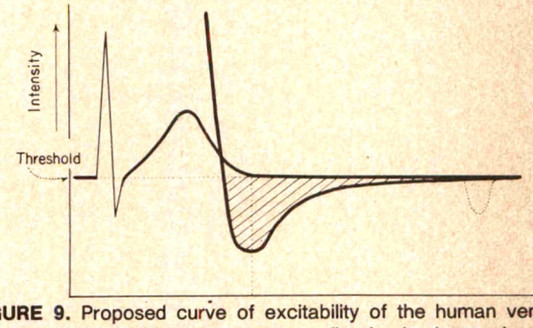

FIGURE 9. Proposed curve of excitability of the human ventricle. The lowest threshold (early supernormal) value is observed near the end of the T wave and is followed by a gradual rise until a plateau is reached. The **dotted area** denotes a late supernormal period due to summation of the subthreshold stimuli with a subsidiary phase 4 of spontaneous depolarization or with electrotonic spread of atrial impulses.

ration of the supernormal phase in the human ventricle is longer than hitherto believed and is dependent on the intensity of subthreshold stimuli (Fig. 2 and 3). A similar observation was made by Linenthal and Zoll,[6] who described a case in which the supernormal period lasted 0.04 and 0.1 second for stimuli of 2+ and 3+ intensity, respectively. This dependence of supernormal excitation on current intensity led us to believe that ventricular excitability was not uniform throughout diastole. The ventricle was very excitable during the period corresponding to the end of the T wave, becoming less so during the subsequent several hundred milliseconds until a diastolic threshold level was attained. (Fig. 9).

Occasionally, otherwise effective subthreshold stimuli failed to elicit a full response especially when they were given early or late in the supernormal period. The electrophysiologic interpretation of this finding could be as follows: During the supernormal phase, especially at its beginning and end, the depolarizing process must be taking place with such low margins of safety that even a small change in cellular environment may affect the sodium transport system, resulting in a temporary depression of excitability.

Enhancing of ventricular excitability by summation: In four cases, as described, the supernormal phase occurred unexpectedly late in diastole. Two characteristics of this finding are worth special mention: (1) The first beat due to late supernormal excitation differed from succeeding beats in contour, and (2) the second period of a late supernormal phase occurred at an interval after the Q wave measuring approximately twice the interval of the first period. These phenomena could be interpreted on the basis of summation of two impulses, one being the otherwise ineffective subthreshold stimulus, the other the potentials from a subsidiary ventricular ectopic pacemaker in the process of spontaneous (phase 4) diastolic depolarization. This could evoke a full ventricular response but the first beat would differ in contour from subsequent beats because its depolarizing process would have begun with an already reduced resting membrane potential.

Wedensky facilitation: This enhancing effect on ventricular excitability by summation has been experimentally demonstrated by Bailey et al.,[12] who elicited full excitation by administering a subthreshold stimulus properly timed with regard to the slow upstroke of the subthreshold depolarization. They called this Wedensky facilitation. Cranefield and Hoffman[13] reported similar results using a microelec-

trode technique in isolated Purkinje tissue. In addition to this temporal relation, spatial closeness of the origins of the stimuli must be a critical factor since electrotonic spread of subthreshold stimuli cannot travel far because of decremental changes.

Another point of evidence in favor of the ability of summation of impulses to produce a full response was found in Case 10, in which an otherwise ineffective subthreshold stimulus elicited a response when it was given at the end of a P wave (Fig. 6). The intensity of the current required for this type of summation was greater than that for the excitation induced at the end of the T wave (Fig. 6C). Similar events occurred in Case 2 (Fig. 7) and Case 8, and Soloff and Fewell[5] reported a similar observation (their Fig. 2). Arbel et al.[14] also demonstrated in man and dog this enhancing effect of atrial depolarization and attributed it to summation of subthreshold stimuli with electrotonic spread of atrial depolarization potentials. Like these authors, we found that this summation could take place whether or not atrial depolarization potentials were conducted to the ventricles (Fig. 6 and 7).

Thus, we have demonstrated by means of endocardial stimulation of the human heart that a supernormal phase of excitability can occur late in diastole and that its duration is dependent on the intensity of subthreshold stimuli. The physiologic basis may be summation of subthreshold stimuli (Wedensky facilitation), but this hypothesis needs confirmation in further studies.

Acknowledgment

We thank Dr. Alfred Pick for his critical review and his assistance in the final formulation of the manuscript.

Hereditary Progressive Atrioventricular Conduction Defect

HENRY T. LYNCH, MD

New data on genetics, including an extensive pedigree and certain aspects of natural history, have been compiled on Family S, which is characterized by a hereditary progressive atrioventricular (A-V) conduction defect. Concordance analysis of heart block in affected parents and their offspring suggests as a working hypothesis transmission of diathesis for the defect by means of a Mendelian autosomal dominant factor. Regression of the defect in several relatives, including reversion from first degree heart block to normal A-V conduction, defies explanation at this time. However, rapport established with the unusually large (1,067 members) and cooperative kindred will permit longitudinal evaluation of these findings.

Hereditary factors are etiologically significant in a variety of cardiovascular problems.[1–10] Their importance in conduction defects was first reported by Morquio[11] in 1901 when he described atrioventricular (A-V) conduction disturbances in five brothers. Two years later Osler[12] described a family whose members had a slow pulse rate and Stokes-Adams attacks. The first electrocardiographic confirmation of familial heart block was reported in 1932.[13,14] Since then, more than 25 families with cardiac conduction disturbances of various kinds have been described.[10]

This report provides new and extended data from a large kindred characterized by a high incidence rate of a specific pattern of A-V conduction defect. This defect typically covers the range of first, second and third degree heart block and constitutes a newly described disorder: hereditary progressive atrioventricular conduction defect.[10] We believe that this study represents the most complete published report of a kindred with a cardiac conduction defect and that the data provide an important contribution toward elucidation of the etiology of the disorder.

Material and Methods

The syndrome of familial A-V conduction defect has been described previously in an initial report[10] on the S kindred. Since then, the study has been extended significantly, facilitating more critical explorations concerning the origin and natural history of the conduction defect (Fig. 1).

The earliest progenitor (generation I), determined in our pedigree search, produced five offspring (generation II), each of whom initiated one subdivision of the S kindred. One subdivision, in turn, produced 13 offspring (generation III), each of whom initiated a separate branch of the subdivision of the kindred. All our examinations have thus far been confined to members of one subdivision (that is, offspring of one person in generation II) composed of 13 branches (each starting in generation III) containing 1,067 persons.

A total of 12 field visits have been made to several midwestern and far western states where specific aggregations of the kindred reside. These field visits have been made with a cardiologist and various paramedical assistants

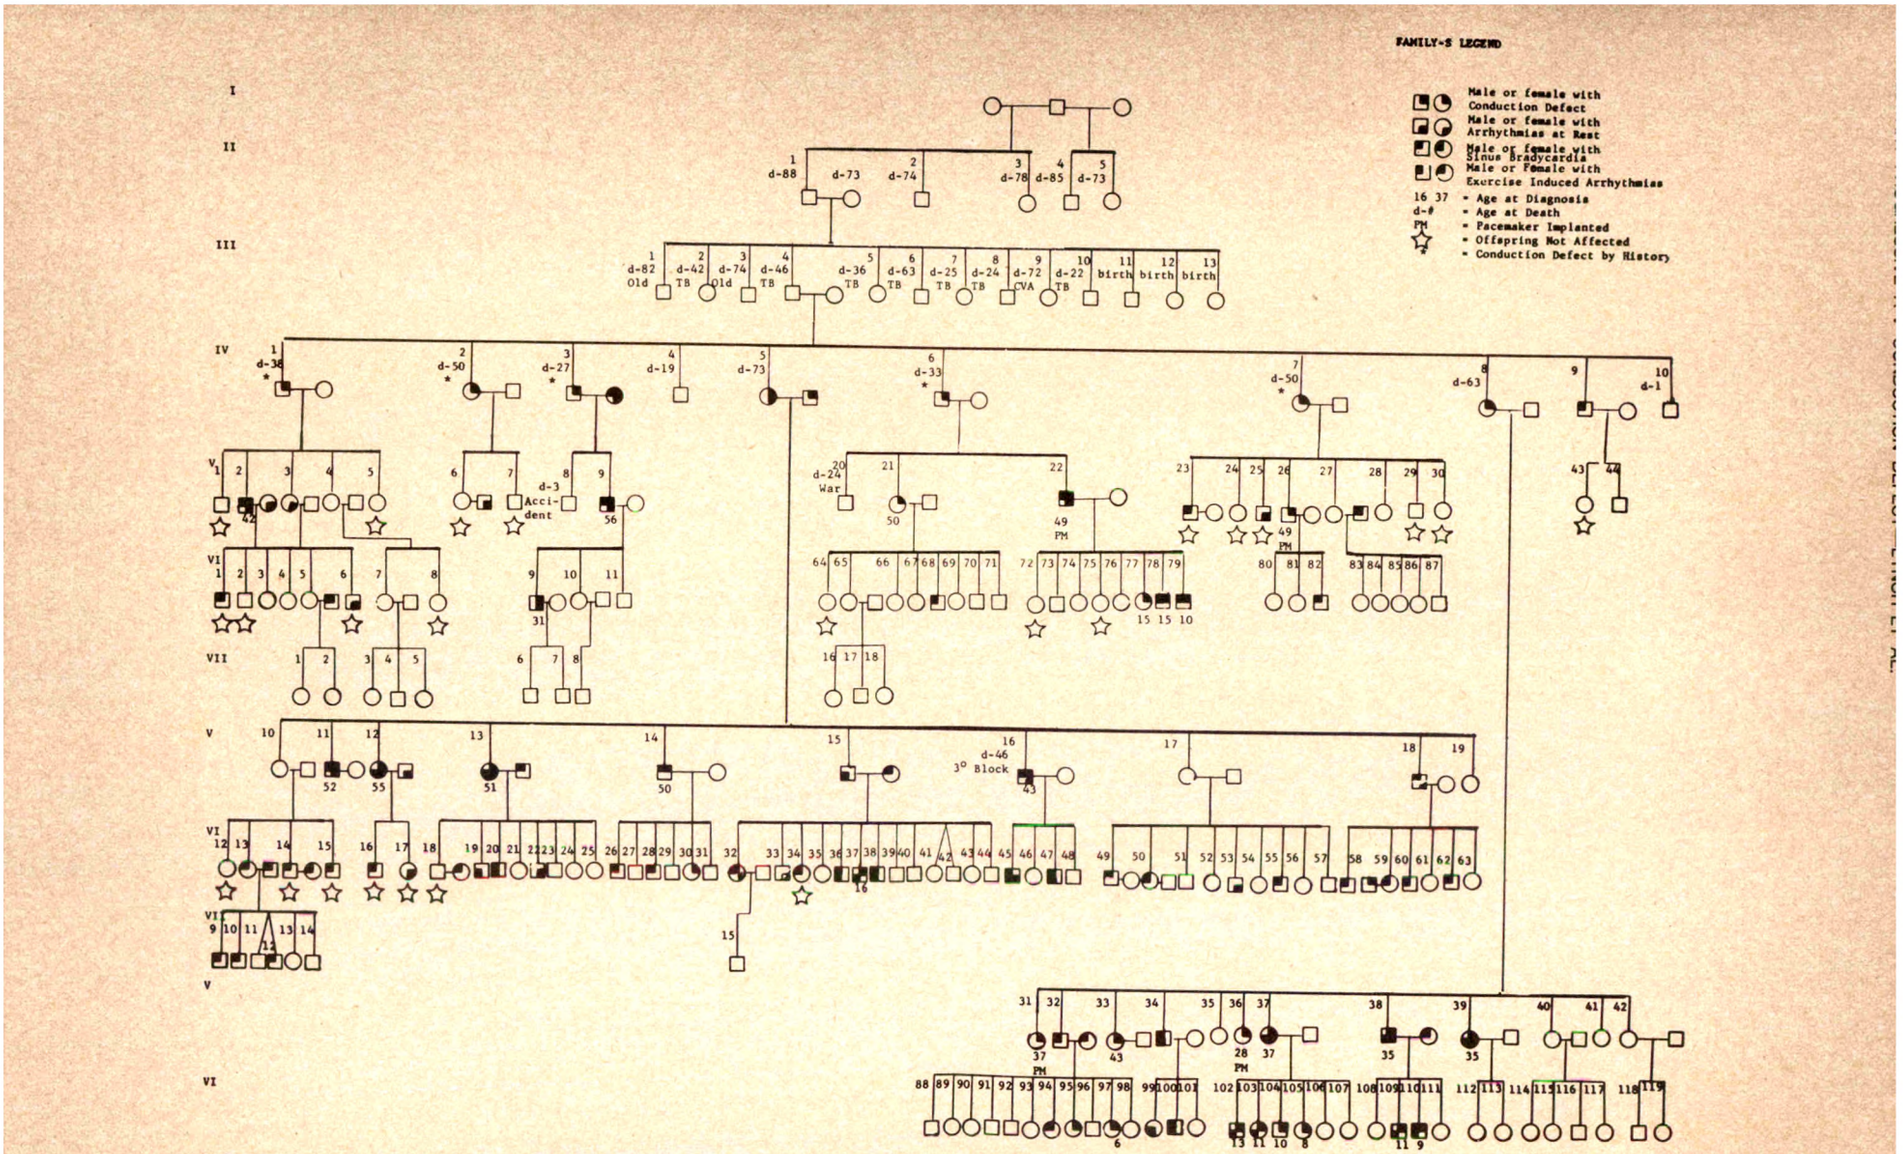

FIGURE 1. Pedigree of Family S showing hereditary progressive atrioventricular conduction defect transmitted through five generations.

who have worked closely with the family for several years, establishing excellent rapport and acquiring detailed familiarity with the family's geneology and medical problems. The help of family physicians has been enlisted so that detailed medical information is constantly made available to the research team. In addition, hospital records have been secured as well as pathologic confirmation of all major disorders including cardiovascular diseases.

We have examined the members of three branches in one subdivision. The examined members in two of these branches have shown no evidence of cardiac disorders. Members of the third branch, studied extensively, manifested a conduction defect.

An extensive pedigree of this kindred has been constructed (Fig. 1). The pedigree is designed to facilitate evaluation of (1) conduction defects, (2) sinus bradycardia, (3) cardiac arrhythmias at rest, and (4) the occurrence of exercise-induced cardiac arrhythmias. As originally reported,[10] the electrocardiographic abnormalities in family S include the following:

"(1) a progressive increase in atrioventricular conduction delay culminating in a complete heart block, (2) QRS complex normal in configuation and duration, (3) a normal QT interval, (4) a poor progression of R wave across the right precordium, (5) no evidence of intraventricular conduction defects, (6) no evidence of any cardiac chamber enlargement, (7) rare atrial and ventricular arrhythmias, only late complications, and (8) progression from first degree to complete heart block usually gradual but occasionally fulminant leading to sudden death within two to three years." [10]

Exercise-induced arrhythmias were defined as documented atrial and ventricular arrhythmias occurring during graded exercise tests. Arrhythmias at rest were defined as arrhythmias occurring in the resting state accompanied by electrocardiographic evidence of atrial or ventricular ectopic activity, or both. Sinus bradycardia (rate less than 60 beats/min) was documented by electrocardiogram.

The occurrence of heart block in the S kindred was subjected to concordance analysis, and the results are listed in Tables I to III.

Results

The S kindred includes five major subdivisions. The first subdivision consists of 13 branches totaling 1,067 members. To date, all examinations have been conducted in only three of these branches. Members of two of the branches have not displayed symptoms of the cardiac disease. One branch consists of 10 families comprising 378 persons of whom 44 died prior to our study. Electrocardiograms have been recorded in 255 of the 334 members (76 percent) of that branch who are still living. Among these 255 members, 87 (34 percent) have an arrhythmia at rest, including sinus bradycardia, and 40 (16 percent) have a conduction defect as determined by electrocardiogram or by reliable history.

We have documented findings of regression as well as progression of the conduction defect in this disorder. Specifically, one male subject (aged 18 years) had definite second degree heart block at one time and, 1 year later, his condition had reverted to first degree heart block. In three children (two 11 year old boys and one 8 year old girl) first degree heart block reverted to normal A-V conduction. In addition, in an 11 year old boy oscillation between first degree heart block and normal A-V conduction has been observed for 4 years.

Results of chest X-ray examination and coronary angiograms, performed in the proband and her similarly affected sister, were normal.[10] In addition, no disorders known to be associated with abnormalities of the cardiac conduction system were found to occur in excess in members of kindred S.

Heart Block, Concordance Analysis

Table I lists the number of observed concordant and discordant pairs in parents with heart block and their offspring in the S kindred. The risks for heart block in the offspring of affected mothers belonging to the S kindred are 0.40 for daughters and 0.29 for sons. These frequencies are not significantly different from each other. The observed risks for heart block

in the offspring of affected fathers are somewhat different from those observed in the offspring of affected mothers. The empiric risk for heart block in daughters of affected fathers is 0.16, and that for sons of affected fathers is 0.31. The risks differ according to sex of the offspring and sex of the affected parent, but the differences are not statistically significant.

Table II shows the distribution of concordance and discordance for heart block among affected members of the S kindred and their siblings, tabulated according to the sex of each affected member and the sex of each sibling. The empiric risks for heart block in siblings of affected members of the S kindred are as follows: for a female with an affected sister, 50 percent; for a female with an affected brother, 42 percent; for a male with an affected brother, 41 percent; and, for a male with an affected sister, 42 percent. There is no statistically significant difference associated with the sex of the sibling at familial risk or with the sex of that individual's affected sibling.

Table III shows the number of persons involved in each of the studied kinship categories, and the empiric risks for the daughters, sons, sisters and brothers of members of the S kindred with heart block.

Discussion

Various cardiovascular disorders have been observed to be familial and some have been associated with simple genetic modes of transmission in certain kindreds. In the broad field of congenital heart disease, the reported incidence of risk in the general population is typically 5 to 7 per 1,000 live births. When a family already has one affected child, however, the risk for subsequent offspring increases to 2 to 4 percent. When two or more siblings are affected, the risk for subsequent offspring of the same parents approaches 5 to 8 percent.[1] Finally, when the broad category of congenital heart disease is subdivided into specific categories, such as supravalvular aortic stenosis or the secundum variety of atrial septal defect, one encounters certain kindreds in which the defect is apparently transmitted by an autosomal dominant gene with variable penetrance.[2,3] Chromosomal disorders, such as the G_1-trisomy syndrome (associated with A-V defect or ventricular septal defect) or Turner's syndrome (associated with coarctation of the aorta or aortic valvular stenosis[4]), are frequently associated with congenital heart defects. The broad category of collagen vascular diseases,[5] such as Marfan's syndrome, Ehlers-Danlos syndrome and Hunter's and Hurler's syndromes, are associated with various congenital heart defects as well as disorders generally characterized as abiotrophies, such as dissecting aortic aneurysm (Erdheim's cystic medial necrosis). Other categories include associations of cardiac defects with hereditary neurologic[6] and primary muscular[7] disorders; and associations of skeletal defects with cardiovascular disease such as those occurring in the heart-limb disorders found in autosomal dominantly inherited Holt-Oram syndrome showing association between upper limb abnormalities and atrial septal defect.[8] Familial occurrence of coronary artery disease has also been reported.[9]

TABLE IV

Hereditary Cardiac Conduction Disturbances and Arrhythmias That Are Not Associated with Intracardiac Defects or Major Medical Disorders

Disturbance	Mode of Genetic Transmission
1. Heritable Q-T prolongation with deafness[15] (Jervell and Lange-Nielsen syndrome)	Autosomal recessive
2. Heritable Q-T prolongation without deafness[16]	Autosomal dominant
3. Possible progressive A-V block in a single family similar to S[17]	Autosomal dominant
4. Prolonged P-R interval (single family)[18]	Autosomal dominant
5. Intraventricular conduction defect and complete heart block[19]	Autosomal dominant
6. Familial bundle branch block[20]	Autosomal dominant
7. Familial atrial fibrillation[21,22]	Autosomal dominant and autosomal recessive
8. Familial sinus node disease[23]	Possible autosomal dominant
9. Familial heart block and sinus bradycardia[24]	Autosomal dominant
10. Familial pure sinus bradycardia[25]	Autosomal dominant
11. Wolff-Parkinson-White syndrome[26]	Autosomal dominant
12. Familial cardiac arrhythmia[27] (ectopic tachyarrhythmias)	Autosomal dominant

Hereditary cardiac conduction disturbances—modes of transmission: Since the initial report of familial conduction disturbance by Morquio,[11] investigators have described families with disorders involving the sinus node, atrioventricular conduction and the bundle of His and its branches. In general, the clinicopathologic features of these conditions in families have been specific. Genetic heterogeneity has frequently been encountered. Table IV lists cardiac conduction disturbances that have been reported to be genetically transmitted, either as specific entities or as components of syndromes.

A trait or character that can be dichotomized (for example, "affected" versus "not affected") may be subjected to comparisons of concordance rates observed in different pair categories. Such comparisons, by themselves, may not prove transmission according to a particular hypothesized genetic mode, but they can be utilized to determine whether the data reveal sex limitation, sex influence or sex linkage in transmission or manifestation of a trait. Concordance comparisons may also indicate whether the observations are consistent with a particular hypothesized mode of genetic transmission. The concordance rate between pairs of affected parents and their offspring, for a trait associated with a single autosomal gene not showing sex influence, equals the product of the probability for transmitting the gene to each off-

spring and the gene's penetrance. Accordingly, the data tabulated in Tables I to III are consistent with concepts that involve no sex influence or sex limitation in transmission or manifestation, and vertical transmission from parent to offspring. We suggest a Mendelian autosomal dominant mode of transmission of diathesis to the conduction defect, with reduced penetrance and somewhat variable expressivity, as a working hypothesis of the etiology of the syndrome in this remarkable kindred. This working hypothesis is consistent with the data showing empiric risks ranging from 0.16 to 0.50 (Table III), but the possibility of additional etiologic factors cannot be excluded.

Comprehension of the natural history of the disorder will require more investigation. The instances of regression of the defect, such as reversion from first degree heart block to normal A-V conduction in three of the children, cannot be explained at this time.

Pathogenesis: The pathogenesis of this syndrome is unknown. Atherosclerosis, particularly of the coronary arteries, was not a striking finding in the two affected patients who underwent coronary arteriography.[10] The heart (autopsy specimen) of one patient who died from this syndrome was examined by us. Unfortunately, because this patient died in an area remote from our medical center and we had not established prior communication with the pathologist who performed the autopsy, special studies of cardiac tissue were not performed. When we received the specimen the right atrium was not present. However, in the remainder of the heart there was no evidence of significant coronary arterial atherosclerosis, heart muscle disease, valvular heart disease or infiltrative diseases. No clues could be obtained on the pathologic features contributory to this patient's sudden death, save that of clinical knowledge that he had a history of complete heart block. Cardiac biopsy specimens obtained from two sisters in Family S who underwent transthoracic pacemaker implantation showed no evidence of a disease process.

Concluding Remarks

The observed rates of pair concordance for heart block between affected parents in the S kindred and their offspring and the empiric risks for such manifestations showed small but not statistically significant differences (0.16 to 0.31) associated with the sex of the affected parent and the sex of the offspring. Smaller sex-related differences were observed in sibling pair concordance rates, which ranged from 0.41 to 0.50. A tentative working hypothesis has been suggested, involving transmission of the diathesis for the disorder by means of a Mendelian autosomal dominant factor. The sex-related differences among the several parent-offspring concordance rates, the smaller sex-related differences among the several sibling-pair concordance rates, and the difference between the parent-offspring and sibling-pair categories limit full acceptance of this hypothesis, but do not negate it.

Abnormalities of Left Ventricular Function and Geometry in Adults with an Atrial Septal Defect

Ventriculographic, Hemodynamic and Echocardiographic Studies

KENNETH A. POPIO, MD

DAVID BECHTEL, BS
MICHAEL V. HERMAN, MD, FACC

Boston, Massachusetts

Left ventricular function and motion in 12 adults with an ostium secundum atrial septal defect were analyzed utilizing biplane cineangiography. Values for left ventricular end-diastolic volume index, stroke volume index, ejection fraction, left ventricular end-diastolic pressure and mean rate of circumferential fiber shortening were compared with values in an age-matched group of 11 normal subjects. Comparisons of ventriculographic and echocardiographic data were also made in 5 patients and 10 control subjects. Cardiac index was smaller in patients than in the normal subjects (3.6 vs. 4.5 liters/min per m^2, $P < 0.01$). Although left ventricular end-diastolic pressure was similar (8 mm Hg in both groups), the end-diastolic volume index was significantly smaller in patients than in normal subjects (56 vs. 76 ml/m^2, $P < 0.05$). Stroke volume index was also significantly smaller in patients (40 vs. 52 ml/m^2, $P < 0.01$). The two groups had similar values for ejection fraction (65 ± 2 percent [standard error of the mean] in patients vs. 68 ± 2 percent in normal subjects), circumferential fiber shortening velocity (1.67 ± 0.13 vs. 1.81 ± 0.15 circumferences/sec), heart rate (91 ± 7 vs. 90 ± 5 beats/min) and mean systemic arterial pressure (92 ± 5 vs. 87 ± 3 mm Hg). Early systolic bulging of the upper ventricular septum toward the right ventricle was seen in 10 of 12 patients with an atrial septal defect but in no normal subject. Echocardiographic data supported these findings. No other abnormalities of motion were consistently noted. It is concluded that the left ventricle of patients with an atrial septal defect is subnormal in volume and abnormal in sequence of contraction of the septum and is characterized by apparent decreased distensibility.

Many investigators[1–10] have concluded that dysfunction of the left ventricle may play a role in the pathophysiology of atrial septal defect. Although it is considered to figure prominently in the congestive heart failure that limits both life expectancy[6–8] and operative results,[8,9] the mechanism for this effect remains unknown. Cineventriculography has not been utilized previously in a systematic manner to investigate the function of the left ventricle in patients with an atrial septal defect. In this study we emphasize ventriculographic and echocardiographic methods to gain further insight into this question.

Methods

Twelve adult patients with an ostium secundum atrial septal defect and without signs of cardiac failure were studied by cardiac catheterization while at rest. Selective or nonselective coronary angiography, performed in 11 of these patients, revealed normal coronary arteries. Data in these patients were compared with similarly obtained data in a group of 11 age-matched control

subjects who underwent cardiac catheterization for evaluation of a "chest pain syndrome" but were found to have no discernible cardiovascular disease.

All subjects had right and left heart catheterization with pressures recorded through a fluid-filled catheter system with an Electronics for Medicine oscillographic recorder. Pulmonary and systemic flow data were measured by the Fick oxygen method. Biplane cineangiography (30° right anterior oblique and 60° left anterior oblique projections) was performed using Siemens radiographic equipment at a filming rate of 100 frames/sec after the injection of contrast material, most often into the left ventricle but occasionally into the left atrium or pulmonary artery. Ventricular volume and mass were determined by a modification of the method of Dodge et al.[11] Premature ventricular contractions and the beats following them were excluded from analysis. Ejection fraction was defined as the ratio of stroke volume to end-diastolic volume, as determined by angiography. Percent shortening of the major and minor axes was measured in both the right anterior oblique and left anterior oblique views. Angiographic cardiac index was determined for the left ventricle. The mean rate of circumferential fiber shortening was measured using a modification of the method of Gorlin et al.[12] and Karliner et al.[13] The mean rate of circumferential fiber shortening was measured in both the right anterior oblique and left anterior oblique projections at both one half and one third the distance from the base to the apex.

The motion of the interventricular septum as determined with ventriculography was compared with the echocardiographic analysis of septal motion in 5 patients with an atrial septal defect and in 10 control subjects. Echocardiograms were obtained using a nonfocused transducer, 2.25 megahertz, 13 mm diameter, and a Unirad Series C ultrasonoscope with a Tektronix strip chart recorder.

Results

The clinical and hemodynamic characteristics of the two study groups are summarized in Table I. These groups were essentially age-matched. Female subjects predominated in the group with an ostium secundum atrial septal defect[7,14] and male subjects in the group with chest pain. No significant difference in pressures was noted between the two groups.

Left ventricular cardiac output and volumes: Figure 1 shows comparisons of angiographically determined cardiac index and its component parts, the angiographic stroke volume and simultaneously determined heart rate. The mean cardiac index in the group with atrial septal defect was significantly lower than in the normal group (3.6 vs. 4.5 liters/min per m^2, P <0.01). The heart rates were essentially the same. The patient group had a significantly lower value for stroke volume than the normal group (41 vs. 52 ml/m^2, P <0.01). These results were unaffected by data from two patients with an atrial septal defect who had sinus tachycardia and reduced stroke volume.

Figure 2 compares the angiographic volumes in the two groups. The mean end-diastolic volume index

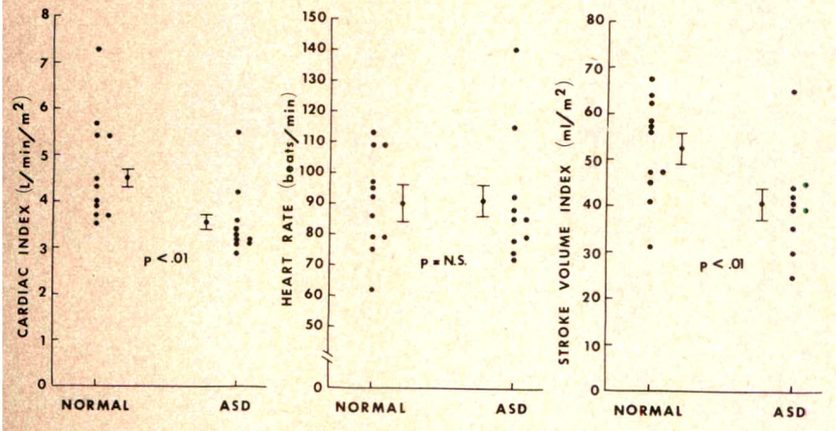

FIGURE 1. Comparisons of angiographically determined cardiac index, heart rate and stroke volume index in normal subjects and the 10 (of 12) patients with atrial septal defect (ASD) in whom quantitative calibration of the ventriculogram was available. N.S. = not significant; p = probability.

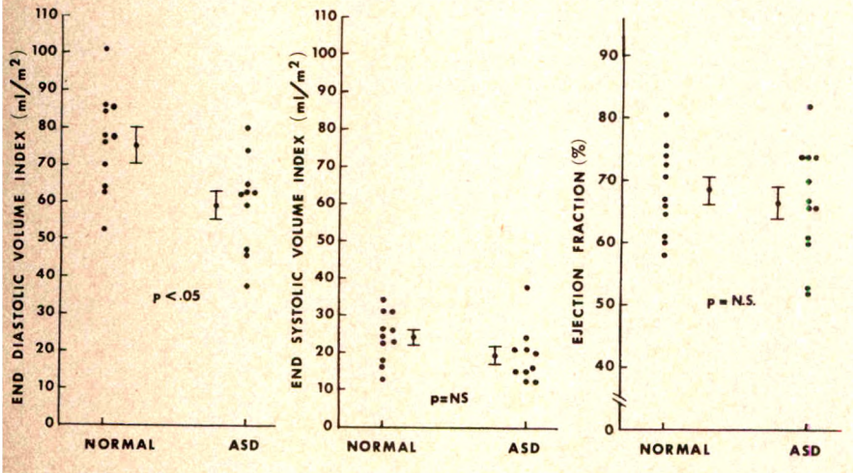

FIGURE 2. Angiographic end-diastolic and end-systolic volume indexes in normal subjects and in the 10 patients with atrial septal defect and calibrated ventriculograms. Ejection fractions were compared in all subjects in the series.

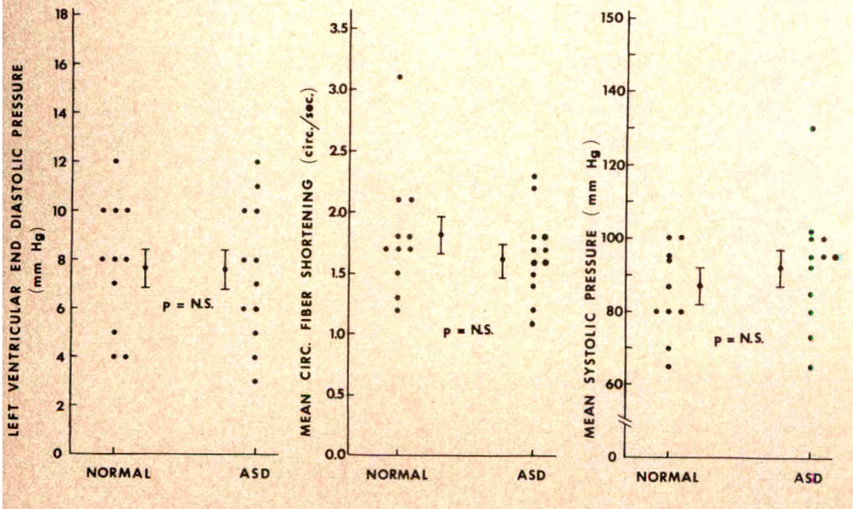

FIGURE 3. Left ventricular end-diastolic pressures, mean rate of circumferential (CIRC.) fiber shortening, and mean systolic systemic arterial pressures in normal subjects and patients with an atrial septal defect (ASD).

was significantly less in the patients with an atrial septal defect than in the normal subjects (59 vs. 75 ml/m^2, P <0.05). However, values for both end-systolic volume index and ejection fraction were similar.

Determinants of left ventricular volumes: There was no statistically significant difference between the two groups in left ventricular end-diastolic pressure, mean systolic arterial pressure or mean rate of normalized circumferential fiber shortening measured in either projection or either chord (see Methods) (Fig. 3).

Regional ventricular shortening: There was no significant difference in the degree of shortening of any axis except the major axis in the left anterior oblique view (Fig. 4).

Motion analysis of the interventricular septum: In all subjects, the first motion of the interventricular septum during systole was an anterior movement of its uppermost portion away from the posterior left ventricular wall (Fig. 5). This occurred within approximately 0.05 second of the initiation of systole. In the normal group, this was followed by uniform inward motion of all ventricular walls, including the septum, throughout the rest of the systole. However, in 10 of the 12 patients with an atrial septal defect, this initial anterior movement of the uppermost septum was followed not by inward contraction but rather by temporary akinesia while an area more distal to it began bulging anteriorly. This last abnormal motion was more pronounced in some patients than in others. In the last phases of systole, uniform inward contraction occurred in the group with atrial septal defect so that the end-systolic ventricle became similar in size and shape to that seen in the control group

Comparison of the degree of shortening of all major and minor axes in both right anterior oblique (RAO) and left anterior oblique (LAO) projections in normal subjects and patients with an atrial septal defect (ASD). The ventricular silhouettes illustrate the particular chords being measured.

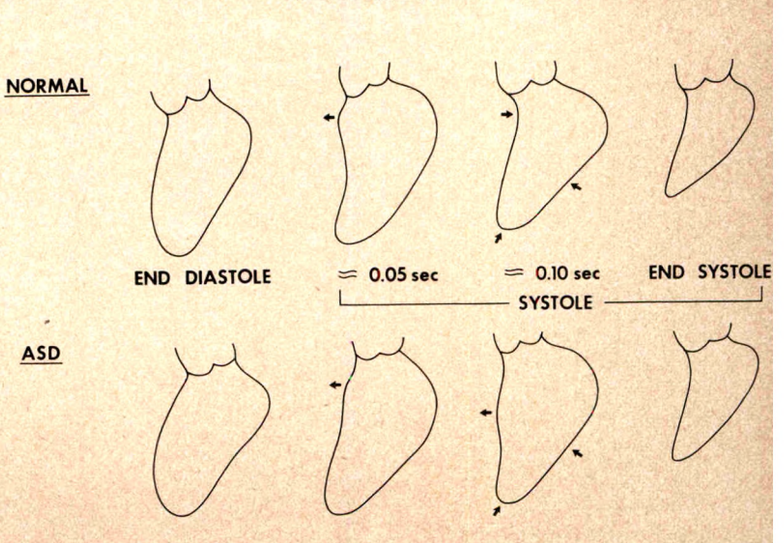

FIGURE 5. Representative outlines of the ventricle in the left anterior oblique view illustrating septal motion during systole for both normal subjects and patients with an atrial septal defect (ASD). **Arrows** indicate direction of movement of a particular area.

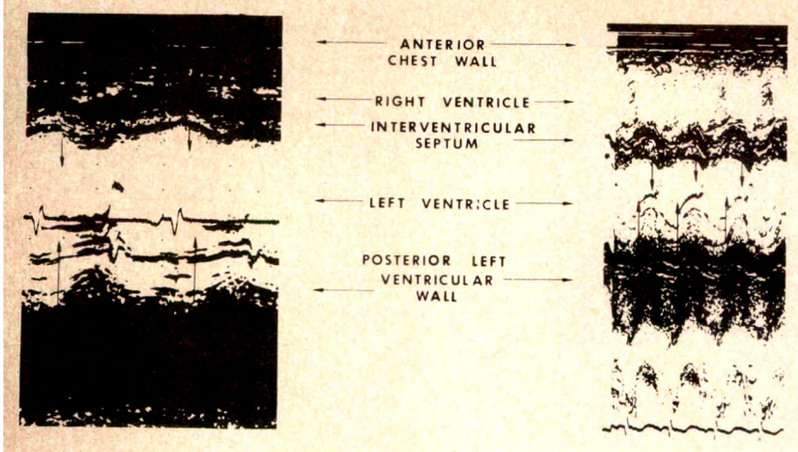

FIGURE 6. Representative echocardiograms from a normal subject and a patient with an atrial septal defect (ASD). **Arrows** indicate the initiation of movement of a particular surface. The recording speed used in the normal example is greater than that used in the echocardiogram from the patient with the septal defect. The latter example illustrates "reverberation."[27]

(Fig. 5). One of the two patients with an atrial septal defect who exhibited entirely normal septal motion had a balanced shunt and pulmonary hypertension.

Ventriculographic-echocardiographic correlations: Septal motion as analyzed with angiography was compared with septal motion determined with echocardiography (Fig. 6). All 11 control subjects had normal echocardiographic septal motion, with the ventricular septum beginning posterior movement nearly simultaneously with the initiation of anterior movement by the posterior left ventricular wall. All five of the patients with an atrial septal defect who had echocardiograms performed manifested abnormal septal motion, in that the septum did not begin movement simultaneously with the posterior wall. Figure 6 illustrates one of several variations (type A as well as type B of septal motion abnormality).[15–18] All five of these patients had the abnormal angiographic septal motion described. Neither of the two patients with an atrial septal defect and normal angiographic septal motion underwent echocardiography.

Discussion

Pathophysiology of atrial septal defect: In 1956 Dexter[1] explained the clinical manifestations of atrial septal defect in terms that have become the accepted pathophysiologic basis of the disorder. Summarizing not only his own earlier work but also that of several others,[19–22] he stated that when an atrial septal defect is large (more than 3 cm^2), pressures during diastole are essentially identical in both atria and in both ventricles. Second, although left ventricular stroke output remains essentially the same over wide ranges of left ventricular end-diastolic pressure, right ventricular stroke output can be large or small at any given level of right ventricular end-diastolic pressure. He interpreted this to mean that at high levels of end-diastolic pressure the left ventricle is malfunctioning since it does not increase its output pari passu. Thus, the failing left ventricle maintains a stable output only at the expense of elevation of its end-diastolic pressure. When right ventricular failure occurs, it results in a decreased stroke volume that leads to an increased residual volume. This increased right ventricular residual volume leads to reduced right ventricular compliance relative to left ventricular compliance. Since the direction of the shunted blood is determined not by a pressure gradient but rather by a difference in relative resistances to flow, right ventricular failure leads to a decreased left to right shunt and ultimately to right to left shunting and cyanosis. Left ventricular failure, on the other hand, leads to increased diastolic pressure and therefore to bilaterally increased atrial pressure and consequently to signs and symptoms of "right heart" congestive failure.

Dexter was unable to explain why the left ventricle should fail in these patients, who do not have increased left ventricular volume or pressure work. Some patients studied had conditions, including hypertension, mitral regurgitation and atrial fibrillation, that might be associated with left ventricular failure, but these were of mild degree and could not fully explain the failure. Tikoff et al.[5] substantiated Dexter's analysis and observed that the incidence of heart failure increased with age. Other investigators found evidence of left ventricular failure during postoperative evaluations but their findings were difficult to separate from the possible influences of operation. For example, Davies et al.[4] reported on seven patients studied because of persistence of symptoms postoperatively; all had elevation of pulmonary capillary wedge or left ventricular end-diastolic pressure, or both.

Tikoff et al.[2] described 13 patients with atrial septal defect who had preoperative heart failure as defined by clinical signs or the presence of a right atrial pressure greater than 8 mm Hg and, thus, bilaterally increased atrial pressure. When these patients were studied 5 months to 10 years after operation, only

one had completely normal hemodynamic findings and only four had marked reduction of symptoms after septal closure.

Left ventricular dysfunction in atrial septal defect: From these studies, one might conclude that some patients with an atrial septal defect have damage to the left ventricle that may persist after closure of the defect and cause symptoms. One still does not know the etiology of the process or how commonly it occurs in any total population of patients with atrial septal defect.

Epstein et al.[23] recently described 12 asymptomatic adult patients who had an atrial septal defect closed surgically. These patients were studied 6 to 15 months postoperatively while performing upright exercise. Although hemodynamic values were essentially normal at rest, during intense upright exercise 7 of the 12 patients had a lower cardiac index than a group of age-matched control subjects (6.6 vs. 8.9 liters/min per m^2). In these patients heart rate, but not stroke volume, was increased appropriately. Their report suggests that left ventricular dysfunction may be present subclinically after operation even in asymptomatic patients. However, since the study was performed postoperatively, it is not helpful in defining the etiology of the dysfunction.

On the other hand, Flamm et al.[10] studied a group of 25 adults with an atrial septal defect before operation both at rest and upon exercise. Ten of these patients had clinical evidence of congestive heart failure at rest and another seven had evidence of dysfunction of the right or left ventricle, or both, with exercise. Left ventricular function was considered abnormal if the following were present: (1) left ventricular end-diastolic pressure greater than 16 mm Hg at rest or during exercise, (2) an increase during exercise in systemic cardiac output by less than 550 ml/min for each 100 ml/min increase in oxygen consumption, or (3) a decrease in left ventricular stroke volume from rest to exercise associated with an increase in left ventricular end-diastolic pressure. Right ventricular function was considered abnormal if the right ventricular stroke volume decreased from rest to exercise in association with an increase in right ventricular end-diastolic pressure. On the basis of these definitions, Flamm et al. found no instances of left ventricular failure unassociated with right ventricular failure. Further, there were eight instances of normal function of both ventricles. They concluded that the left ventricle of these adult patients with an atrial septal defect was generally normal before operation and failed only as a result of right ventricular failure.

Manifestations and cause of left ventricular dysfunction: In our studies of adults with various sizes of atrial septal defect we have shown evidence that the left ventricle is not entirely normal in its performance or in its morphologic characteristics. These patients are characterized by a presumably chronically low systemic cardiac index due to a decrease in stroke volume rather than in heart rate (as also found by Epstein et al.[23]). The decreased stroke volume is due to a decreased end-diastolic volume with a normal ejection fraction. Attempts to define further this apparent disorder of cardiac autoregulation have yielded evidence of (1) normal afterload (systemic arterial pressure), (2) unchanged contractility during ejection (mean rate of circumferential fiber shortening and ejection fraction), and (3) normal heart rate.

The only abnormality among the indexes of contractility that we measured was the degree of shortening of the major axis in the left anterior oblique view. This axis shortened less in patients with an atrial septal defect than in normal adults. However, the degree of shortening in this axis may not be comparable in these two groups. Enlargement of the right ventricle is known to cause rotation of the heart so as to push the left ventricle posteriorly[15]; this change would so alter the left anterior oblique view of the left ventricle that the chord connecting the aortic valve with the "apex" might no longer measure a similar dimension as in normal subjects.

The coexistence of a decreased left ventricular end-diastolic volume and a normal left ventricular end-diastolic pressure is abnormal. This alteration in end-diastolic volume-pressure relation suggests that the left ventricle may be less distensible than normal. To test this possibility further, low molecular weight dextran was given to a patient with atrial septal defect not included in this series. Administration of 500 ml of 10 percent dextran (weight/volume) in 5 percent dextrose in water produced a 100 percent increase in left ventricular end-diastolic pressure (from 6 to 12 mm Hg) associated with a minimal, if any, increase in end-diastolic volume index (59 to 61 ml/m^2). Although the magnitude of change in the left ventricular end-diastolic pressure is not abnormal,[24] the discrepancy between change in pressure and volumes implies that the left ventricle is less distensible than normal at end-diastole.

Decreased distensibility might compromise the ability to increase the preload to the ventricle and thus contribute to the low systemic cardiac index. However the difficulty in adjusting preload may be due simply to the interatrial shunt's ability to limit the volume reaching the left ventricle. We were unable in this study to define the relation of these two possibilities. Nevertheless, the presence of a low systemic cardiac output should ordinarily stimulate some kind of compensatory mechanism to drive the output toward normal. For example, why is there not an increase in venous filling, reduction in systemic impedance or increase in heart rate to compensate for the small left ventricular output? Possible explanations might include a disorder of neural control, or perhaps the existence of pulmonary volume receptors capable of overriding the systemic circuit's signals because of increased flow in the pulmonary vasculature. The results of Epstein et al.[23] show that the limitation on cardiac output response to exercise after

surgical closure of the atrial septal defect is secondary to an inability to increase stroke volume. This observation implies that the left ventricle itself is central to this disorder of hemostasis.

Causes of decreased left ventricular distensibility: If, in fact, the left ventricle has decreased distensibility, what is the cause? It has been suggested[1,5] that the encroachment of a hypertrophied septum into the left ventricular cavity might interfere with left ventricular filling. This has been referred to as a "reversed Bernheim's syndrome." In two patients with atrial septal defect, Harken is said[1] to have palpated the cavity of the left ventricle during exploratory cardiotomy and found that the septum obliterated the cavity. Although no further investigation of the possibility has been reported, echocardiographic analysis of our cases revealed no such obliteration. Furthermore, septal thickness was normal by echocardiography (average 9 mm compared with accepted normal values of 9.7 mm).[25]

Coexistent coronary artery disease might produce a less distensible left ventricle. None of these patients had discernible coronary arterial obstruction. Additionally, no abnormality of left ventricular motion was observed except for that involving the septum (Fig. 5). This abnormality of septal motion seen in angiograms correlates well with the abnormality observed in echocardiograms.

Finally, an increased left ventricular mass or thickness could produce such a postulated decrease in distensibility. Left ventricular thickness is hard to ascertain by angiography in the presence of right ventricular enlargement. However, biventricular angiography allows definition of each ventricular outline and thus an estimation of left ventricular wall thickness separate from that of the right ventricle. Left ventricular mass so determined in three patients was decreased with respect to both body size and left ventricular volume.[26] Echocardiographic analysis of posterior left ventricular wall thickness in another three patients revealed normal findings (average 10 mm, normal 9.1 ± 0.9 [standard deviation] mm).[25] Even from these small numbers of observations, one can state that left ventricular mass is not increased above normal.

Thus, it seems that none of these possibilities adequately explains the existence of decreased left ventricular distensibility. One might hypothesize that lifelong lack of normal stretch induced by normal filling might lead to a less elastic left ventricle.

In conclusion, the presence of abnormal indexes of left ventricular function in these patients suggests that left ventricular dysfunction may be a common finding in adult patients with an atrial septal defect. The superimposition of a mild degree of such stresses as hypertension, age, atrial fibrillation or mitral regurgitation might then result in clinical heart failure. There is abundant evidence that this disorder of left ventricular function persists after the atrial septal defect is surgically closed.

Phasic Left Ventricular Blood Velocity Alternans in Man

KENNETH B. DESSER, MD, FACC
ALBERTO BENCHIMOL, MD, FACC

Phoenix, Arizona

With use of the Doppler ultrasonic flowmeter catheter, phasic instantaneous left ventricular blood flow velocity was measured by radiotelemetry in 28 subjects during pacemaker-evoked pulsus alternans. Blood velocity alternation was more manifest at faster pacing rates. Four patients demonstrated diastolic blood velocity alternans at the mitral valve. Discordant right heart pressure and left ventricular blood velocity alternation was recorded in three subjects. In one such patient, rate-related shifts of concordant and discordant left ventricular blood velocity alternans occurred. Intermediate or variant forms of alternation, comprising weak and strong beats in a ratio of 2:1, were noted in two subjects.

This study provides the first comprehensive description of left ventricular blood velocity alternans in man. The observed phenomena may be related to an altered inotropic state or to beat to beat variations in end-diastolic fiber length.

Pulsus alternans is a well recognized physical sign of underlying cardiac dysfunction. Most studies of pulsatile alternation have been performed utilizing direct or indirect pressure measurements,[1] left ventricular volume estimation[2] and the assessment of various indexes of myocardial contractility.[3] Furthermore, aortic or peripheral arterial blood velocity alternation has been recorded in a few patients with compromised left ventricular function[4] and in some normal subjects during rapid cardiac pacing.[5]

A recent study from this laboratory[6] has demonstrated the feasibility of directly measuring blood cell velocity in the left ventricle of conscious man by means of Doppler catheter velocimetry. We describe here initial observations of left ventricular blood velocity alternation in human subjects.

Material and Method

Twenty-eight subjects composed the study group. There were 25 men and 3 women whose ages ranged from 17 to 73 years (mean 54). Twenty-one patients had coronary artery disease, three had hypertension, three had no evidence of cardiovascular abnormality and one had primary cardiomyopathy. The three normal subjects were studied because of the presence of chest pain or systolic murmurs that were originally thought to represent heart disease. All diagnoses were established on the basis of complete right and left heart catheterization, selective coronary cineangiography and indicator-dilution curves. Studies were performed with subjects in the postabsorptive state in the supine position. After informed consent was obtained, the right brachial artery and a medial antecubital vein were surgically exposed using local anesthesia (1 percent lidocaine). A saline-filled no. 7 or 8 Zucker bipolar pacing catheter was introduced into the vein and advanced to the right heart chambers for the purpose of obtaining pressures or elective right atrial and ventricular pacing. Pressures were measured by connecting the catheter to a Statham P23Db strain gauge transducer. Pacing was performed with a Cordis Synchrocor pacemaker.

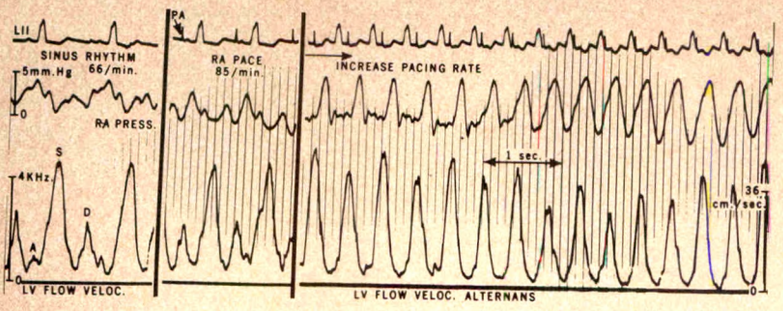

FIGURE 1. Simultaneously recorded lead II (L II) of the electrocardiogram, right atrial pressure (RA PRESS.) and left ventricular (LV) outflow tract blood velocity (VELOC.) in a 48 year old man with coronary artery disease. During sinus rhythm **(left panel)** and right atrial pacing (RA PACE) at a rate of 85/min, **(middle panel)** peak levels of left ventricular blood velocity are stable. Progressive cardioacceleration **(right panel)** results in classic "high-low" alternation of blood velocity. The percent difference between peak velocity levels of strong and weak beats is greatest when the pacing rate is increased rapidly. A = atrial; D = diastolic; PA = pacing stimulus artifact; S = systolic.

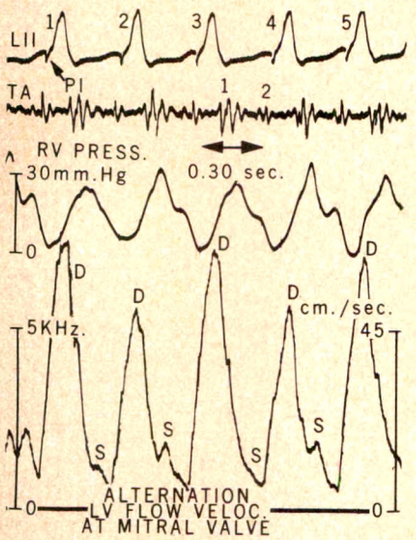

FIGURE 2. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, right ventricular pressure (RV PRESS.) and phasic left ventricular blood velocity at the mitral valve of a 61 year old woman with primary cardiomyopathy. Even-numbered QRS complexes (2 and 4) result in higher peak levels of systolic and diastolic mitral valve blood velocity during right ventricular pacing. Note the concordant peak systolic right ventricular pressure alternation. PI = pacing impulse; other abbreviations as in Figure 1.

Phasic instantaneous left ventricular blood velocity was measured by radiotelemetry utilizing a Doppler flowmeter catheter. Details concerning the method for such measurement have recently been described[6] and can be summarized as follows: The crystal-tipped catheter is passed from the brachial artery to the aorta and advanced across the aortic valve into the left ventricle under constant fluoroscopic image intensification. On the basis of the anatomic site of measurement, three major patterns of left ventricular blood velocity could be distinguished: outflow tract, major systolic ejection wave with smaller diastolic wave; midcavity, biphasic or triphasic blood velocity wave forms; and mitral valve, dominant pandiastolic wave followed by a small systolic component. All blood velocity signals, lead II of the electrocardiogram, right heart pressures, and in a few cases the apex cardiogram, phonocardiogram or external carotid pulse tracing, were simultaneously recorded on a DR-12 Electronics for Medicine oscilloscopic-photographic recorder.

In 23 cases left ventricular blood velocity alternans occurred during the course of right heart pacing at different driving rates. In the remaining subjects, catheter-evoked right ventricular premature depolarizations were electively introduced during cardiac pacing, thereby resulting in postextrasystolic blood velocity alternation.

Results

Critical right atrial or ventricular driving rates required for appreciable left ventricular blood velocity

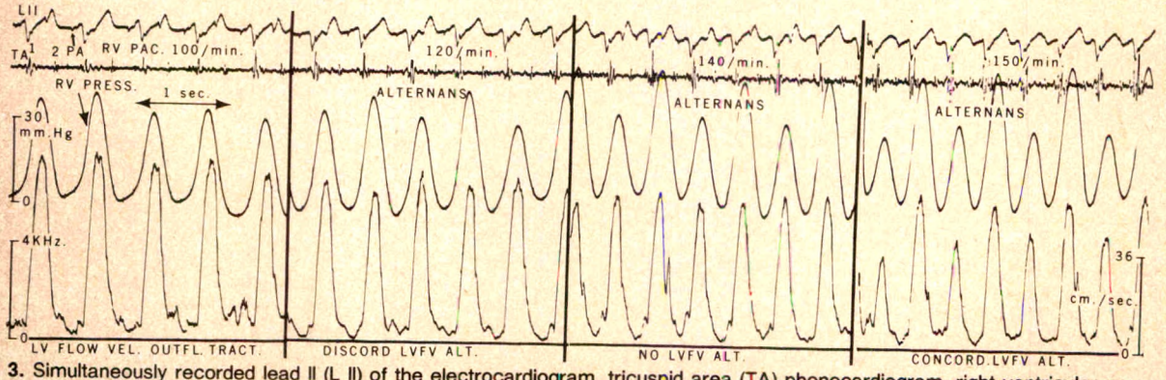

FIGURE 3. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, right ventricular pressure (RV PRESS.) and left ventricular outflow tract blood velocity during right ventricular pacing in a 30 year old man with coronary artery disease. At a driving rate of 120/min **(second panel from left),** discordant alternation occurs. A pacing rate of 140/min **(third panel)** results in right ventricular pressure alternans without concomitant left ventricular blood velocity alternation. Concordant alternation of left ventricular blood velocity and right ventricular pressure unexpectedly occurs at a driving rate of 150/min **(fourth panel).** CONCORD = concordant; DISCORD = discordant; LVFV ALT = left ventricular flow velocity alternans; LV = left ventricular; OUTFL. = outflow; PA = pacing stimulus artifact; RV PAC. = right ventricular pacing; VEL. = velocity.

alternation in 23 subjects ranged from 100 to 160 beats/min. In the vast majority of cases (19 of 23), outflow tract blood velocity alternans of a classic "high-low" nature was more manifest when the heart rates were increased rapidly (Fig. 1). All four patients in whom inflow tract blood velocity was recorded at the mitral valve manifested high amplitude diastolic blood velocity waves followed by low amplitude systolic blood velocity waves for each series of alternating beats. In one of these subjects, concordant peak right ventricular pressure alternans was simultaneously recorded during right ventricular pacing (Fig. 2). When the flow velocity catheter tip was withdrawn from the mitral valve to the outflow tract position it was noted that the low and high amplitude systolic blood velocity waves in the inflow tract correlated with similar systolic alternation at the site of the outflow tract. Such correlation was facilitated by noting the relation of the respective blood velocity wave forms to alternate QRS complexes on a simultaneously recorded electrocardiogram during cardiac pacing and withdrawal of the Doppler catheter.

Discordant alternation: Recordings obtained from three patients demonstrated discordant right ventricular or pulmonary arterial peak pressure alternans; that is, a low peak systolic left ventricular outflow tract blood velocity wave was inscribed at the same time as the higher right ventricular or pulmonary arterial pressure. One subject displayed an unusual variation of discordant biventricular alternans. At lower right ventricular driving rates discordant peak left ventricular outflow tract blood velocity and right ventricular pressure alternation occurred. During more rapid pacing rates the left ventricular blood velocity and right ventricular pressure recordings were in phase, with resulting concordant high-low alternation (Fig. 3). When the pacing rate was reduced within a short period of time, a transition from concordant to discordant alternation was observed (Fig. 4).

Combined electrical and blood velocity alternans: Two subjects manifested combined electrocardiographic and left ventricular blood velocity alternation. In one, a catheter-evoked premature ventricular depolarization produced a period of postextrasystolic electromechanical alternans. Higher amplitude QRS complexes resulted in ventricular contractions that produced reductions in left ventricular outflow tract blood velocity and right ventricular pressure and smaller deflections in the external carotid pulse tracing (Fig. 5). In the second patient, a pacemaker-induced episode of ventricular tachycar-

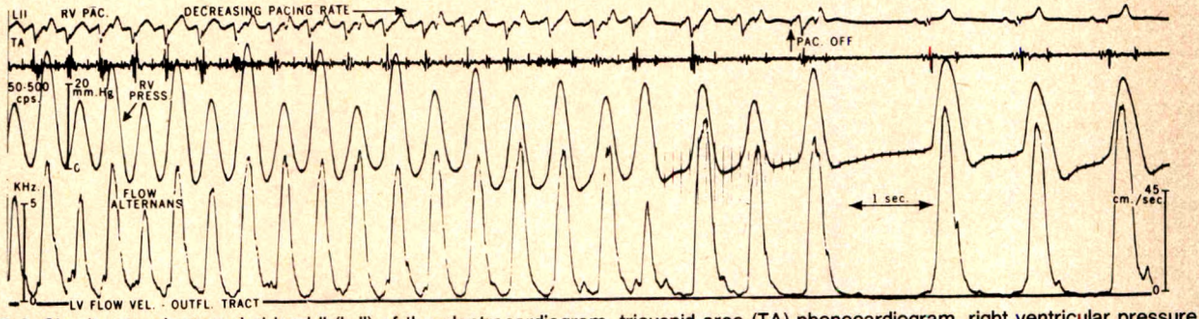

FIGURE 4. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, right ventricular pressure (RV PRESS.) and left ventricular outflow tract blood velocity during a decreasing ventricular pacing rate in a 30 year old man with coronary artery disease. The first seven QRS complexes are associated with concordant right ventricular pressure and left ventricular blood velocity alternans. The eighth and ninth beats result in two peak left ventricular blood velocity waves of equal magnitude, while right ventricular pressure alternans continues. The 10th through 16th beats produce discordant biventricular alternation. Note that the alternans is more prominent during the faster heart rate. PAC. OFF = pacing discontinued; other abbreviations as in Figure 3.

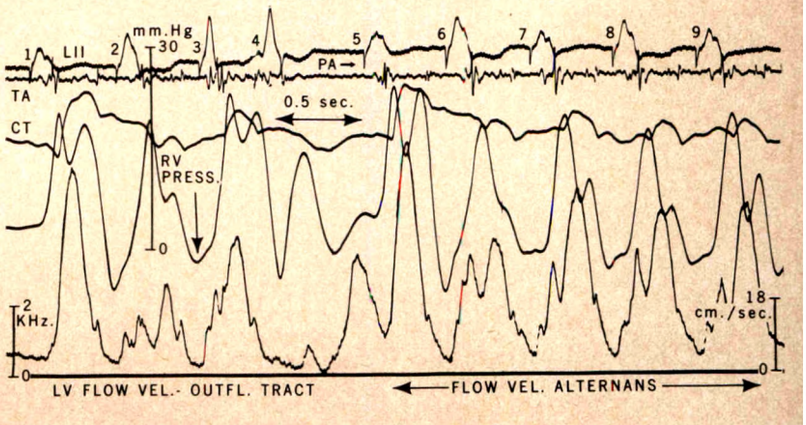

FIGURE 5. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, external carotid arterial pulse tracing (CT), right ventricular pressure (RV PRESS.) and phasic left ventricular outflow tract blood velocity during right ventricular pacing in a 52 year old man with coronary artery disease. A catheter-evoked ventricular premature depolarization (beat 4) results in postextrasystolic electromechanical alternation. Note that the QRS complexes of greater amplitude (6 and 8) are associated with smaller deflections in the carotid pulse tracing, lesser peak right ventricular pressures and lower left ventricular outflow tract blood velocity waves. Abbreviations as in Figure 3.

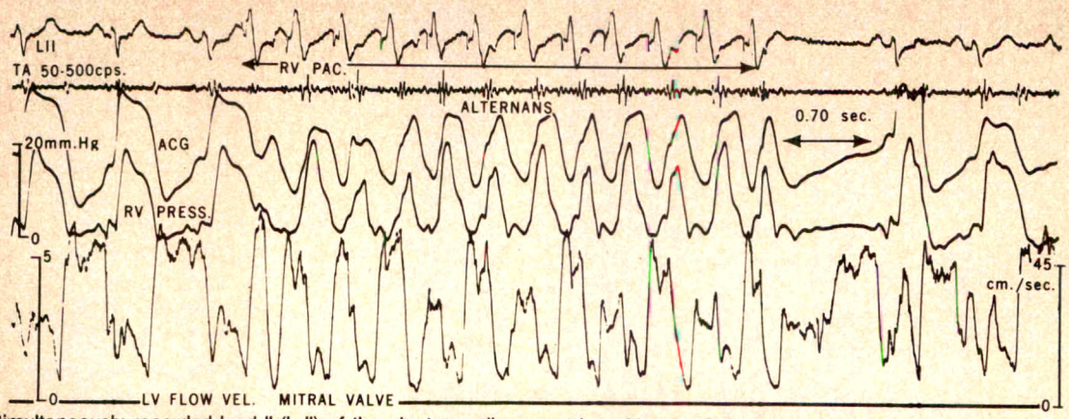

FIGURE 6. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, apex cardiogram (ACG), right ventricular pressure (RV PRESS.) and left ventricular blood velocity at the mitral valve of a 66 year old man with coronary artery disease. Total electromechanical alternans commences with the fourth QRS complex of a pacemaker-induced episode of ventricular tachycardia. Alternating QRS complexes of greater positive polarity are associated with a broader peak plateau in the apex cardiogram, greater right ventricular pressure and larger systolic and diastolic blood velocity waves at the mitral valve. Abbreviations as in Figure 3.

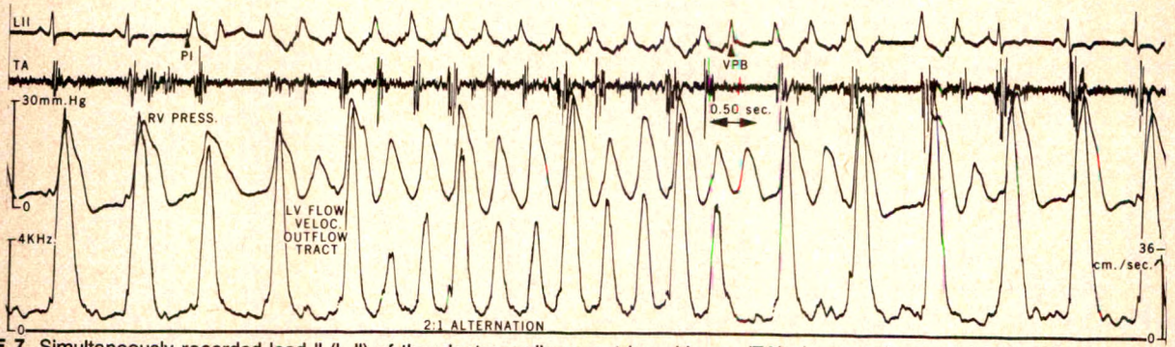

FIGURE 7. Simultaneously recorded lead II (L II) of the electrocardiogram, tricuspid area (TA) phonocardiogram, right ventricular pressure (RV PRESS.) and left ventricular outflow tract blood velocity in a 53 year old man with coronary artery disease. Rapid right ventricular pacing (rate 140/min) results in three periods of variant biventricular alternation. Lower peak right ventricular pressures and peak left ventricular blood velocity waves alternate with beats of greater amplitude in a ratio of 2:1 (that is, every third beat manifests greater amplitude of pressure and blood velocity). The alternation is terminated by a ventricular premature beat (VPB). LV = left ventricular; PI = pacing impulse; VELOC. = velocity.

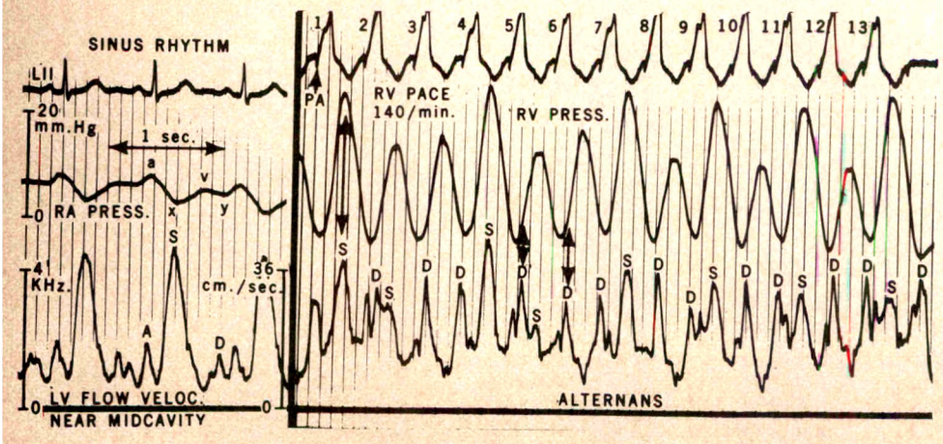

FIGURE 8. Simultaneously recorded lead II (L II) of the electrocardiogram, right heart pressures and left ventricular blood velocity in a 40 year old man with coronary artery disease. **Right panel** shows midcavity blood velocity during right ventricular pacing at a rate of 140/min. Beats 1 to 7 result in right ventricular pressure and left ventricular midcavity blood velocity alternation in a 2:1 ratio. Beats 8 to 13 demonstrate classic "high-low" concordant alternation of pressure and systolic blood velocity. Peak diastolic (D) blood velocity waves remain relatively stable throughout the recording. Note that the highest peak systolic (S) blood velocity and right ventricular pressure waves are associated with more prominently notched QRS complexes. LV = left ventricular; PA = pacing stimulus artifact; PACE = pacing; PRESS. = pressure; RA = right atrial; RV = right ventricular; VELOC. = velocity.

dia effected alternation of the apex cardiogram, right ventricular pressure and left ventricular blood velocity at the mitral valve (Fig. 6).

Variant blood velocity alternans: Intermediate variations of phasic left ventricular blood velocity, unrelated to respiration, were observed in two patients. Low blood velocity waves alternated with high blood velocity waves in a ratio of 2:1. In one such patient, this was the only form of alternation observed and variation of peak blood velocity occurred independently of any identifiable atrial contractions during the course of ventricular pacing. In addition, there was concordant 2:1 right ventricular pressure alternans (Fig. 7). One 40 year old man with coronary artery disease manifested an unusual variant of left ventricular blood velocity alternation (Fig. 8). A sustained period of alternation composed of low and high amplitude biventricular systolic beats in a ratio of 2:1 abruptly evolved into classic "high-low" alternans. At the same time, those beats of greatest amplitude were generated by QRS complexes with prominent notching.

Discussion

This report represents the first comprehensive description of blood velocity alternation within the left ventricle of man. Continuous measurements of aortic[4] and peripheral arterial[5] blood velocity waves in patients during natural and pacemaker-evoked arrhythmias have demonstrated that larger pulse amplitudes during the course of pressure alternation were associated with greater peak blood velocity in these vessels. The results described here indicate that these beat to beat fluctuations of blood flow are based on alternating levels of blood cell velocity within the left ventricle. Accentuation of left ventricular blood velocity alternans during increasing heart rate can be ascribed to greater disparity in end-diastolic fiber lengths[2,7] or differences in inotropic state[3] during cardioacceleration.

Blood velocity alternans in the left ventricular inflow tract: Of interest was alternation of the blood flow velocity recorded in the left ventricular inflow tract at the mitral valves of four subjects. Stronger beats produced both larger systolic and strikingly greater diastolic inflow tract blood velocity waves. The larger systolic waves represented forward ejection velocity at the mitral valve, sensed by the crystal-tipped catheter.[6] On the other hand, augmented diastolic waves during ventricular pacing in the absence of coordinated atrioventricular contraction, suggested either changing mitral valve areas, more rapid diastolic left ventricular expansion or greater left ventricular relaxation[3,7] after stronger beats of pulsus alternans. This study did not determine the mechanism responsible for this phenomenon, and further investigation of alternating levels of left ventricular filling velocity appears warranted.

Biventricular alternans: Concordant aortic blood velocity, right ventricular pressure and right atrial blood velocity alternation have been previously noted in man.[8] In addition, there have been reports of independent pulsus alternans in the greater and lesser circulations.[9] Recordings obtained from one subject described in this study demonstrated a rate-related transition of discordant to concordant biventricular alternans. In this patient, alternation of right ventricular end-diastolic fiber length or contractile force was a constant feature during rapid ventricular pacing. At critical heart rates, discordant left ventricular blood velocity alternation evolved into a state in which left ventricular contractions were presumably of equal magnitude. When the pacing rate was increased, left ventricular contractions began to alternate again and blood velocity came into phase with strong and weak right ventricular beats. These observations suggest that varying right or left ventricular blood velocity alternation, concordant or discordant, can be manifested in a variety of ways, dependent on the heart rate and inotropic state of each ventricle. In 1960, McIntosh[10] described recordings from a patient with right ventricular pressure alternation and a subtle shift of concordant to discordant brachial arterial alternans. These changes occurred during a stable heart rate and were attributed to unequal ventricular distension after summation of diastolic filling and a larger residual volume in either ventricle.

Variant or intermediate forms of left ventricular blood velocity alternation: These forms of alternans are particularly noteworthy and may represent a "warm-up" phase preceding established pulsus alternans. Demonstration that the last high peak left ventricular blood velocity wave in a cycle of 2:1 alternation was the first strong beat in succeeding classic pulsus alternans lends credence to this proposition. Other variations of the same phenomenon may occur, but we have encountered only weak and strong left ventricular contractions with corresponding low and high peak blood velocity waves in a ratio of 2:1.

The underlying mechanism for pacemaker-induced electrocardiographic alternation with concomitant left ventricular blood velocity alternans is unclear. In general, electrical alternation is frequently accompanied by pulsus alternans whereas the reverse relation is unusual.[11] It is possible that alternating intramyocardial tension and coronary blood flow in some manner render a portion of the myocardium more refractory to depolarization during every other beat.

Clinical implications: The limitations and advantages of Doppler flowmetry for the measurement of phasic instantaneous left ventricular blood velocity have previously been discussed in detail.[6] Furthermore, the conditions producing blood velocity alternans in this study were mainly artificial in nature. In the case of classic alternation, the results described here represent electively induced models of the naturally occurring phenomenon that has been noted during various forms of tachycardia. Further investigation will be required to identify other more unusual

forms of alternans during clinically encountered tachyarrhythmias. Application of this technique provides insight into the varied expression of left ventricular blood cell velocity alternans.

The Coronary Arteries in Marfan's Syndrome

A Morphologic Study

ANTON E. BECKER, MD, FACC
JAN-PAUL van MANTGEM, MD

Amsterdam, The Netherlands

The coronary arteries of five hearts of patients known to have had Marfan's syndrome were studied microscopically. In four of the five cases the extramural coronary arteries showed structural changes consisting of accumulations of acid mucopolysaccharides and a concomitant disruption of the connective tissue elements. These changes closely resembled the changes that frequently occur in the aorta and that are generally described as "cystic medial necrosis." They are considered to be an important expression of wall weakening. In one case a laceration, probably traumatic, of a coronary artery led to formation of an "incomplete dissecting aneurysm."

"Cystic medial necrosis" was found once in the proximal segment of the sinus nodal artery and once in the musculoelastic layer of a coronary artery that reached the atrioventricular node from the ventricular septum by perforating the anulus fibrosus. However, in contrast to findings in a previous report, the intramural coronary arteries were otherwise unaffected. The clinical significance of these data is as yet unknown particularly since these alterations are intramural and initially do not cause narrowing of the lumen. Nevertheless, the possibility of coronary arterial involvement by the metabolic disorder of Marfan's syndrome should always be considered during clinical assessment of this lesion.

Myocardial ischemia in patients with Marfan's syndrome is most frequently caused by a dissecting aneurysm of the ascending aorta that encroaches upon the segment of origin of a coronary artery. Thus far, only one case of Marfan's syndrome has been recorded in which a *primary* dissecting aneurysm of a coronary artery was observed.[1] However, many reports of cardiac manifestations of Marfan's syndrome give scant mention to the state of the coronary arteries. To the best of our knowledge, only James et al.[2] have considered in detail the pathology of coronary arteries in this disease. They reported that the smaller intramyocardial arteries showed alterations characteristic of an obliterative process; these changes were particularly prominent in the sinus nodal and atrioventricular nodal arteries of the two hearts they studied.

Our interest in the condition of the coronary arteries in Marfan's syndrome was initiated by the admission of an 18 year old woman with Marfan's syndrome into our Department of Cardiology. This patient had aortic and mitral valve insufficiency complicated by severe angina pectoris that could not be explained solely on the basis of augmented myocardial demand. On clinical grounds, aortic dissection seemed unlikely. Our clinical colleagues' question—"Are the coronary arteries involved in Marfan's syndrome?"—and their report on the lack of published data on this subject prompted this investigation of the coronary arteries in five hearts from patients with Marfan's syndrome.

Material and Methods

The study comprises a morphologic investigation of five hearts from patients with Marfan's syndrome. Four of the five patients were men aged 21, 23, 29 and 32 years, respectively. The one woman in this series was 51 years of age. All five patients had the characteristic features of Marfan's syndrome and were admitted to the hospital with a dissecting aneurysm in a markedly dilated ascending aorta and with signs of aortic valve incompetence. None of the five patients had rhythm or conduction disturbances. Two patients underwent combined reconstructive surgery for their aneurysm and insertion of an aortic valve prosthesis. One patient (Case 5) died in the immediate postoperative peri-

FIGURE 1. Case 5. od from a recurrent aortic tear. Another (Case 3) had an anteroseptal myocardial infarction after surgery and died 2 months later from progressive pump failure. The three other patients were being medically treated in the hospital when they died as a result of cardiac tamponade caused by a ruptured aneurysm.

Autopsy findings confirmed the clinical diagnosis in each instance. In no instance did the aortic dissection encroach upon the coronary arteries themselves, although there was a marked narrowing of the lumen of the proximal segments due to compression by the hematoma.

Pathologic studies: The coronary arteries were completely sectioned along their epicardial course at intervals of approximately 3 mm. Sections were taken whenever gross inspection of the cut surfaces revealed an abnormality. In addition, routine sections were taken in each case from (1) the main stem of the coronary artery, (2) the proximal segment of the anterior descending artery at a point 1 cm from its origin, (3) the proximal segment of the left circumflex artery at a point 1 cm from its origin, and (4) from the right coronary artery at a point approximately 1 cm from its aortic origin. The areas of the sinus and atrioventricular nodes were sectioned in blocks and studied microscopically in each case. In addition, both the sinus nodal artery and the atrioventricular nodal artery were dissected grossly and routine sections taken from their proximal segments. The intramural arteries were studied in sections of the left ventricular myocardium taken (1) anteriorly near the apex, and (2) posteriorly near the crux cordis.

The sections were stained with either hematoxylin-eosin or an elastic tissue stain. Additional stains such as the alcian blue stain for acid mucopolysaccharides and combinations of this technique with connective tissue stains and the periodic acid-Schiff stain were applied as deemed necessary.

Results

The observations with respect to the extramural and intramural coronary arteries in the five hearts are summarized in Table I.

+ = present; — = absent.

AVA = atrioventricular nodal artery; LAD = left anterior descending coronary artery; LCA = left main coronary artery; LCx = left circumflex artery; RCA = right coronary artery; SNA = sinus nodal artery.

Extramural coronary arteries: In four of the five hearts changes were observed in the extramural coronary arteries (Fig. 1). These changes were primarily confined to the media but were also present in the musculoelastic layer of the intima (Fig. 1). They were characterized by accumulations of a mucoid material that gave a positive reaction with alcian blue staining, indicating the presence of acid mucopolysaccharides. At the site of these accumulations the normal appearance of the arterial wall was disrupted (Fig. 1 and 2). In some instances, only the smooth muscle cells of the media were separated, whereas the

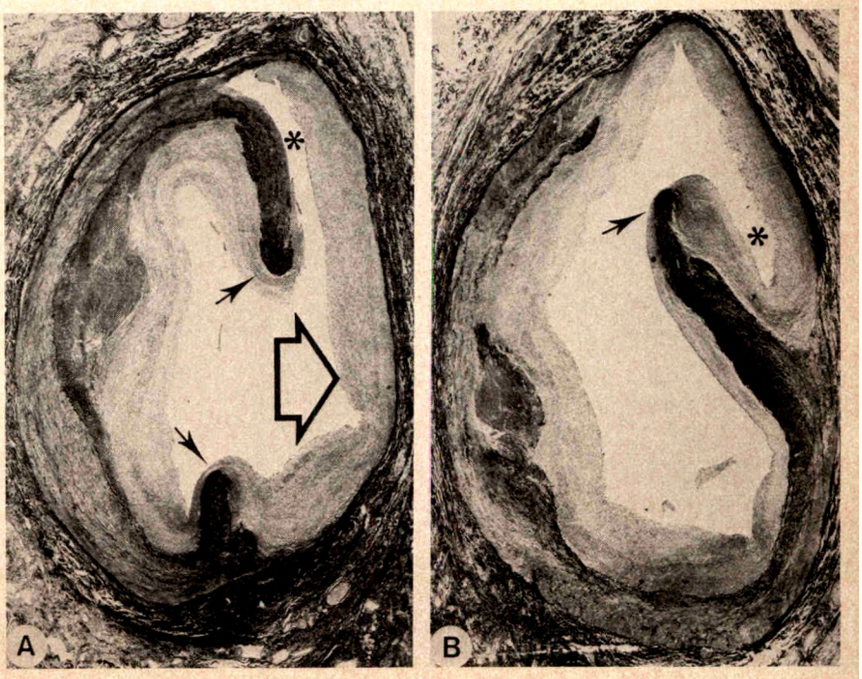

FIGURE 3. Case 3. Photomicrographs of cross sections of the left main stem artery. The artery shows an abrupt laceration of the media **(arrows)** with a partial dissection **(*)** and aneurysmal dilatation **(open arrow).** The outer wall at the latter site consists of adventitia and remnants of the disrupted media. The wall on the luminal aspect is composed of loosely arranged, vascular connective tissue, which has the features of organized thrombosis. (Elastic tissue stain ×25, reduced by 27 percent.)

collagen and elastic fibrils seemed intact. In other instances, the changes were more pronounced. These areas revealed actual disruption of connective tissue fibers together with the formation of pools of mucoid material and fine fibrillar material that produced wide separation in the muscular layer (Fig. 2). The internal elastic lamina at these sites also showed irregular fragmentations, and occasionally the mucoid material of the media was continuous by way of these interruptions with similar pools within the musculoelastic layer of the intima. The musculoelastic layer otherwise showed no distinction from the layer normally encountered.

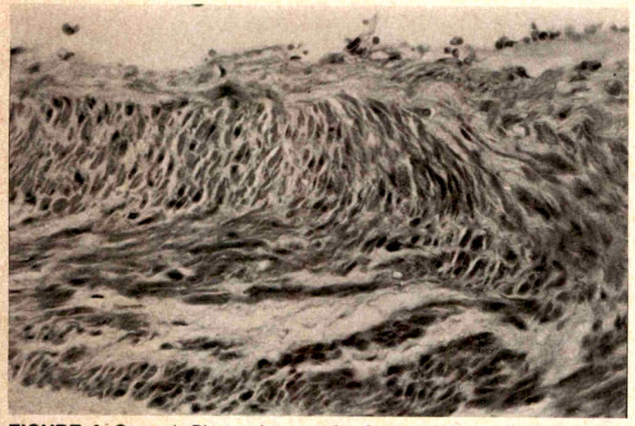

FIGURE 4. Case 1. Photomicrograph of part of the wall of the sinus nodal artery, just after its origin from the right coronary artery. The section shows a moderate accumulation of mucoid material in the media with disruption of the muscular layer. The artery no longer showed this abnormality when sectioned more peripherally. (Hematoxylin-eosin stain ×350, reduced by 31 percent.)

When present, the mucoid changes described were observed in most of the extramural coronary arteries (Table I). In one instance (Case 3) a complicated lesion was encountered in the main stem of the left coronary artery. This lesion consisted of an abrupt laceration of the wall together with incomplete rupture of the vessel and aneurysmal-like dilatation (Fig. 3). The outer wall of this dilated arterial segment consisted only of adventitia and sparse remnants of the disrupted media (Fig. 3). The wall on the luminal aspect was composed of loosely arranged and highly vascular "young" connective tissue (Fig. 3). The patency of the artery was considerably reduced by this lesion. The media in this particular segment exhibited some of the previously described mucoid accumulations. Such accumulations became particularly pronounced beyond the bifurcation in the proximal parts of both the left anterior descending and the left circumflex coronary arteries. These two vessels were not otherwise changed. The heart showed a large anteroseptal infarction that extended onto the lateral wall of the left ventricle, producing involvement of the anterolateral papillary muscle.

Sinus nodal artery: In only one instance in this series was the sinus nodal artery affected (Case 1). The vessel showed a moderate accumulation of acid mucopolysaccharides in the media, together with a slight increase in fine fibrillar connective tissue content and some separation of muscle cells (Fig. 4). The intima of the artery showed a musculoelastic layer of normal configuration and structure. The segment of the artery thus involved was close to the origin from the main right coronary artery. Inside the sinus node itself, however, the artery did not reveal any of these changes. The sinus nodal artery in the remaining four

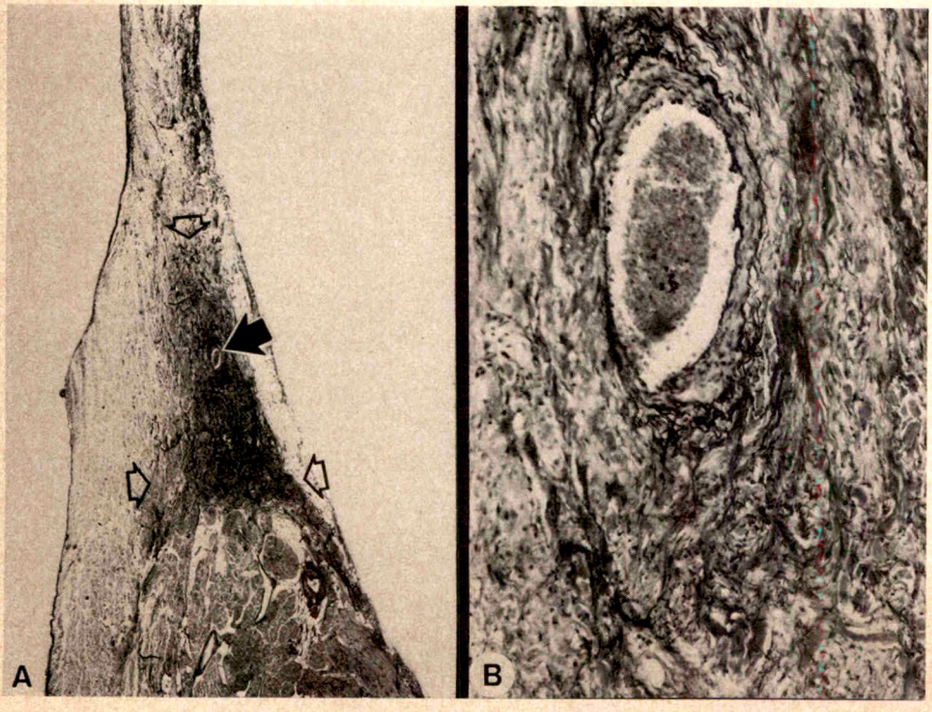

FIGURE 5. Case 5. Photomicrographs of the sinus node and embedded sinus nodal artery. **A,** the nodal area **(light arrows)** shows the normal arrangement for a young person. The sinus nodal artery **(solid arrow)** is normally positioned. **B,** detail of sinus node and its nutrient artery. The latter is normal in structure. The node itself shows a compact arrangement without mucoid pooling, consistent with young age. (Elastic tissue stain ×15 **[A]** and 140 **[B]**, reduced by 23 percent.)

hearts was normal in both its extranodal and intranodal course (Fig. 5).

Atrioventricular nodal artery: The segment of the atrioventricular nodal artery that originated from the U loop at the crux cordis showed a normal muscular structure in each case. A musculoelastic layer was always present and continued in the arterial segment that ramified within the node. It was of interest that a moderately large artery, which penetrated the fibrotic anulus from the ventricular septum toward the atrioventricular node, always exhibited a markedly pronounced musculoelastic layer. Furthermore, this layer originated rather abruptly when the artery came close to the fibrotic anulus and continued to be present in the penetrating segment and in part on the atrial aspect of the anulus (Fig. 6). In one instance (Case 4) the artery showed a pool of mucopolysaccharides that separated the elastic fibrils in the musculoelastic layer (Fig. 7). In the remaining four cases this change was not observed.

Intramural coronary arteries: The intramural coronary arteries were normal in each case. Only in the immediate environs of an infarct (Case 3) was intimal fibrosis noted. Mucoid changes or obliterative intimal proliferations were not observed.

Discussion

Pathogenesis of coronary arterial lesions: Our study revealed that the coronary arteries may indeed exhibit pathologic lesions in patients with Marfan's syndrome. In fact, four of the five hearts studied revealed a structural abnormality in the vessel walls (Table I). The abnormality consisted of an accumulation of acid mucopolysaccharides within the vessel

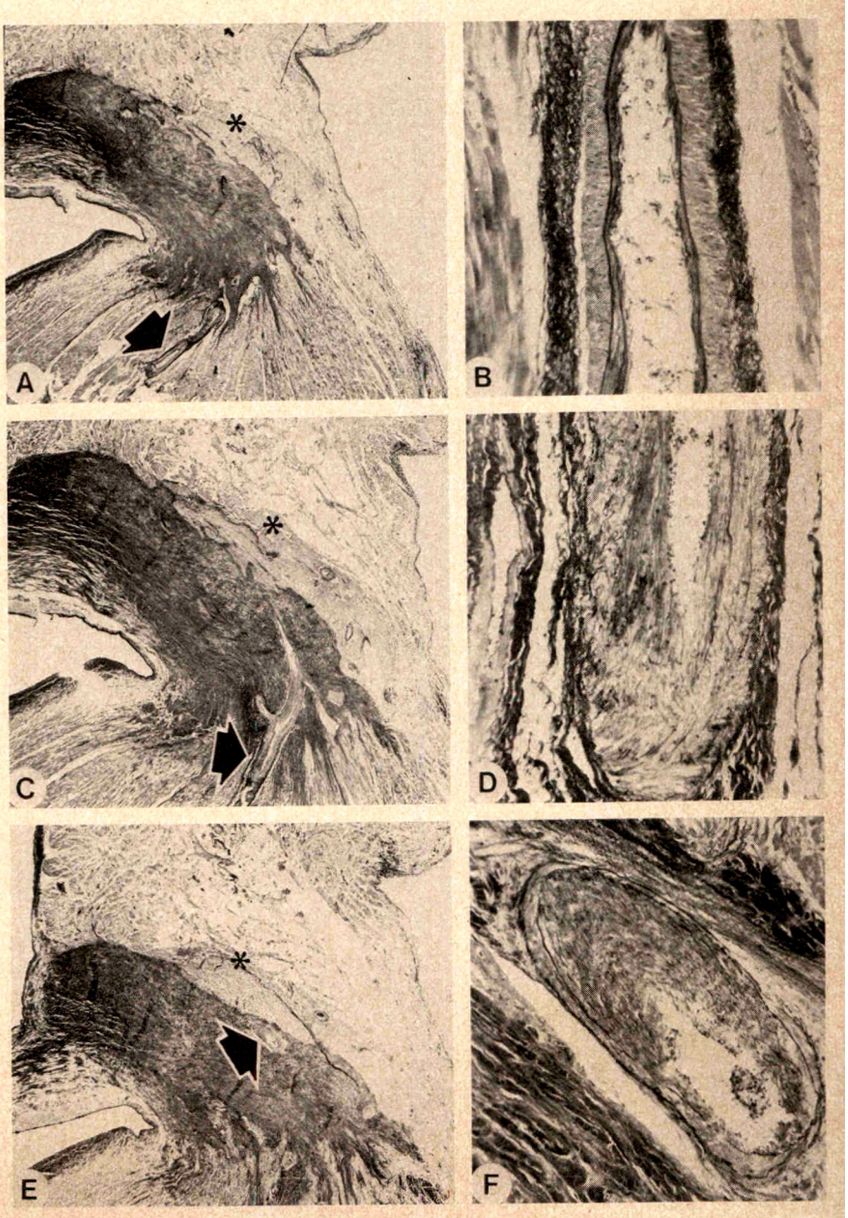

FIGURE 6. Case 5. Photomicrographs of successive sections of the atrioventricular nodal area showing the structural changes in a septal coronary artery **(arrows)** that penetrated the anulus fibrosus on its way to the atrioventricular node **(*)**. **A** and **B,** the artery is approaching the anulus fibrosus and is of a normal muscular type. **C** and **D,** the same artery has penetrated the anulus fibrosus. Its structure has altered, and there is now a marked musculoelastic intimal layer. **E** and **F,** the artery has nearly traversed the anulus fibrosus and is in close apposition to the atrioventricular node. The marked musculoelastic intimal layer is still present. The thickness of this layer is exaggerated since the artery is tangentially sectioned. (Elastic tissue stain ×15 **[A, C** and **E]** and 140 **[B,D** and **F]**, reduced by 27 percent.)

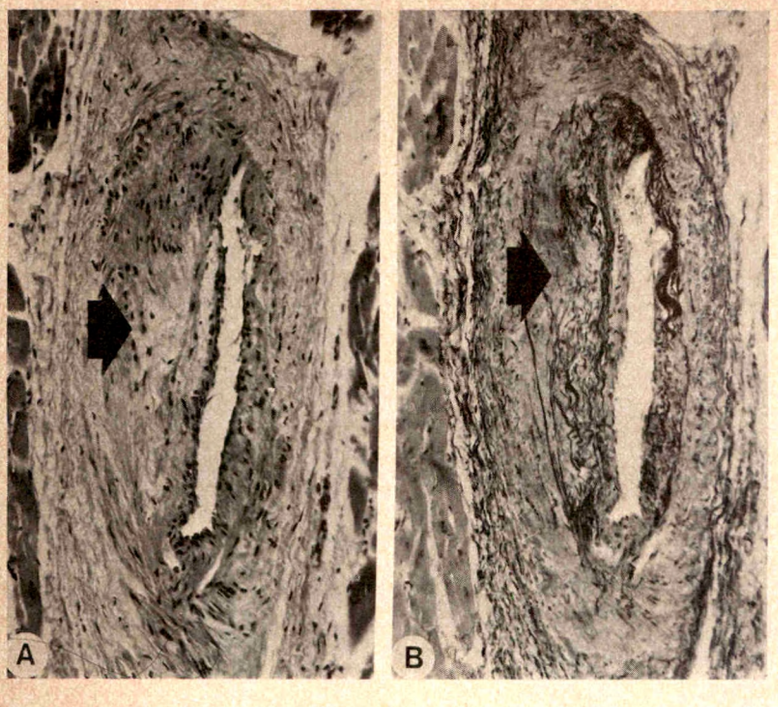

FIGURE 7. Case 4. Photomicrographs of septal coronary artery near the anulus fibrosus. **A,** the artery shows a pool of mucopolysaccharides **(arrow)** in the musculoelastic intimal layer. **B,** the elastic tissue stain of the same area shows a disruption of the elastic fibrils at that particular site **(arrow).** (Hematoxylin-eosin stain [**A**] and elastic tissue stain [**B**] ×140, reduced by 25 percent.)

walls, accompanied by disruption of connective tissue elements. This latter feature was less pronounced than that found in the extensive lesions that may occur in the aorta in Marfan's syndrome. However, although the coronary arteries are of a muscular type and normally possess only sparse connective tissue fibrils, the histologic findings of pooling of acid mucopolysaccharides with disruption of the preexisting wall structure were similar to those observed in the aorta. It is usual to classify such alterations as "cystic medial necrosis." [3]

The pathogenesis of this alteration in Marfan's syndrome is still a matter of dispute, although it is generally agreed that it is in some way related to the metabolic disorder affecting the connective tissues.[4] It should be stated, however, that "cystic medial necrosis" as such is present in the normal aging aortic wall[5,6] and in the pulmonary arteries in cases of long-standing pulmonary hypertension[7,8]; it has also been described in some cases of dissection of a coronary artery unrelated to Marfan's syndrome.[9–11] The "cystic medial necrosis" in Marfan's syndrome is already present at an early age and then to an extensive degree. We therefore feel justified in interpreting the changes in our specimens as an expression of the underlying metabolic disorder that was known to be present.

One may speculate on the possibility that similar changes in the coronary arteries previously described in young persons, whether or not accompanied by a dissection, are indeed "formes frustes" of Marfan's syndrome.[10,12] The structural changes observed in our specimens were particularly prominent in the extramural coronary arteries. As far as we are aware, this feature of Marfan's syndrome has not been specifically reported previously. It is only in a review article of the pathology of angina pectoris that Vlodaver et al.[13] mentioned a case of Marfan's syndrome with "changes of cystic nature" in the media of the coronary arteries, associated with focal fibrous thickening of the intima.

James et al.[2] described obliterative proliferative changes in the intramural coronary arteries in Marfan's syndrome but made no mention of any abnormality of the extramural coronary arteries. In this study we found only one specimen in which the proximal segment of the sinus nodal artery showed degenerative changes, although without appreciable narrowing of the lumen; the artery was normal when embedded within the node itself. However, our five cases were randomly selected cases of Marfan's syndrome, in which no patient had disturbances of rhythm or atrioventricular conduction. In contrast, the two cases of James et al.[2] were particularly selected and studied for these latter reasons. The atrioventricular nodal artery in our five cases was also normal, again in contrast to findings in the cases reported by James et al.[2] The vessel did exhibit a distinct musculoelastic intimal layer. However, we interpret this feature as a normal occurrence. In one instance the arterial branch from the ventricular septum that normally perforates the anulus fibrosus to reach the atrioventricular node showed an accumulation of acid mucopolysaccharides within the musculoelastic layer. We believe that this constituted an abnormality that could be related to the underlying connective tissue disorder.

Coronary dissecting aneurysms: We believe that the "cystic medial necrosis" as encountered in the coronary arteries in these cases is an expression of an affected arterial wall. As such, its presence could indicate an intrinsic weakening of the vessel, which

could therefore be more easily lacerated. This view is in accordance with recent opinions on the development of so-called spontaneous laceration lesions of the aortic wall.[6,14] Indeed, in one of our five cases a complicated lesion of the left coronary main stem fulfilled the histologic criteria for such spontaneous lesions. The media of this artery showed an abrupt interruption of its wall with the formation of an aneurysm. The outer wall of the aneurysm was composed of remnants of the outer layer of the preexistent media, further strengthened by adventitia. When reconstructed from the many slides taken, the lesion could be considered to have resulted from a broad tear in the inner wall which had then expanded to form a saccular aneurysm. Lesions of this type in the aortic wall have been classified as "incomplete dissecting aneurysms." [6,14–16]

As far as we are aware, this case is the first documentation of this lesion in a coronary artery. It is most likely that the laceration that affected the vessel was caused during reconstructive surgery on an aneurysm of the ascending aorta 2 months before the patient's death. The broad layer of newly formed intima that covered the remnants of the media is consistent with a time lag of 2 months and is a recognized feature of long-standing complete and incomplete dissecting aneurysms of the aorta.[17] The occurrence of an incomplete dissection in a coronary artery in a patient with Marfan's syndrome illustrates that these arteries can be vulnerable to trauma, probably as a result of the same mechanisms that render the aorta so vulnerable.

Clinical implication: The finding of the changes of "cystic medial necrosis" in three other cases indicates that these arteries also had the potential for laceration. In our opinion, the latter complication is the major hazard of coronary arterial involvement in Marfan's syndrome since the lesions are intramural and initially do not cause narrowing of the lumen. The latter could also account for the rarity of functional coronary artery disease among the cardiovascular complications of Marfan's syndrome. Nevertheless, our findings indicate that, morphologically, the coronary arteries are indeed involved by a process similar to that affecting the aortic wall. Therefore, the possibility of coronary arterial involvement should always be considered during the clinical evaluation of the patient with Marfan's syndrome.

Acknowledgment

We thank our clinical colleagues of the University Department of Cardiology, Wilhelmina Gasthuis, who suggested the need for this study, and Mrs. H. J. Dijk for the histologic sections and Mr. R. E. Verhoeven for the photographs.

Clinical Applications of the Threshold Tracking Pacemaker

THOMAS A. PRESTON, MD, FACC
DAVID L. BOWERS, BSEE

Seattle, Washington

The concept of automatic threshold tracking is the most recent adaptation of artificial cardiac pacemakers to physiologic needs. Earlier pacemaker innovations were primarily in the area of timing of impulse delivery, whereas more recent changes have focused on alteration of the amplitude and duration of the pacemaker stimulus. Matching of this stimulus to the cardiac excitation threshold is important because a stimulus greater than necessary is wasteful of battery energy and may produce arrhythmias, whereas a stimulus of less than threshold intensity fails to pace the heart. Because of the wide range of clinically encountered threshold levels it is impossible to design a fixed output pacer that is efficient and safe for all patients at all times.

The threshold tracking pacemaker searches for and finds the threshold level, and adjusts its stimulus to just above this level. The device ensures an adequate safety margin of stimulation, but reduces the stimulus level to the lowest safe level possible. It is fully automatic, adjusts immediately to any threshold changes and is not dependent on manual alteration.

The threshold tracking pacemaker (supported by Vitatron Medical, B.V.) represents a new generation of pacemaker with automatic control of the pacemaker stimulus. It repeatedly searches for and finds the threshold level and adjusts its stimulus to just above this level, ensuring an adequate safety margin and continuous effective pacing but reducing the stimulus to the lowest safe level possible. This device is fully automatic, adjusts immediately to any threshold changes and is not dependent on manual alteration. It was tested clinically in six patients and performed according to specifications. Much additional testing is necessary before the instrument is certified for widespread use, but it appears to offer a significant advance in artificial cardiac pacing.

Instrumentation

A detailed description of the threshold tracking pacemaker has been previously reported.[1] The prototype unit has a range of 0 to 15 milliamperes and is a constant current ventricular-inhibited device. Its essential feature is its capacity to sense for presence or absence of ventricular response (QRS complex) during a 20 to 40 msec period after each pacemaker stimulus. If the pacemaker output is above threshold level, the stimulus amplitude is reduced by 0.5 milliampere decrements until a stimulus fails to evoke a ventricular response, with threshold lying between the last suprathreshold stimulus and the subthreshold stimulus. When the stimulus is reduced to below threshold level, the absence of a response is detected, and 40 msec after the subthreshold stimulus another (backup) stimulus is delivered that is 0.5 milliamperes greater and 1.0 msec longer in duration (Fig. 1). Because the backup stimulus is greater in current and duration than the subthreshold stimulus, it should be great enough to evoke a ventricular response unless there has been a sudden increase of threshold since the previous beat. As a safety feature, if the backup stimulus does not elicit a response, a second backup stimulus with a

From the Harborview Medical Center, Division of Cardiology, University of Washington, Seattle, Wash. Manuscript accepted January 15, 1975.

Address for correspondence: Thomas A. Preston, MD, Harborview Medical Center, 325 Ninth Ave., Seattle, Wash. 98104.

further 0.5 milliampere increment is delivered 40 msec after the first backup pulse.

Continuous and programmed modes: In the prototype model there are two operating modes, continuous and programmed. In the continuous mode, the cycle of testing for threshold is continuously repeated. The pacemaker probes down to lower output levels to determine threshold, provides output at a level above threshold, and then repeats the cycle. When threshold is stable, one test cycle spans three heartbeats and four pacer stimuli (one subthreshold pulse) (Fig. 1). In the programmed mode, the pacemaker determines threshold and sets the output at a preset safety margin (0.5 milliamperes) above threshold level. The output is then kept constant unless an elevation of threshold results in a stimulus that does not produce a response, in which case a second stimulus of greater amplitude and pulse duration is delivered 40 msec after the subthreshold stimulus. The system is automatically reset to the higher stimulus level to compensate for the higher threshold. In the programmed mode the pacemaker does not continuously search for threshold but is programmed to search automatically for threshold at time intervals set by the operator (every 30 seconds or every 2 or 8 minutes) (Fig. 2). In either the continuous or programmed mode, a subthreshold stimulus at any time is followed by a backup stimulus that is above threshold level (or two backup stimuli if necessary). Only with the rare exception of a sudden and pronounced rise in threshold, such as can be produced by pulling back the pacing catheter, are the backup stimuli insufficient to evoke a response.

Methods

After the system was proved feasible and safe in animals,[1] it was tested seven times in six patients. Five of the patients had complete heart block, and one patient was undergoing pacing for control of arrhythmias. In four of the tests the electrode system included a standard bipolar temporary pacing catheter positioned in the apex of the right ventricle and an indifferent electrode plate attached to the right arm. In three tests we used a tripolar electrode with two electrodes spaced 1 cm apart at the distal tip and the third (indifferent) electrode 23 cm back from the distal tip.[2] In all tests pacing was between the distal (cathode) and indifferent (anode) electrodes, with sensing between the proximal of the bipolar pair and the indifferent electrodes.

The threshold tracking pacemaker was tested in each patient for proper sensing and stimulation under several conditions—at rest, with forceful breathing and with the patient in various positions. In three of the seven tests the pacing catheter was inserted at the time of the test, and the system was monitored during positioning of the catheter in the right ventricular apex and during manipulation of the catheter tip to different sites within the right ventricle. All these maneuvers were attempts to produce sudden changes in threshold that would test the ability of the pacemaker to react with the appropriate change in output.

Results

In the first two patients testing was incomplete because of sensing problems that developed when the pacemaker output was at a high level. Redesign of the circuitry corrected this problem and subsequent patient testing yielded successful results. Each patient underwent pacing for 30 to 60 minutes without complication or malfunction. The pacemaker performed to the designed specifications of sensing all

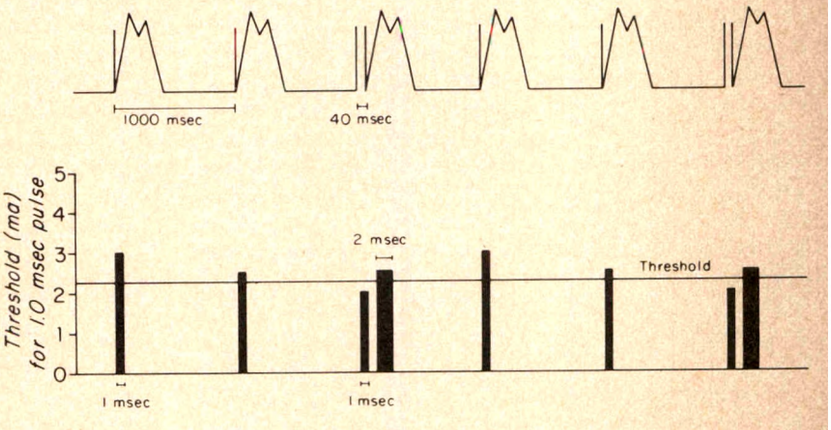

FIGURE 1. Scheme of operation of threshold tracking pacemaker. **Above,** electrocardiogram. **Below,** stimulus output (milliamperes) of pacemaker. Threshold is 2.3 milliamperes. The third stimulus (2.0 milliamperes) is below threshold level and does not evoke a response; it is followed 40 msec later by a larger stimulus that is above threshold level. (Reprinted from Preston and Bowers,[1] by permission.)

Programmed tracking mode for sensing for threshold. **Above,** electrocardiogram (5 mm/sec). **Middle,** pacemaker stimulus in 0.5 milliampere steps. **Bottom line,** 0.0 milliampere reference. **At left,** the stimulus level increases after movement of the pacing catheter to a higher threshold position. About 1 minute later (**right**) the unit automatically searches down for threshold and resets at a lower stimulus level. It is programmed to search for threshold every 2 minutes. (Reprinted from Preston and Bowers,[1] by permission.)

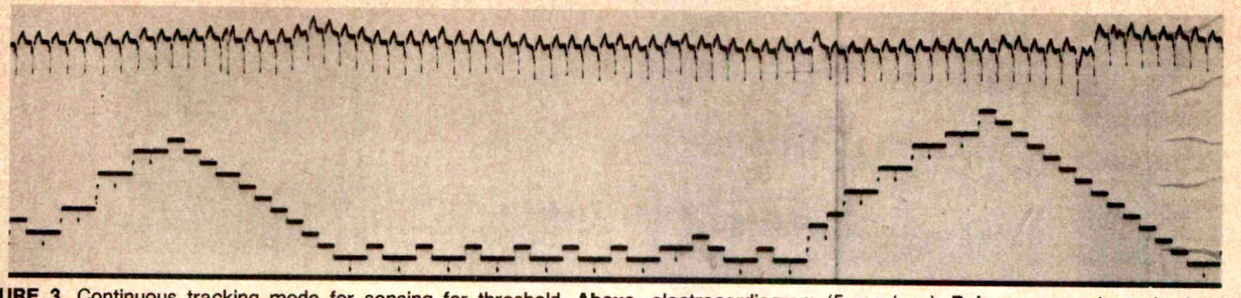

FIGURE 3. Continuous tracking mode for sensing for threshold. **Above,** electrocardiogram (5 mm/sec). **Below,** pacemaker stimulus level. Marked sudden inspiration results in catheter movement and rise in threshold. The pacemaker tracks to the higher level without missing a beat.

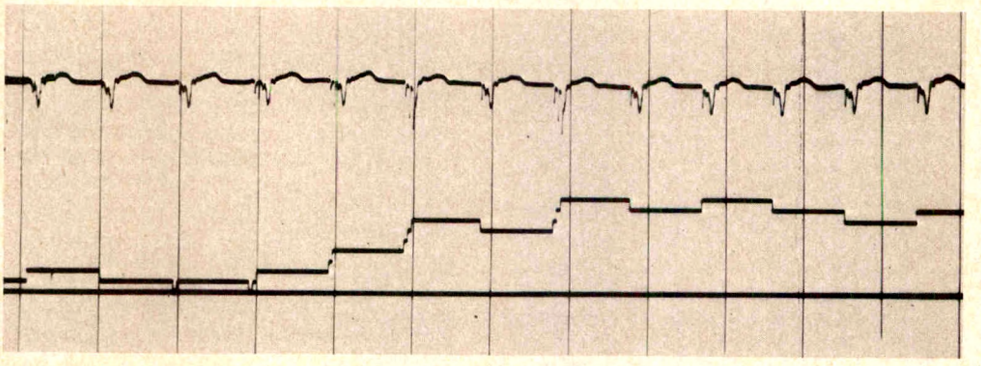

FIGURE 4. Pacemaker in continuous tracking mode. **Above,** electrocardiogram (5 mm/sec). **Below,** pacemaker stimulus level in 0.5 milliampere steps. The base line is 0.0 milliamperes. **At left,** threshold is between 0.0 and 0.5 milliamperes, and the pacemaker continuously tracks between 0.0 and 1.0 milliamperes. After the third beat the catheter was suddenly withdrawn 2 cm, resulting in a rise in threshold. The pacemaker then tracked to a higher output level, sometimes using two backup pulses (fourth, fifth, sixth and eighth beats).

ventricular beats of spontaneous or pacemaker-induced origin and of detecting the absence of ventricular depolarization after delivery of subthreshold stimuli. The pacemaker correctly responded to subthreshold stimuli by increasing the output amplitude of backup pulses. It performed as expected in the two modes of operation, continuous and programmed. When threshold changes were induced by sudden deep respiration or coughing, changes in patient position or manipulation of the catheter, the pacemaker automatically adjusted output amplitude to the new threshold level (Fig. 3 and 4). Only by manually changing the position of the pacing catheter tip were we able to produce a change in threshold great enough to require two backup pulses. The pacemaker tracked threshold elevations rapidly enough to maintain pacing except when the catheter tip was suddenly jerked backward from a low to a high threshold position. In this latter circumstance, one paced beat was missed (the regular stimulus and two backup stimuli were subthreshold), but the unit recovered to capture the next beat.

Discussion

Clinical testing of the threshold tracking pacemaker indicated its effectiveness and safety in patients requiring temporary pacing for acute medical problems. The reliability of the system must be determined by further long-term testing, but these first tests demonstrate its feasibility. Reliability is most directly a function of adequate sensing of spontaneous or pacemaker-induced beats, and the reliability of sensing is determined by the electrode system. The system contains safeguards to transform the pacemaker to the asynchronous mode in the absence of adequate sensing, so that a sensing failure would have the same result as with an ordinary noncompetitive (demand) pacemaker. In clinical testing we attempted to produce sensing failures by sudden movements of the patient or the pacing catheter but, except when the electrode was removed from the right ventricle, sensing was always adequate. Electromagnetic interference and interference from myopotentials did not occur, but the system has not been thoroughly tested for these problems. In all instances the threshold tracking pacemaker performed as a noncompetitive pacemaker and was properly inhibited by all spontaneous (nonpacemaker-induced) beats.

Advantages: The advantages of the threshold tracking pacemaker are: (1) Pacemaker output is kept in an optimal range above excitation threshold but well below fibrillation threshold; (2) the system automatically adjusts for threshold changes without missed beats or alteration in rate; (3) the system aids in electrode positioning by automatically displaying threshold level; (4) catheter or electrode stability can be monitored continuously and long-term histograms can be recorded to document threshold changes in the long-term operation of the pacing system; and (5) the system is useful in evaluating acute threshold changes secondary to activity or position of the pa-

tient or to drug therapy. Ultimately, the threshold tracking pacemaker will be incorporated into implantable units, which may increase pacemaker life by tailoring pacemaker output to beat by beat requirements. As more data are collected with regard to the requirements and potential of this unit, changes will probably occur in stimulus output.

Requirements of sensing system: The only type of pacemaker that can optimally match output against threshold and remain safe is one that will frequently and automatically test for threshold level and deliver a stimulus that is always suprathreshold but no more above threshold than is necessary to ensure effective pacing. At the Fourth International Symposium on Cardiac Pacing,[3] two automatic threshold sensing systems were reported[4,5] and a third[6] was demonstrated. Subsequently, a fourth system was reported.[7]

The essential feature of the threshold tracking pacemaker is its ability to sense for the presence or absence of ventricular depolarization after a pacing stimulus. To determine whether or not each pacemaker stimulus evoked a ventricular response the pacemaker must detect an electrical signal (QRS complex) during the 100 msec period after each stimulus. This is technically exceedingly difficult and is the limiting factor in any threshold tracking pacemaker. Ordinary noncompetitive (demand) pacemakers have a sensing refractory period of 250 to 350 msec after each delivered stimulus. This period occurs because 250 to 350 msec elapse before the afterpotential, which may be as great as 1 volt after the pacemaker stimulus, is dissipated to a level that will permit the pacemaker to sense reliably a 2 to 3 millivolt intracardiac depolarization. Reliable sensing during the 100 msec interval after the pacer stimulus requires stabilization of the electrode afterpotential in order to detect the depolarization signal.

Backup pulses to ensure continuous pacing: The pacemaker developed by Mugica et al.[4] has four output levels. In this unit an external magnet is used to trigger the pacemaker to search lower output levels for threshold, and a subthreshold stimulus is always followed by a missed beat. The system developed by Funke[6] has a greater number of output levels but also misses one ventricular depolarization every time the output falls below threshold level.

We believe that it is important to have backup pulses following subthreshold stimuli so as to avoid missing a heartbeat. When the suprathreshold backup pulse is delivered 40 to 50 msec after the subthreshold stimulus, the delay of 40 to 50 msec is sufficiently short so that there is no effective change in the heart rate (Fig. 1). Similarly, the beat to beat interval following a backup pulse is shortened by 40 to 50 msec compared with the basic pacing rate, but this change is not perceptible to the patient. The unit determines threshold by reduction of stimulus levels, but backup pulses ensure continued pacing without missing a beat and with an imperceptible change in cardiac rate. The unit was designed with a limit of two backup pulses to avoid any possibility of stimulation during the vulnerable period of a pacemaker-induced depolarization that was not sensed. A first backup pulse is delivered 40 msec after the basic stimulus and, if necessary, a second backup pulse is delivered 80 msec after the basic stimulus. If the basic driving stimulus does evoke a ventricular depolarization that is not properly sensed (worst case), a second backup pulse 80 msec later would still be too early to fall during the vulnerable period of ventricular repolarization. However, stimuli occurring in the period beginning 120 msec after the basic stimulus could fall in the vulnerable period of an unsensed depolarization after the basic stimulus. For this reason we limited the pacemaker to two backup pulses and believe that all backup pulses must occur within 100 msec of the basic stimulus. A backup pulse later than 100 msec after the basic stimulus would also cause a great enough change in the ventricular beat to beat interval to be perceived as a rate change by some patients.

The possibility of a dropped (nonpaced) ventricular beat is minimal with the threshold tracking pacemaker. A sudden change of the pacing electrode to a higher threshold position can result in a missed beat, but we found that ordinary physiologic alterations, such as deep breathing and changes in body position, produced threshold elevations of low enough magnitude to permit the pacer to track upward without missing a beat. Only by sudden withdrawal of the pacing catheter were we able to produce an instant rise in threshold so great that the pacemaker could not compensate without missing a beat. Sudden marked catheter movement does occasionally occur in clinical practice, as with "catheter displacement," and is often associated with loss of pacing. In cases of "catheter displacement" without loss of pacing, there may well be one or more missed beats at the time of catheter movement. We do not consider that the possibility of one missed beat during catheter movement is a serious limitation of the threshold tracking pacemaker.

Variations in threshold and optimal pacemaker stimulus: Since implantable pacemakers first became commercially available, recognition of factors that determine threshold has led to design of electrodes with lower thresholds. This has allowed the use of lower stimulus levels, but there is evidence that with lower threshold electrodes the percent change from acute to chronic threshold is greater than with electrodes that have higher acute thresholds.[8] Thus, the pacemaker manufacturer is still faced with designing pacemakers to match thresholds that range over a wide span. With some of the newer electrodes threshold at the time of implantation is often lower than 0.1 milliamperes,[9] whereas other long-term electrode thresholds uncommonly reach as high as 10 milliamperes (pulse duration 0.5 to 1.0 msec), producing a wide range of clinically encountered thresholds with the maximal level ranging up to 100 times the minimal level.

The necessity of providing a stimulus above threshold level is obvious. Were there no detrimental

or disadvantageous effects of pacing at very high stimulus levels, setting the stimulus at 20 milliamperes (1.0 msec) would ensure pacing in all but exceedingly rare cases. However, the optimal pacemaker stimulus level is a *threshold* stimulus, that is, a stimulus of the minimal level producing a propagated cardiac depolarization. To the extent that the stimulus exceeds the threshold level there is (1) unnecessary current drain from the battery, (2) an increased risk of pacemaker-induced ventricular fibrillation, and (3) a possible increase in tissue reaction or electrode damage, or both. The problem of pacemaker-induced ventricular arrhythmias is probably minimal, but is a potential complication of ventricular pacing.[10] Any noncompetitive (demand) pacer can malfunction and deliver stimuli during the ventricular vulnerable period. Spear et al.[11] demonstrated in dogs that the greater the current intensity delivered during the vulnerable period, the greater is the temporal dispersion in recovery of excitability, associated with a decrease in ventricular fibrillation threshold immediately after the application of current. They concluded that "since the intensity of the current delivered to the myocardium does influence vulnerability, pacemaker current output should be of as low intensity as possible to minimize these effects." The concept of the threshold tracking pacemaker is concordant with this physiologic premise.

In the future, the concept of immediate automatic monitoring of the result of an applied stimulus may be an impetus to further advances in medical technology.

Tricuspid Atresia: Clinical Course in 101 Patients

MACDONALD DICK, MD
DONALD C. FYLER, MD
ALEXANDER S. NADAS, MD

Boston, Massachusetts

The clinical profile and course of 101 patients with tricuspid atresia seen at the Children's Hospital Medical Center, Boston, were reviewed; the electrocardiograms, hemodynamic data, associated anomalies, complications of the malformation and surgical results were outlined and a definition of anatomic types and radiologic groups formed in order to facilitate therapeutic decisions. Overall survival to 15 years of age was approximately 50 percent. Tricuspid atresia type I (normally related great arteries), group A (decreased pulmonary vascularity) was the most frequent category (54 percent); without surgery, these patients had only a 10 percent chance of survival beyond the 1st year of life. Surgical intervention improved chance of survival to 15 years of age to 50 percent. Overall surgical mortality was 23 percent. The Waterston shunt is the procedure of choice in symptomatic small infants with diminished pulmonary flow (group A). Type II patients with increased pulmonary blood flow (group B) would benefit from a pulmonary arterial band. In contrast, patients with group B, type I atresia would rarely need a pulmonary arterial band. Patients with spontaneously changing hemodynamics (group C) usually require a shunt later in life than those in group A, with more favorable operative results. Our experience indicates the continued need of early surgical palliation. New surgical approaches, such as the right atrial-pulmonary arterial anastomosis, may result in a more prolonged survival.
